where Γ represents the perimeter of the wire in which the current I flows.

10.2.3 Biot-Savart law

Form the latest development, we get:

$$\mathrm{d}\vec{B}=\frac{\mu_0}{4\pi}\frac{I\mathrm{d}\vec{l}}{r^2} \tag{10.2.41}$$

Remember that at the last stage of our previous developments (we have specified it implicitly) the integration path is perpendicular to the electric current! But the magnetic field can not be zero at any point of the current line. Therefore, we are led to write what is hidden:

$$\mathrm{d}\vec{B}=\frac{\mu_0 I\mathrm{d}\vec{l}}{4\pi r^2}\cdot 1=\frac{\mu_0 I\mathrm{d}\vec{l}}{4\pi r^2}\cdot\sin\left(\frac{\pi}{2}\right) \tag{10.2.42}$$

The above relation allows us thus, by extension, to write in a more general form:

$$\boxed{\mathrm{d}\vec{B}=\frac{\mu_0 I\sin(\alpha)}{4\pi r^2}\cdot\vec{l}=\frac{\mu_0 I\vec{l}\times\vec{r}}{4\pi r^2}} \tag{10.2.43}$$

which is nothing else than the "Biot-Savart law" often presented first in high-school classes as starting point from the study of magnetism (originally it was experimentally determined in 11820 (holocene calendar) by Jean-Baptiste Biot and Félix Savart with the mathematical help of Simon de Laplace).

This latter relation may as well be written (very important form):

$$\mathrm{d}\vec{B}=\frac{\mu_0}{4\pi r^3}I\mathrm{d}\vec{l}\times\vec{r}=\frac{\mu_0}{4\pi r^3}\frac{\mathrm{d}Q}{\mathrm{d}t}\mathrm{d}\vec{l}\times\vec{r}=\frac{\mu_0}{4\pi r^3}\mathrm{d}Q\frac{\mathrm{d}\vec{l}}{\mathrm{d}t}\times\vec{r}=\frac{\mu_0\mathrm{d}Q}{4\pi r^3}\vec{v}\times\vec{r} \tag{10.2.44}$$

Therefore:

$$\boxed{\vec{B}=\frac{\mu_0 Q}{4\pi r^3}\vec{v}\times\vec{r}} \tag{10.2.45}$$

Here we fall back on the non-relativistic approximation of the magnetic field as we have determined it in our study of Special Relativity (see section Special Relativity page 5694), where we have prove that:

$$\vec{B}=\frac{Q}{c^2\varepsilon_0 4\pi r^3}\frac{1-v^2/c^2}{\left[(1-(v^2/c^2)\sin^2(\theta)\right]^{3/2}}\vec{v}\times\vec{r} \tag{10.2.46}$$

Another important form of the expression for the magnetic field is:

$$\mathrm{d}\vec{B}=\frac{\mu_0}{4\pi}\frac{I\mathrm{d}\vec{l}\times\vec{r}}{r^3}=\frac{\mu_0}{4\pi}\frac{(J\cdot S)\mathrm{d}\vec{l}\times\vec{r}}{r^3} \tag{10.2.47}$$

As the current density $\vec{J}$ is collinear $\mathrm{d}\vec{l}$, we can write:

$$\mathrm{d}\vec{B}=\frac{\mu_0}{4\pi}\frac{(S\mathrm{d}l)\vec{J}\times\vec{r}}{r^3}=\frac{\mu_0}{4\pi}\frac{\mathrm{d}V\vec{J}\times\vec{r}}{r^3}\mathrm{d}V=\frac{\mu_0}{4\pi}\frac{\vec{J}\times\vec{r}}{r^3}\mathrm{d}V \tag{10.2.48}$$

Therefore:

$$\boxed{\vec{B}=\frac{\mu_0}{4\pi}\oint\limits_V \frac{\vec{J}\times\vec{r}}{r^3}\mathrm{d}V} \tag{10.2.49}$$

An important remark is necessary to our level of our discussion in the context of pre-university academic studies, mathematical formulations of magnetic and electric fields are considered as unprovable laws from which we later deduce the Maxwell's equations (furthermore the developments are not of the most aesthetic and rigorous type). The experimental aspect of such important relations can give a negative image of theoretical physics to students. It is therefore clear that at university, we have an approach somewhat less pragmatic.

Indeed, we postulate the Schrödinger equation (see section Wave Quantum Physics page 4759) which we use to prove the non-relativistic formulation of Coulomb's law with the Yukawa theory (see section Quantum Field Theory page 5164). Then, during the study of relativity (see section Special Relativity page 5694), we determine the relativistic form of Coulomb's law. Then we admit the existence of the magnetic field whose expression is experimentally given by the Lorentz force (see further below in this section) and by the properties of Lorentz transformations and knowledge of the relativistic expression of the Coulomb's law, we determine the expression of relativistic magnetic field. Then, by non-relativistic approximation, we fall back on the Biot-Savart law. This approach is much more welcomed by students but not necessarily accessible to all levels.

Now let us come back on the Biot-Savart law. An important example in astrophysics of the Biot-Savart law in the context of plasma jets accretion disks are the unique circular current loops (we also have to add to this the Lorentz force in the relativistic framework for understanding the dynamics of these jets).

10.2.3.1 Magnetic field for a current loop

The figure below is a good example of a current loop seen from profile:

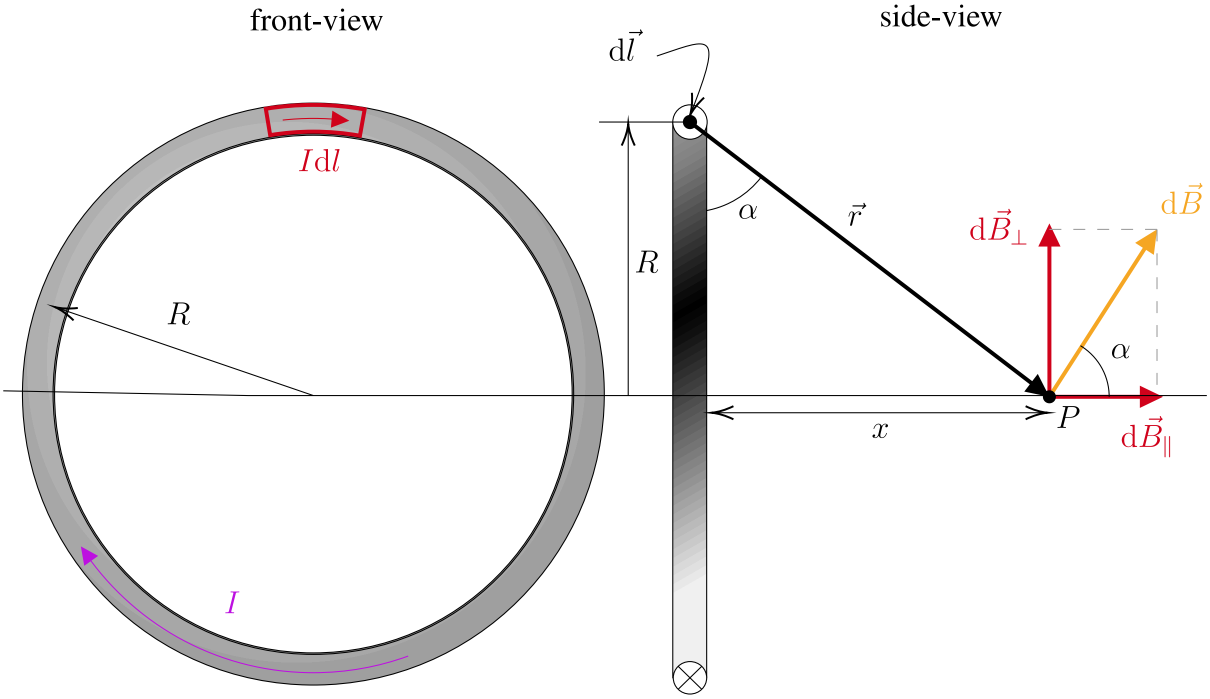

Figure 10.36: **Magnetic field for a current loop**

So we have a circular loop of radius R traversed by an electric current of intensity I. The objective is to calculate $\vec{B}$ at a point P on the axis of the loop.

The vector $\mathrm{d}\vec{l}$ corresponding to an elementary electric current at the top of the loop exits perpendicularly from the plane of the page (screen). The angle θ between this vector and $\vec{r}$ is therefore $\pi/2$. The plane formed by $\mathrm{d}\vec{l}$ and $\vec{r}$ is normal to the figure. The vector $\mathrm{d}\vec{B}$ produced by this elementary electric current is normal to this plane by the form of the Biot-Savart law. It is therefore in the plane of the figure and at a right angle with the vector $\vec{r}$ as shown on the figure.

Let us decompose $\mathrm{d}\vec{B}$ into two parts: the first $\mathrm{d}\vec{B}_{||}$ is along the axis of the loop and the second $\mathrm{d}\vec{B}_\perp$ is perpendicular to this axis. Only the component $\mathrm{d}\vec{B}_{||}$ contributes to the total magnetic induction at the point P. This is because the components $\mathrm{d}\vec{B}_{||}$ of all elementary currents are positioned on the axis and they are added directly. As for the components $\mathrm{d}\vec{B}_\perp$, they are directed in different directions perpendicular to that axis so that, by symmetry, their contribution is zero on this axis (be really careful with this special case!).

We get:

$$B=\int \mathrm{d}B_{||} \tag{10.2.50}$$

It is a scalar integral performed on all elementary currents. We get by the Biot-Savart law:

$$\mathrm{d}B=\frac{\mu_0 I}{4\pi}\frac{\mathrm{d}l\sin(\pi/2)}{r^2} \tag{10.2.51}$$

In addition, we have according to the figure above:

$$\mathrm{d}B_{||}=\mathrm{d}B\cos(\alpha) \tag{10.2.52}$$

Combining these relations, we get:

$$\mathrm{d}B_{||}=\frac{\mu_0 I}{4\pi}\frac{\cos(\alpha)\mathrm{d}l}{r^2} \tag{10.2.53}$$

The figure reveals that r and α are not independent variables. We can express them in function of the new variable x, the distance between the center of the loop and the point P. The relations between these variables are:

$$\begin{aligned} r&=\sqrt{R^2+x^2}\\ \cos(\alpha)&=\frac{R}{r}=\frac{R}{\sqrt{R^2+x^2}} \end{aligned} \tag{10.2.54}$$

Substituting these values in the expression of $\mathrm{d}B_{||}$, we obtain:

$$\mathrm{d}B_{||}=\frac{\mu_0 IR}{4\pi(R^2+x^2)^{3/2}}\mathrm{d}l \tag{10.2.55}$$

We notice that for all the elementary currents, I, R, x have respectively the same values. Integrating this differential gives:

$$B=\int\mathrm{d}B_{||}=\frac{\mu_0 IR}{4\pi(R^2+x^2)^{3/2}}\oint\mathrm{d}l=\frac{\mu_0 IR}{4\pi(R^2+x^2)^{3/2}}2\pi R=\frac{\mu_0 IR^2}{2(R^2+x^2)^{3/2}} \tag{10.2.56}$$

An important point of this relation is therefore $x=0$ we get:

$$\boxed{B=\frac{\mu_0 I}{2R}} \tag{10.2.57}$$

Another important application of the Biot-Savart law consists to take the previous example, but for any continuous falt shape and considered as punctual and we would like to know the value of the field elsewhere than on the axis of symmetry. The results will be very useful when we will study the Corpuscular Quantum Physics and therefore the magnetic properties of metals.

10.2.3.2 Magnetic field for an infinite wire

Let us also prove (it is an interesting example!) that from the Biot-Savart law:

$$\mathrm{d}B=\frac{\mu_0}{4\pi}\frac{I\mathrm{d}l\sin(\theta)}{r^2} \tag{10.2.58}$$

we can get for an infinite straight wire of radius R the relation:

$$B=\frac{\mu_0 I}{2\pi r} \tag{10.2.59}$$

for $r > R$ that we get already earlier with the Ampère's theorem (which shows the equivalence between the two ways of calculating!).

Let us choose for the infinite straight wire below x as variable:

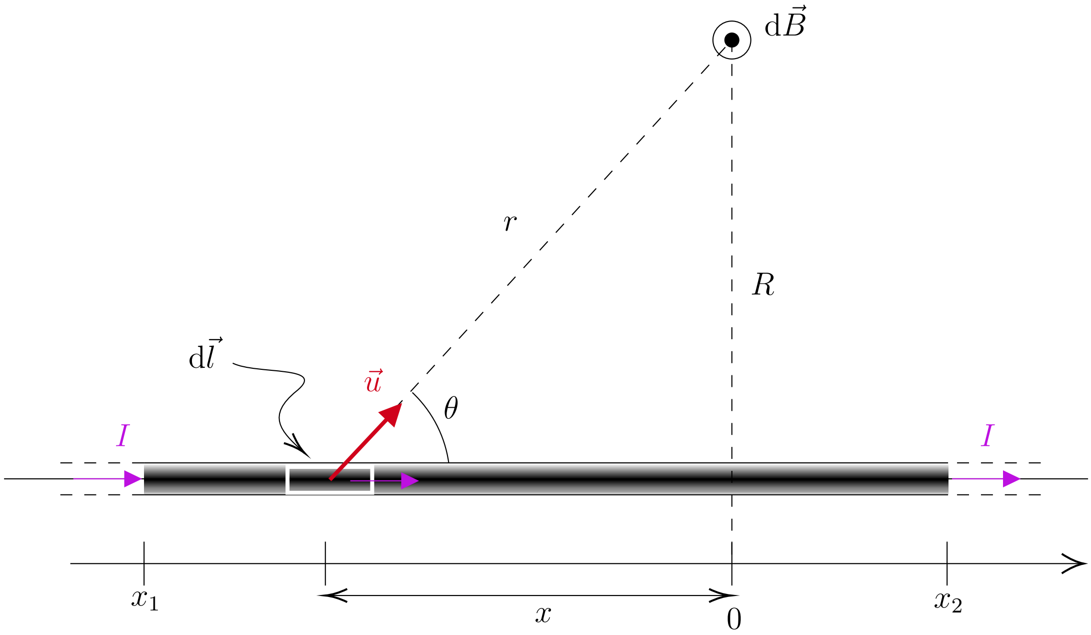

Figure 10.37: **Infinite straight wire**

We then have from the figure above:

$$\begin{aligned} \mathrm{d}l &= \mathrm{d}x \\ r &= \sqrt{x^2+R^2} \\ \sin(\theta) &= \frac{\theta}{r} = \frac{R}{x^2+R^2} \end{aligned} \tag{10.2.60}$$

hence:

$$B = \frac{\mu_0}{4\pi}\frac{I\mathrm{d}x\sin(\theta)}{r^2} = \frac{\mu_0}{4\pi}\frac{I\mathrm{d}x}{r^2}\frac{R}{r} = \frac{\mu_0}{4\pi}IR\frac{\mathrm{d}x}{(x^2+R^2)^{3/2}} \tag{10.2.61}$$

By integrating:

$$\begin{aligned} B &= \frac{\mu_0}{4\pi}IR\int_{x_1}^{x_2}\int\limits_{x_1}^{x_2}\frac{1}{(x^2+R^2)^{3/2}}\mathrm{d}x = \frac{\mu_0}{4\pi}IR\left[\frac{x}{R^2(x^2+R^2)^{1/2}}\right]\Bigg|_{x_1}^{x_2} \\ &= \frac{\mu_0 I}{4\pi R}\left(\frac{x_2}{(x_2^2+R^2)^{1/2}-\dfrac{x_1}{(x_1^2+R^2)^{1/2}}}\right) \end{aligned} \tag{10.2.62}$$

For the remaining part of the development, the trick is to use the following configuration:

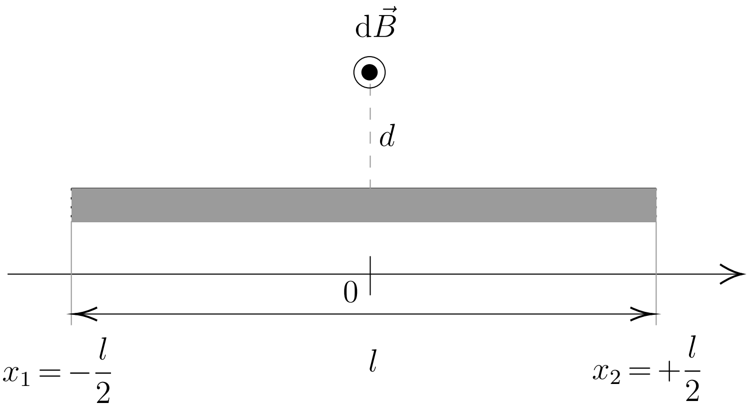

Figure 10.38: **Piece of the infinite wire**

Therefore:

$$x_2 = \frac{l}{2} \qquad x_1 = -\frac{l}{2} \qquad R = d \tag{10.2.63}$$

Which gives us:

$$B = \frac{\mu_0 I}{4\pi d}\left[\frac{l/2}{\left(\frac{l^2}{4}+d^2\right)^{1/2}} - \frac{-l/2}{\left(\frac{l^2}{4}+d^2\right)^{1/2}}\right] = \frac{\mu_0 I}{4\pi d}\frac{l}{\sqrt{\frac{l^2}{4}+d^2}} \tag{10.2.64}$$

After simplification:

$$B = \frac{\mu_0 I l}{2\pi\sqrt{l^2+4d^2}} = \frac{\mu_0 I l}{2\pi d l\sqrt{l^2+\frac{4d^2}{l^2}}} = \frac{\mu_0 I}{2\pi l\sqrt{l^2+\frac{4d^2}{l^2}}} \tag{10.2.65}$$

and so when the wire length tends is very big relatively to l we get for the magnetic field outside the wire ($d > R$):

$$B = \frac{\mu_0 I}{2\pi l\sqrt{l^2+\underbrace{\frac{4d^2}{l^2}}_{\to 0}}} \cong \frac{\mu_0 I}{2\pi d} \tag{10.2.66}$$

Inside of the cable, the circulation integral around a circular path of radius, $r < R$, is the same:

$$\oint \vec{B}\cdot \mathrm{d}\vec{l} = B2\pi r \tag{10.2.67}$$

However, in this case, the smaller Amperian loop does not enclose all of the current flowing through the cable. We are told that the current density, J, is uniform in the cable. We can thus determine the current per unit area (i.e. the current density) that flows through the whole cable, and use that to determine how much current flows through the surface with area πr^2 that is defined by the Amperian loop:

$$J = \frac{I}{A} = \frac{I}{\pi R^2} \tag{10.2.68}$$

And by definition:

$$I_{\text{enc}} = J\left(\pi r^2\right) = \frac{I}{\pi R^2}\left(\pi r^2\right) = I\frac{r^2}{R^2} \qquad (10.2.69)$$

Finally, we can apply Ampère's Law to determine the magnitude of the magnetic field inside the cable:

$$\oint \vec{B}\cdot d\vec{l} = \mu_0 I_{\text{enc}} \qquad (10.2.70)$$

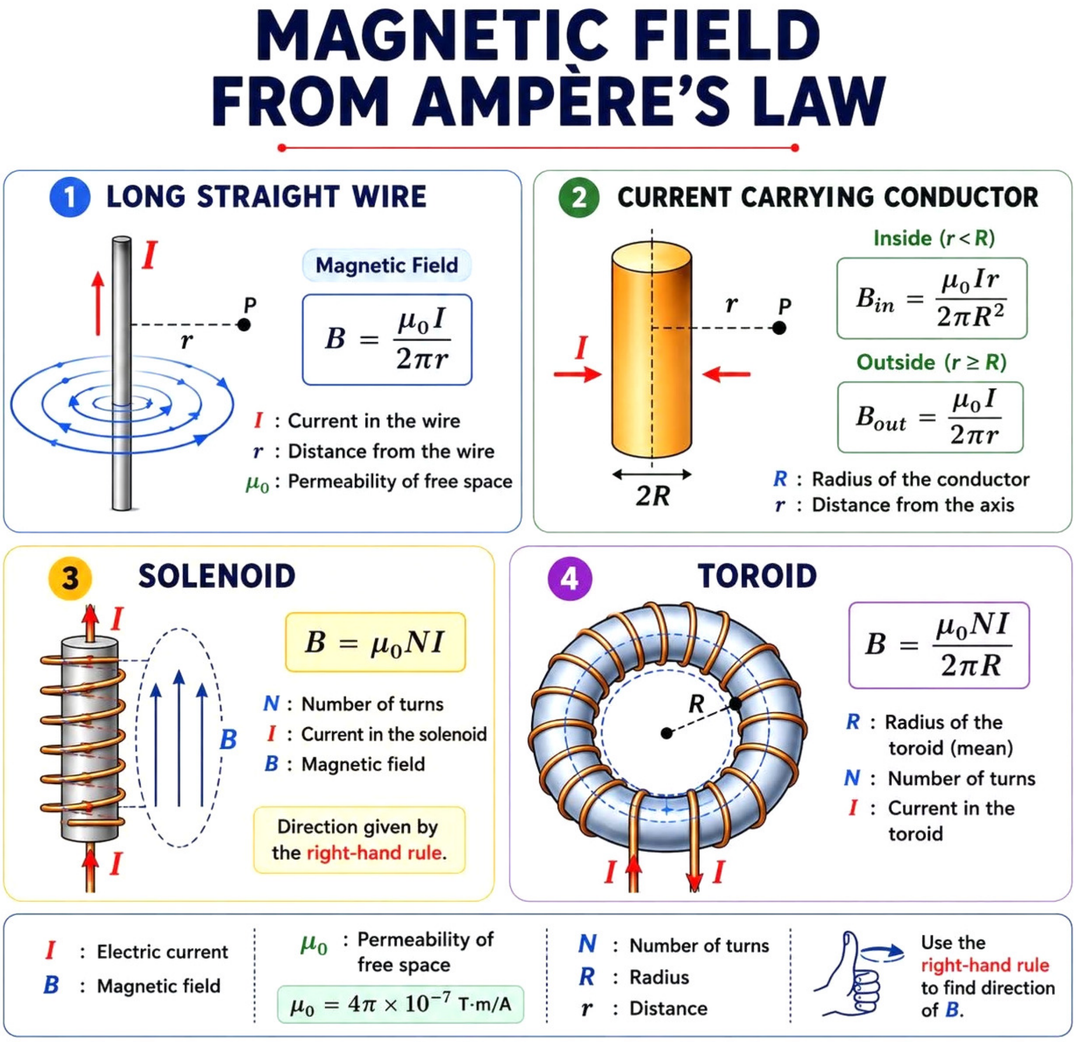
Therefore:

$$B(2\pi r) = \mu_0 I \frac{r^2}{R^2} \qquad (10.2.71)$$

Hence:

$$B = \frac{\mu_0 I}{2\pi R^2} r \qquad (10.2.72)$$

and we find that the magnetic field is zero at the center of the cable $(r = 0)$, and increases linearly up to the edge of the cable $(r = R)$.



MAGNETIC FIELD

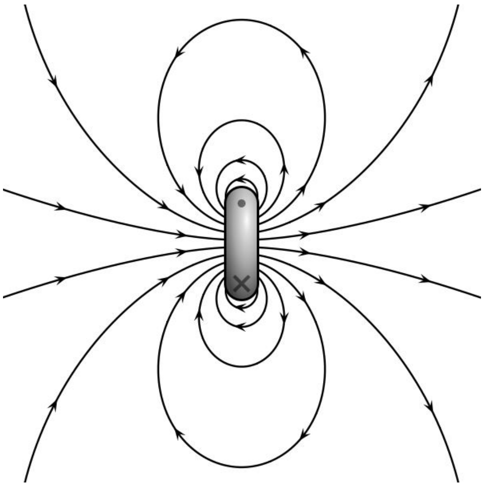
Use the right-hand rule to find direction of B.

10.2.4 Magnetic dipole

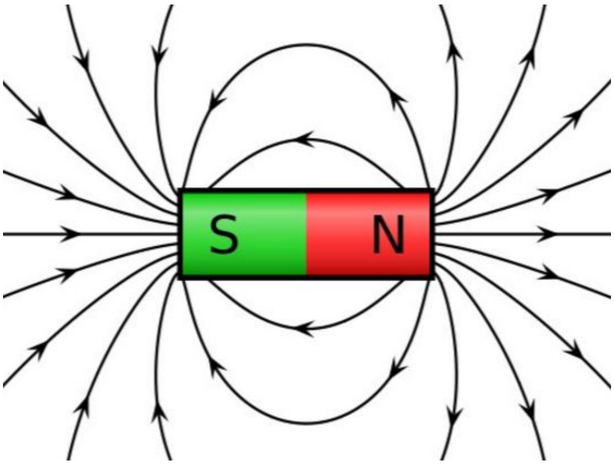
The magnetic dipole has as its electrostatic counterpart enormous importance in the study of magnetic properties of materials for which it allows to develop good theoretical models.

Before reading what follows, we strongly advise the reader (this even more than an advice) to read absolutely everything about the development of the rigid electric dipole moment in the section of Electrostatic. Indeed, most calculations that follow have the same reasoning, mathematical developments and approximations to some tiny nuances. We do not therefore wish to make the same intermediate calculations already present when calculating the electric dipole moment (however, if you really have trouble on reading what follow, we are ready to complete the missing as always in this textbook).

A magnetic dipole is the limit of either a closed loop of electric current or a pair of poles as the dimensions of the source are reduced to zero while keeping the magnetic moment constant.



(a) Magnetic dipole as a current loop (source: Wikipedia)



(b) Magnetic dipole as a magnet

Figure 10.39: Microscopic dipoles point of views

It is a magnetic analogue of the electric dipole, but the analogy is not complete. In particular, a magnetic monopole, the magnetic analogue of an electric charge, has never been observed. Moreover, one form of magnetic dipole moment is associated with a fundamental quantum property: the spin of elementary particles.

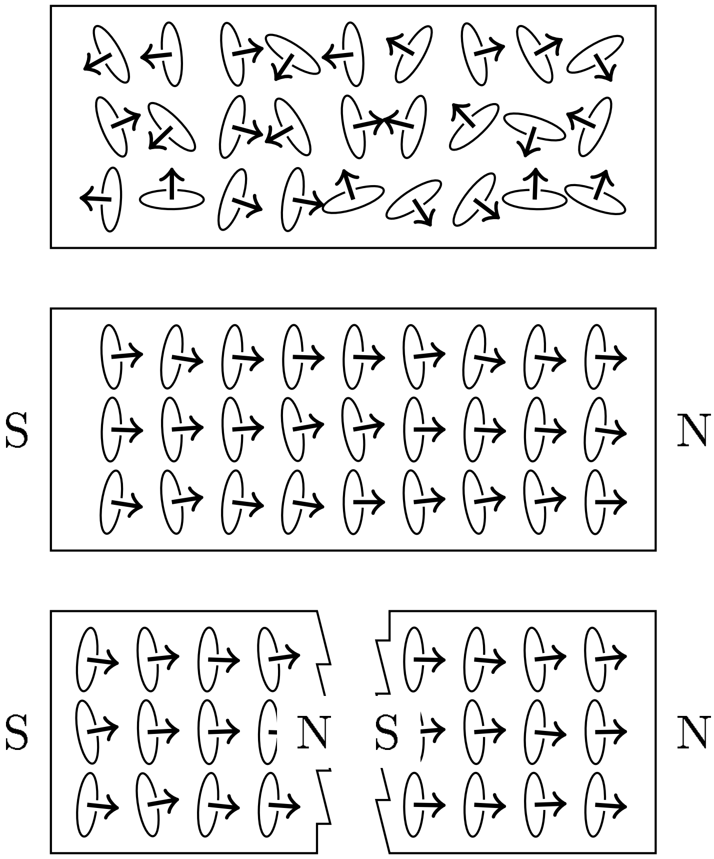


Figure 10.40: **Magnetic dipole (magnet) broken with small spin naively highlighted (author: Jimmy Roussel)**

Some planets as the Earth have a magnetic field quite similar to a magnetic dipole (but quite not homogeneous and not static):

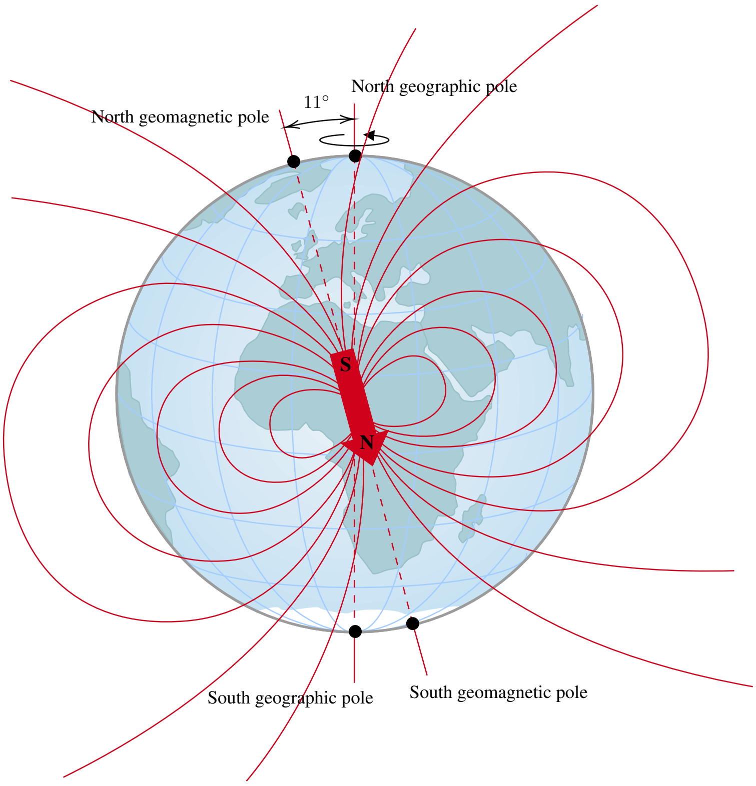

Figure 10.41: Earth viewed as an ideal magnetic dipole

The magnetic dipole, however, has a significant difference in relation to the practical case we impose us as part of its study ... there are no two electric charges! Indeed, electric charges at rest emit in a first approximation (this is experimental and theoretical fact...) an intrinsic magnetic field far too low to be considered interesting in the context of the study of the magnetic properties of materials. However, we should clarify something interesting (very cool), the elementary Coulomb electric charges are modelled sometimes (wrongly!) by physicists as a sphere rotating on itself (the "spin") and are represented as a superposition of small circular loops (oh... a loop we already know something like this) that are infinitely small so an observer in the rest frame (center of the electric charge) can interpret the overall Coulomb electric charge as a current moving in the different current loops, thereby inducing an intrinsic magnetic field (not pretty!?).

In the image below we can see a "standard magnetic compass" and a "dip circle" that differ in purpose and orientation. A magnetic compass is designed to indicate horizontal direction by aligning its needle with the horizontal component of Earth's magnetic field, making it ideal for navigation. In contrast, a dip circle measures the angle of dip (magnetic inclination), which is the angle between the magnetic field and the horizontal plane. Its needle pivots in a vertical plane, allowing it to study the vertical component of Earth's magnetic field, often used in geomagnetic research. Essentially, the compass focuses on direction, while the dip circle explores magnetic field inclination.

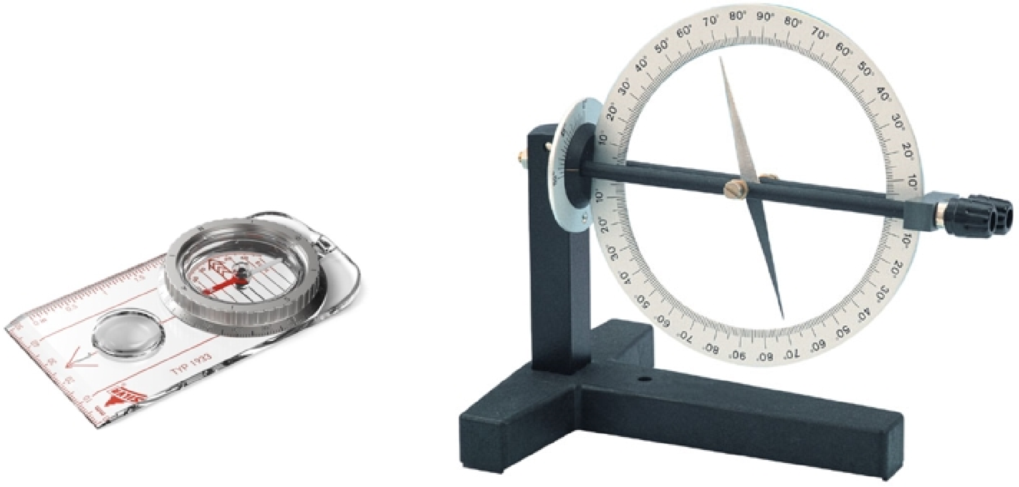

Figure 10.42: **Standard magnetic compass and Dip circle**

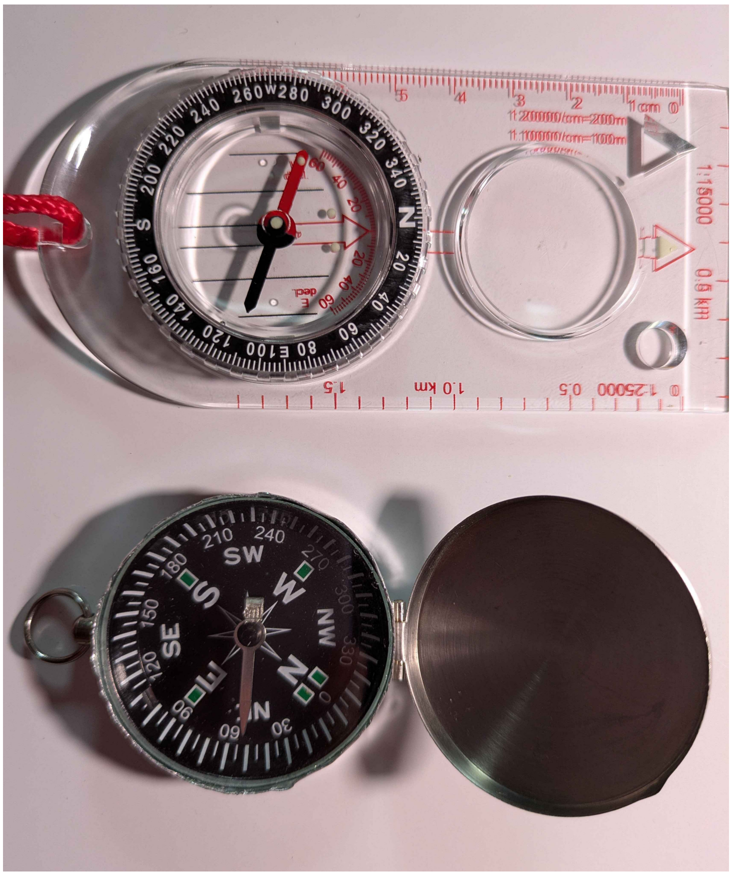
And below we have side by side a classic compass with its complete needle which respectively indicates North and South and a compass whose needle has been cut (it remains however a magnetic dipole) and which aligns with the South but with a little less accuracy than the compass above since its center of moment of force has been moved outside its support.



Remark

Nothing special visible to the human eye happens to a compass at vicinity of the North or South magnetic pole of our planet. Indeed, a magnetic field that is perfectly homogeneous and perfectly perpendicular to the ground (or perfectly horizontal) exists only in laboratories in a well constraint and controlled environment. On the North and South magnetic poles of our planet there will therefore still be a horizontal component that will make the compass work as usual.

In short, let us consider a flat loop (help... another loop again...), of any shape, center on O, through which travel a permanent and constant current I and where one of the points of the loop is denoted by P. We want to calculate the magnetic field generated by this coil at any point M in space, located at a distance r of the loop (specifically, at large distances compared to the size of the loop).

Remark

Personally there are some steps in the calculation that I find... well... very far unconvincing... but... there are so many approximations anyway that these problematic steps can bee see as details only... hummm...

We put:

$$\vec{r}=\overrightarrow{\text{O}M} \quad \vec{r}\,'=\overrightarrow{PM} \quad \vec{\rho}=\overrightarrow{\text{O}P}=\vec{r}-\vec{r}\,' \quad \vec{u}=\frac{\vec{r}}{r} \tag{10.2.73}$$

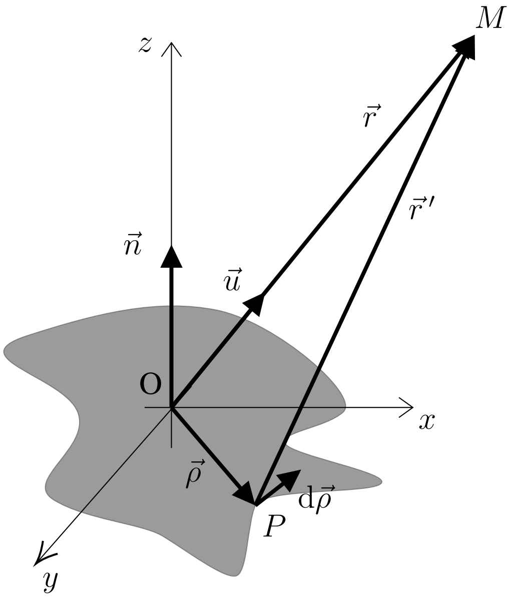


Figure 10.43: **Magnetic dipole study configuration**

So we will use the Biot-Savart law:

$$\vec{B}=\frac{\mu_0}{4\pi}\oint\frac{\vec{J}\times\vec{r}}{r^3}\mathrm{d}V \tag{10.2.74}$$

under the assumption that the point M is located at great distance from the loop. What gives us the right to write:

$$\vec{B}(M)\cong\frac{\mu_0 I}{4\pi}\oint\frac{\mathrm{d}\vec{l}\times\vec{r}'}{r^3}\mathrm{d}V \tag{10.2.75}$$

But as $\mathrm{d}\vec{l}=\mathrm{d}\vec{\rho}$ therefore:

$$\vec{B}(M)\cong\frac{\mu_0 I}{4\pi}\oint\frac{\mathrm{d}\vec{\rho}\times\vec{r}'}{r^3}\mathrm{d}V \tag{10.2.76}$$

Let us evaluate the term $\vec{r}'/r^3$ for points M located far away from the current loop (at the denominator we used the cosine theorem as during our study of the rigid electric dipole moment in the section Electrostatics):

$$\begin{aligned}\frac{\vec{r}'}{r^3}&=\frac{\vec{r}-\vec{\rho}}{(r^2+\rho^2-2\vec{r}\circ\vec{\rho})^{3/2}}\cong\frac{\vec{r}-\vec{\rho}}{r^3\left(1-2\dfrac{\vec{r}\circ\vec{\rho}}{r^2}\right)^{3/2}}\cong\frac{\vec{r}-\vec{\rho}}{r^2}\left(1+3\frac{\vec{r}\circ\vec{\rho}}{r^2}\right)\\&\cong\frac{\vec{u}}{r^2}-\frac{\vec{\rho}}{r^3}+3\frac{\vec{u}\circ\vec{\rho}}{r^3}\vec{u}\end{aligned} \tag{10.2.77}$$

where we did like the rigid electric dipole moment a Taylor limited development to order 1.

Remark

The last approximation is very rough in the sense that it is a clever choice of the terms to neglect to achieve a visually aesthetic result and to define the magnetic dipole moment (see further below) ...

Putting this expression into the Biot-Savart law, we get:

$$\vec{B}(M)\cong\frac{\mu_0 I}{4\pi r^2}\left[\oint\mathrm{d}\vec{\rho}\times\vec{u}-\frac{1}{r}\oint\mathrm{d}\vec{\rho}\times\vec{\rho}+\frac{3}{r}\oint\mathrm{d}\vec{\rho}\times\vec{u}(\vec{u}\circ\vec{\rho})\right] \tag{10.2.78}$$

Let us evaluate each term involved in the parenthesis separately:

1. $\displaystyle\oint\mathrm{d}\vec{\rho}\times\vec{u}=\left(\oint\mathrm{d}\vec{\rho}\right)\times\vec{u}=(\vec{\rho}(P_0)-\vec{\rho}(P_0))\times\vec{u}=\vec{0}\times\vec{u}=\vec{0}$

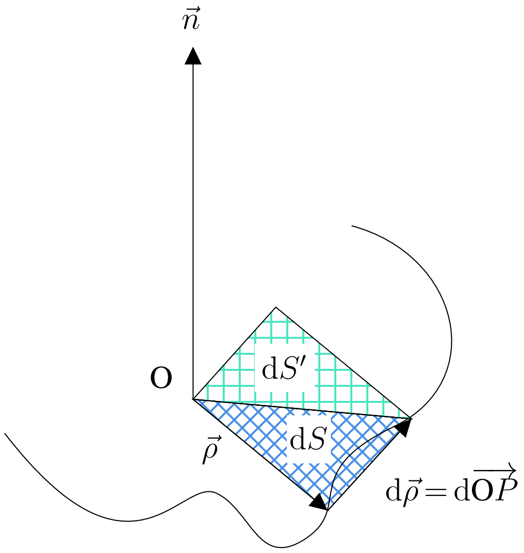
   since the vector $\vec{u}$ is independent of the point P on the current loop and we do a curvilinear integration along the entire turn, returning to the starting point.

2. $\displaystyle -\frac{1}{r}\oint\mathrm{d}\vec{\rho}\times\vec{\rho}$

   By the properties of the vector product:

   $$-\frac{1}{r}\oint\mathrm{d}\vec{\rho}\times\vec{\rho}=\frac{1}{r}\oint\vec{\rho}\times\mathrm{d}\vec{\rho} \tag{10.2.79}$$

   But since $\mathrm{d}\vec{\rho}$ and $\vec{\rho}$ are perpendicular and in a same plane, we have $\vec{\rho}\times\mathrm{d}\vec{\rho}$ which is the infinitesimal surface $\mathrm{d}S'$ of a rectangle and it represents nothing as the abscissa is curved relatively O. Indeed:



$\vec{n}$
O
$\mathrm{d}S'$
$\mathrm{d}S$
$\vec{\rho}$
$\mathrm{d}\vec{\rho}=\mathrm{d}\overrightarrow{\mathrm{O}P}$

So we can write:

$$\vec{\rho}\times\mathrm{d}\vec{\rho}=\mathrm{d}S\vec{n}=2\mathrm{d}S\vec{n}\Leftrightarrow\vec{\rho}\times\mathrm{d}\vec{\rho}=2\mathrm{d}S\vec{n} \tag{10.2.80}$$

where $\vec{n}$ is the vector normal to the plane of the loop (base vector of the z-axis). This result is generally valid regardless of the surface.

Hence:

$$-\frac{1}{r}\oint\mathrm{d}\vec{\rho}\times\vec{\rho}=\frac{1}{r}\oint\vec{\rho}\times\mathrm{d}\vec{\rho}=\frac{1}{r}\oint 2\mathrm{d}S\vec{n}=\frac{1}{r}\vec{n}2\oint\mathrm{d}S=\frac{2S}{r}\vec{n} \tag{10.2.81}$$

3. $\oint\mathrm{d}\vec{\rho}\times\vec{u}(\vec{u}\circ\vec{\rho})=-\vec{u}\times\oint\mathrm{d}\vec{\rho}(\vec{u}\circ\vec{\rho})$ by the properties of the cross product (see section Vector Calculus page 1830).

We will use these relations to calculate the unknown integral of the start of our study. If we decompose the vector $\vec{\rho}$ and $\vec{u}$ in the base $(\vec{e}_1,\vec{e}_2)$ generating the plane of the loop, we get:

$$\mathrm{d}\vec{\rho}(\vec{u}\circ\vec{\rho})=\mathrm{d}\rho_1(\rho_1u_1+\rho_2u_2)\vec{e}_1+\mathrm{d}\rho_2(\rho_1u_1+\rho_2u_2)\vec{e}_2 \tag{10.2.82}$$

as $\mathrm{d}\rho_3=0$ and $\rho_3=0$.

We also have:

$$\begin{gathered}\oint\rho_1u_1\mathrm{d}\rho_1=\frac{u_1}{2}(\rho_1^2(P_0)-\rho_1^2(P_0))=0\\ \oint\rho_2u_2\mathrm{d}\rho_2=\frac{u_2}{2}(\rho_2^2(P_0)-\rho_2^2(P_0))=0\end{gathered} \tag{10.2.83}$$

Hence:

$$\oint\mathrm{d}\vec{\rho}(\vec{u}\circ\vec{\rho})=u_2\oint\rho_2\mathrm{d}\rho_1\vec{e}_1+u_1\oint\rho_1\mathrm{d}\rho_2\vec{e}_2=u_2\vec{e}_1\oint\rho_2\mathrm{d}\rho_1+u_1\vec{e}_2\oint\rho_1\mathrm{d}\rho_2 \tag{10.2.84}$$

Let us recall that:

$$\vec{\rho}\times\mathrm{d}\vec{\rho}=\mathrm{d}S'\vec{n}=2\mathrm{d}S\vec{n}\Leftrightarrow\frac{\vec{\rho}\times\mathrm{d}\vec{\rho}}{2}=\mathrm{d}S\vec{n} \tag{10.2.85}$$

In the form of components (only the third term is non-zero since $\mathrm{d}\rho_3=0$ and $\rho_3=0$), we have:

$$\frac{1}{2}(\rho_1\mathrm{d}\rho_2-\rho_2\mathrm{d}\rho_1)=\mathrm{d}S \tag{10.2.86}$$

hence:

$$\rho_1\mathrm{d}\rho_2-\rho_2\mathrm{d}\rho_1=2\mathrm{d}S\Leftrightarrow\rho_1\mathrm{d}\rho_2=\mathrm{d}S\qquad\rho_2\mathrm{d}\rho_1=-\mathrm{d}S \tag{10.2.87}$$

Which brings us to write:

$$\oint\mathrm{d}\vec{\rho}(\vec{u}\circ\vec{\rho})=u_2\vec{e}_1\oint\rho_2\mathrm{d}\rho_1+u_1\vec{e}_2\oint\rho_1\mathrm{d}\rho_2=-u_2\vec{e}_1\oint\mathrm{d}S+u_1\vec{e}_2\oint\mathrm{d}S \tag{10.2.88}$$

Therefore:

$$-(u_2\vec{e}_1S-u_1\vec{e}_2S)=-S(u_2\vec{e}_1-u_1\vec{e}_2)=-S\left(u_2\begin{pmatrix}1\\0\\0\end{pmatrix}-u_1\begin{pmatrix}0\\1\\0\end{pmatrix}\right)=S\begin{pmatrix}-u_2\\u_1\\0\end{pmatrix} \tag{10.2.89}$$

We notice that the latter relation is equal to:

$$S(\vec{n}\times\vec{u})=S\begin{pmatrix}0\\0\\1\end{pmatrix}\times\begin{pmatrix}u_1\\u_2\\u_3\end{pmatrix}=S\begin{pmatrix}-1\cdot u_2\\1\cdot u_1\\0\end{pmatrix}=S\begin{pmatrix}-u_2\\u_1\\0\end{pmatrix} \tag{10.2.90}$$

Then finally:

$$\oint\mathrm{d}\vec{\rho}(\vec{u}\circ\vec{\rho})=S\vec{n}\times\vec{u} \tag{10.2.91}$$

By bringing together these results we obtain for the magnetic field:

$$\vec{B}(M)\cong\frac{\mu_0I}{4\pi r^2}\left[\frac{2S}{r}\vec{n}-\frac{3\vec{u}}{r}\times(S\vec{n}\times\vec{u})\right] \tag{10.2.92}$$

We see therefore an important quantity that appears because it fully describes the spire seen from a great distance, namely the "magnetic local dipole moment" or simply "magnetic dipole moment":

$$\boxed{\vec{\mu}_l=IS\vec{n}} \tag{10.2.93}$$

also often denoted by $\vec{\mathcal{M}}$ by some practitioners. The magnetic moment has then for units $[\mathrm{A}\cdot\mathrm{m}^2]=[\mathrm{J}\cdot\mathrm{T}^{-1}]=[\mathrm{N}\cdot\mathrm{m}\cdot\mathrm{T}^{-1}]$.

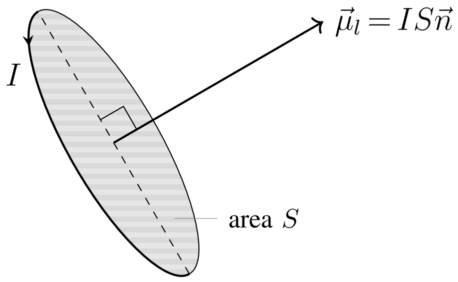


Figure 10.44: **Magnetic dipole**

We then have the prior-previous relation that can be written:

$$\vec{B}(M)\cong\frac{\mu_0}{4\pi r^2}\left[\frac{2\vec{\mu}_l}{r}-\frac{3\vec{u}}{r}\times(\vec{\mu}_l\times\vec{u})\right]\cong\frac{\mu_0}{4\pi}\left[\frac{2\vec{\mu}_l}{r^3}-\frac{3\vec{u}}{r^3}\times(\vec{\mu}_l\times\vec{u})\right] \tag{10.2.94}$$

By making use of the property of the double vector product (see section Vector Calculus page 1835):

$$\vec{u}\times(\vec{\mu}_l\times\vec{u})=(\vec{u}\circ\vec{u})\vec{\mu}_l-(\vec{u}\circ\vec{\mu}_l)\vec{u}=\vec{\mu}_l(\vec{u}\circ\vec{u})-\vec{u}(\vec{u}\circ\vec{\mu}_l) \tag{10.2.95}$$

We then get another form of expression of the approximate magnetic field generated by a dipole:

$$\begin{aligned}\vec{B}(M)&\cong\frac{\mu_0}{4\pi}\left[\frac{2\vec{\mu}_l}{r^3}-\frac{3\vec{u}}{r^3}\times(\vec{\mu}_l\times\vec{u})\right]\cong\frac{\mu_0}{4\pi r^3}\left[2\vec{\mu}_l-3(\vec{\mu}_l(\vec{u}\circ\vec{u})-\vec{u}(\vec{u}\circ\vec{\mu}_l))\right]\\&=\frac{\mu_0}{4\pi r^3}\left[2\vec{\mu}_l-3\vec{\mu}_l\underbrace{(\vec{u}\circ\vec{u})}_{=1}+3\vec{u}(\vec{u}\circ\vec{\mu}_l))\right]=\frac{\mu_0}{4\pi r^3}\left[3\vec{u}(\vec{u}\circ\vec{\mu}_l)-\vec{\mu}_l\right]\end{aligned} \tag{10.2.96}$$

It is in the latter form that we found the most often the expression of the magnetic moment in the literature.

This relation has to be compared (for fun) with the expression for the electric field for a rigid electric dipole:

$$\boxed{\begin{aligned}\vec{B}&\cong\frac{\mu_0}{4\pi r^3}\left[3\vec{u}(\vec{u}\circ\vec{\mu}_l))-\vec{\mu}_l\right]\\\vec{E}&\cong\frac{1}{4\pi\varepsilon r^3}\left[3\vec{u}_r(\vec{u}_r\circ\vec{p}))-\vec{p}\right]\end{aligned}} \tag{10.2.97}$$

and thus we see that there is perfect correspondence.

We still arrived to put this in a fairly identical and aesthetics and form after some approximations...

We have also:

$$\vec{\mu}_l\circ\vec{u}=\|\vec{\mu}_l\|\cdot\|\vec{u}\|\cos(\theta)=\mu_0\cos(\theta) \tag{10.2.98}$$

Therefore:

$$\vec{B}(M)\cong\frac{\mu_0}{4\pi r^3}\left[3\vec{u}\mu_l\cos(\theta)-\vec{\mu}_l\right] \tag{10.2.99}$$

Remember that the magnetic field due to a magnetic dipole moment, $\vec{\mu}_l$ at a point $\vec{R}$ relative to it may be written:

$$\vec{B}(r)\cong\frac{\mu_0}{4\pi r^3}\left[3\vec{u}\,(\vec{u}\circ\vec{\mu}_l)-\vec{\mu}_l\right] \tag{10.2.100}$$

where μ_0 is the vacuum permeability. In geomagnetism, it is usual to write the radial and angular components of $\vec{B}$ as:

$$\begin{aligned}B_r&=-2B_0\left(\frac{R_\mathrm{E}}{r}\right)^3\cos(\theta)\\B_\theta&=-B_0\left(\frac{R_\mathrm{E}}{r}\right)^3\sin(\theta)\\B_\phi&=0\end{aligned} \tag{10.2.101}$$

where θ is polar (colatitude) angle (relative to the magnetic North pole), ϕ is the azimuthal angle (longitude), and R_E is the Earth's radius, about $6,370$ [km].

Indeed consider the dipole to lie along the y-axis: $\vec{\mu}_l = \mu_l \vec{\jmath}$ and define $\vec{B}_0$ to be the field perpendicular to $\vec{\mu}_l$ at a distance R_E from it (i.e. on the Earth's magnetic equator):

$$\vec{B}_0 = -\frac{\mu_0 \mu_l}{4\pi R_\text{E}^3}\vec{\jmath} = B_0 \vec{\jmath} \tag{10.2.102}$$

Hence:

$$\vec{\mu}_l = \mu_l \vec{\jmath} = \frac{\vec{B}_0 4\pi R_\text{E}^2}{\mu_0} \tag{10.2.103}$$

Therefore:

$$\vec{B}(r) \cong \frac{\mu_0}{4\pi r^3}\left[3\vec{u}\left(\vec{u}\circ\vec{\mu}_l\right) - \vec{\mu}_l\right] = -B_0\left(\frac{R_\text{E}}{r}\right)^3 \left[3\cos(\theta)\vec{u} - \vec{\jmath}\right] \tag{10.2.104}$$

The radial component of the magnetic field is therefore:

$$B_r = \vec{B}(r)\circ\hat{\vec{r}} = -B_0\left(\frac{R_\text{E}}{r}\right)^3 \left[3\cos(\theta) - \cos(\theta)\right] = -2B_0\left(\frac{R_\text{E}}{r}\right)^3 \cos\theta \tag{10.2.105}$$

Its angular component is perpendicular to this:

$$B_\theta = \vec{B}\cdot\hat{\vec{\theta}} = -B_0\left(\frac{R_\text{E}}{r}\right)^3 \left[-\vec{\jmath}\circ\hat{\vec{\theta}}\right] = -B_0\left(\frac{R_\text{E}}{r}\right)^3 \sin(\theta) \tag{10.2.106}$$

Remark

As we can see it these are not the polar equations of a section of a (regular) torus! Therefore it is wrong to say that the field lines of a magnetic dipole are shaped like a "torus". The conventional terminology is to say that it is shaped liked a "dipolar geometry".

With this definition, B_0 denotes the magnitude of the mean value of the field at the magnetic equator on the Earth's surface, about $31.2\,[\mu\text{T}]$. With these definitions, we can plot the dipole component of the Earth's magnetic field as a Python™ Matplotlib streamplot. We first construct a meshgrid of (x, y) coordinates and convert them into polar coordinates with the relations:

$$\begin{aligned} r &= \sqrt{x^2+y^2} \\ \theta &= \text{atan}\,2\left(\frac{y}{x}\right) \end{aligned} \tag{10.2.107}$$

We can then use the relation above to calculate B_r and B_θ and convert back to Cartesian coordinates to plot the streamplot. The θ coordinate is offset by $\alpha = 9.6^\circ$ to account for the current tilt of the Earth's magnetic dipole with respect to its rotational axis.

Here is the Python™ code from Christian Hill (physicist and chemist) taken from `https://scipython.com/blog/visualizing-the-earths-magnetic-field/`:

```python
import sys
import numpy as np
import matplotlib.pyplot as plt
from matplotlib.patches import Circle

# Mean magnitude of the Earth's magnetic field at the equator in T
B0 = 3.12e-5
# Radius of Earth, Mm (10^6 m: mega-metres!)
RE = 6.370
# Deviation of magnetic pole from axis
alpha = np.radians(9.6)

def B(r, theta):
    """Return the magnetic field vector at (r, theta)."""
    fac = B0 * (RE / r)**3
    return -2 * fac * np.cos(theta + alpha), -fac * np.sin(theta + alpha)

# Grid of x, y points on a Cartesian grid
nx, ny = 64, 64
XMAX, YMAX = 40, 40
x = np.linspace(-XMAX, XMAX, nx)
y = np.linspace(-YMAX, YMAX, ny)
X, Y = np.meshgrid(x, y)
r, theta = np.hypot(X, Y), np.arctan2(Y, X)

# Magnetic field vector, B = (Ex, Ey), as separate components
Br, Btheta = B(r, theta)
# Transform to Cartesian coordinates: NB make North point up, not to the right.
c, s = np.cos(np.pi/2 + theta), np.sin(np.pi/2 + theta)
Bx = -Btheta * s + Br * c
By = Btheta * c + Br * s

fig, ax = plt.subplots()

# Plot the streamlines with an appropriate colormap and arrow style
color = 2 * np.log(np.hypot(Bx, By))
ax.streamplot(x, y, Bx, By, color=color, linewidth=1, cmap=plt.cm.inferno,
              density=2, arrowstyle='->', arrowsize=1.5)

# Add a filled circle for the Earth; make sure it's on top of the streamlines.
ax.add_patch(Circle((0,0), RE, color='b', zorder=100))

ax.set_xlabel('$x$')
ax.set_ylabel('$y$')
ax.set_xlim(-XMAX, XMAX)
ax.set_ylim(-YMAX, YMAX)
ax.set_aspect('equal')
```

```
plt.show()
```

That gives:

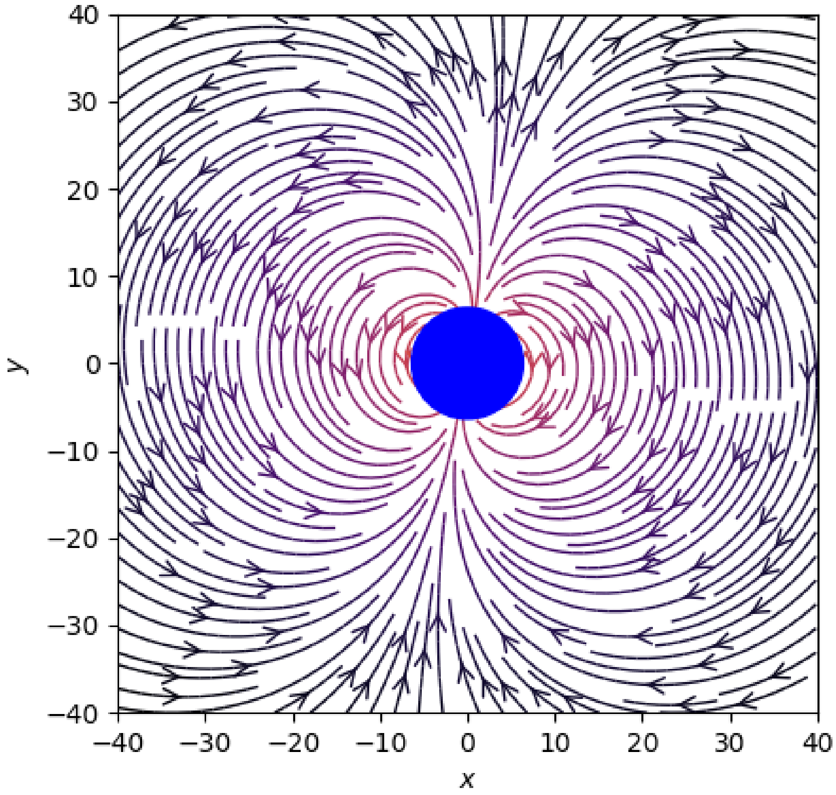

Figure 10.45: **Visualizing dipole magnetic field with Python™ (author: Christian Hill)**

The origin of the magnetic field of any material must be microscopic. Using the Bohr model of the atom (see section Corpuscular Quantum Physics page 4626) we can convince ourselves that atoms (at least some) have an intrinsic magnetic dipole moment. Indeed, the Bohr model of the Hydrogen atom consists of an electron of electric charge $q=-e$ in circular motion around a central nucleus (a proton with an electric charge $q=+e$) with a period $T=2\pi\omega$.

If we look over long time scales compared to T, it is as if there was an electric current:

$$I=\frac{q}{T}=\frac{q\omega}{2\pi} \tag{10.2.108}$$

So we have indeed a sort of circular loop, of mean radius equal to the average distance to the proton, i.e. the Bohr radius r_0 (see section Corpuscular Quantum Physics page 4630). The Hydrogen atom therefore have an intrinsic magnetic moment of:

$$\boxed{\vec{\mu}_l=IS\vec{n}=\frac{q\omega}{2\pi}\pi r_0^2\vec{n}=\frac{q\omega}{2}r_0^2\vec{n}=\frac{q}{2m}m\omega r_0^2\vec{n}=\frac{q}{2m}\vec{b}} \tag{10.2.109}$$

where $\vec{b}$ is the momentum of the electron and $q/2m$ the "gyromagnetic factor" (this result is very important for the Langevin model of diamagnetism!).

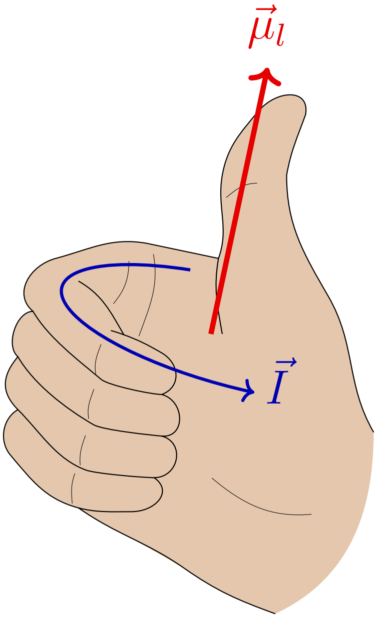

Figure 10.46: **Magnetic moment right-handed rule (author: Izaak Neutelings)**

This reasoning can be generalized to other atoms. Indeed, a set of electric charges in rotation about an axis will produce a magnetic moment proportional to the total angular momentum. This happens even if the total electric charge is zero (material or neutral atom): what matters is the (scalar) existence of a current.

Remark

We deduce then immediately that for a non-conductive ring of radius R having a linear charge density ρ, turning at a rate $\omega=2\pi/T$ we then have:

$$\vec{\mu}_l=IS\vec{n}=\frac{\rho 2\pi R}{T}\pi R^2\vec{n}=\frac{Q}{2\pi}\omega R^2\vec{n} \tag{10.2.110}$$

So this is the magnetic moment of a rotating non-conductive ring!

So in fact, we can qualitatively explain the magnetic properties of materials based on the orientation of the magnetic moments of the atoms that compose them:

- "Non-magnetic materials": These are materials where the magnetic moments are randomly distributed, there is no intrinsic magnetic field.
- "Diamagnetic materials": these are the materials that subjected to a magnetic field, have their magnetic moments that opposed to it and are (marginally) repelled by magnets. They therefore induce a magnetic moment opposite to the magnetic field direction.
- "Paramagnetic materials": it is the materials for which moments can be oriented in the direction of an external magnetic field and can therefore be magnetized so (attracted) momentarily. They therefore induce a magnetic moment in the direction of the magnetic field.

- "Ferromagnetic materials": are materials whose moments are already oriented in a particular direction, permanently (natural magnets).

Remark

Earth is known to have a dipolar magnetic field where the magnetic north pole corresponds to the geographic South Pole (at a given angle value). At the macroscopic level, the explanation for the existence of the magnetic field observed on the stars is still far from satisfactory. The theory of "dynamo effect" trying to explain the fields observed by the presence of currents, mainly azimuthal, in the core of stars. Several known facts remain partially unsolved:

- The magnetic cycles: the Sun (actually a G2V-type star, aka yellow dwarf) has a large-scale magnetic field similar to that of Earth, approximately dipolar. However, there is a polarity inversion every 11 years. For the Earth, geophysicists were able to show that there had been a reversal about $700,000$ years before.
- Non-alignment with the angular momentum of the celestial body: it is of the order of ten degrees for the Earth, it is perpendicular for Neptune!

Let us consider now a non-conducting disc of radius R, charge Q and uniform charge density σ is rotating about an axis passing through its center and perpendicular to its plane with an angular velocity ω. To determine it's magnetic moment (not a bad approximation of a non-relativistic Black Hole accretion disc), we divide the disk into many small rings of width $\mathrm{d}r$. The current produced by the ring is the total charge contained divided by the period for one rotation. Thus:

$$\mathrm{d}I=\frac{\sigma(2\pi r\mathrm{d}r)}{\omega/(2\pi)} \tag{10.2.111}$$

Factoring in the area of each ring gives

$$\mathrm{d}\mu=(\pi r^2)\frac{\sigma(2\pi r\mathrm{d}r)}{\omega/(2\pi)}=\sigma\omega\pi r^3\mathrm{d}r \tag{10.2.112}$$

Therefore:

$$\mu_l=\int\limits_0^R\sigma\omega\pi r^3\mathrm{d}r=\frac{1}{4}\sigma\omega\pi R^4 \tag{10.2.113}$$

Or in vector form we have then the magnetic moment of a rotating disc:

$$\boxed{\vec{\mu}_l=\frac{1}{4}\sigma\pi R^4\vec{\omega}} \tag{10.2.114}$$

Let us now consider a non-conductive sphere shell of radius R rotating a constant speed ω around the Z axis with a uniform surface electric charge σ

We split the sphere into thin segments (each corresponding to a ring), each one having for magnetic moment:

$$\mathrm{d}\mu_l=\mathrm{d}I\mathrm{d}S \tag{10.2.115}$$

where $\mathrm{d}S$ is the area enclosed by the segment (keep in mind that the projected radius is $r = R\sin(\theta)$):

$$\mathrm{d}S = 2\pi r\mathrm{d}r = 2\pi R\sin(\theta)\mathrm{d}r \tag{10.2.116}$$

The current $\mathrm{d}I$ on each segment is :

$$\mathrm{d}I = \frac{\mathrm{d}Q}{T} = \frac{\omega}{2\pi}\mathrm{d}Q \tag{10.2.117}$$

The charge on each segment is:

$$\mathrm{d}Q = \sigma\mathrm{d}s \tag{10.2.118}$$

Where $\mathrm{d}s$ is the surface area of the segment (see section Geometric Shapes page 2964):

$$\mathrm{d}s = r^2\sin(\theta)\mathrm{d}\theta\mathrm{d}\phi = R^2\sin^3(\theta)\mathrm{d}\theta\mathrm{d}\phi \tag{10.2.119}$$

This results in:

$$\mathrm{d}Q = \sigma R^2\sin^3(\theta)\mathrm{d}\theta\mathrm{d}\phi = \frac{q}{4\pi R^2}R^2\sin^3(\theta)\mathrm{d}\theta\mathrm{d}\phi \tag{10.2.120}$$

We now have an expression for $\mathrm{d}I$:

$$\mathrm{d}I = \frac{\omega QR^2\sin^3(\theta)}{8\pi^2R^2}\mathrm{d}\theta\mathrm{d}\phi \tag{10.2.121}$$

Now we can calculate the moment of each segment:

$$\mathrm{d}\mu_l = \frac{\omega QR^2\sin^3(\theta)}{8\pi^2R^2}2\pi r\mathrm{d}r\mathrm{d}\phi\mathrm{d}\theta = \frac{\omega Q}{4\pi}\sin^3(\theta)r\mathrm{d}r\mathrm{d}\phi\mathrm{d}\theta \tag{10.2.122}$$

Integrating this over the whole sphere gives:

$$\begin{aligned}\mu_l &= \frac{\omega Q}{4\pi}\int_0^R r\mathrm{d}r\int_0^\pi \sin^3(\theta)\mathrm{d}\theta\int_0^{2\pi}\mathrm{d}\phi = \frac{\omega Q}{4\pi}\frac{1}{2}R^2 2\pi\int_0^\pi \sin^3(\theta)\mathrm{d}\theta = \frac{\omega QR^2}{4}\int_0^\pi \sin^3(\theta)\mathrm{d}\theta\\ &= \frac{\omega QR^2}{4}\frac{4}{3} = \frac{\omega QR^2}{3}\end{aligned} \tag{10.2.123}$$

Hence the magnetic moment for a spherical shell:

$$\boxed{\mu_l = \frac{\omega QR^2}{3}} \tag{10.2.124}$$

Remark

It seems that the result is the same for a ball instead than for a spherical shell. If it's true, it's a useful example for some special exotic astronomical objects.

To see a last pretty practical case of the magnetic dipole, remember that in the section Electrostatics, we had shown that in spherical coordinates we had for the electric dipole:

$$E_r = \frac{p\cos(\theta)}{2\pi\varepsilon r^3} \quad E_\theta = \frac{p\sin(\theta)}{4\pi\varepsilon r^3} \quad E_\phi = 0 \tag{10.2.125}$$

And as we have shown there is perfect correspondence between the magnetic and electric dipole moment, then we can immediately write:

$$\boxed{B_r=\frac{\mu_0\mu_l\cos(\theta)}{2\pi r^3}\qquad B_\theta=\frac{\mu_0\mu_l\sin(\theta)}{4\pi r^3}\qquad B_\phi=0} \tag{10.2.126}$$

We can then deduce the norm of the magnetic field vector:

$$\begin{aligned}B=\|\vec{B}\|&=\sqrt{B_r^2+B_\theta^2+B_\phi^2}=\sqrt{\left(\frac{\mu_0\mu_l\cos(\theta)}{2\pi r^3}\right)^2+\left(\frac{\mu_0\mu_l\sin(\theta)}{4\pi r^3}\right)^2}\\&=\frac{\mu_0\mu_l}{2\pi r^3}\sqrt{\cos^2(\theta)+\frac{\sin^2(\theta)}{4}}=\frac{\mu_0\mu_l}{2\pi r^3}\sqrt{\frac{1}{4}(4\cos^2(\theta)+\sin^2(\theta))}=\frac{\mu_0\mu_l}{4\pi r^3}\sqrt{4\cos^2(\theta)+\sin^2(\theta)}\\&=\frac{\mu_0\mu_l}{4\pi r^3}\sqrt{4\cos^2(\theta)+(1-\cos^2(\theta))}=\frac{\mu_0\mu_l\sqrt{3\cos^2(\theta)+1}}{4\pi r^3}=\frac{\mu_0\mu_l\sqrt{1+3\cos^2(\theta)}}{4\pi r^3}\end{aligned} \tag{10.2.127}$$

Therefore at the North Pole we have:

$$\begin{aligned}B_r(r,0,\phi)&=\frac{\mu_0\mu_l\cos(\theta)}{2\pi r^3}=\frac{\mu_0\mu_l}{2\pi r^3}\\B_\theta(r,0,\phi)&=\frac{\mu_0\mu_l\sin(\theta)}{4\pi r^3}=0\end{aligned} \tag{10.2.128}$$

and at the equator:

$$\begin{aligned}B_r\left(r,\frac{\pi}{2},\phi\right)&=\frac{\mu_0\mu_l\cos(\theta)}{2\pi r^3}=0\\B_\theta\left(r,\frac{\pi}{2},\phi\right)&=\frac{\mu_0\mu_l\sin(\theta)}{4\pi r^3}=\frac{\mu_0\mu_l}{4\pi r^3}\end{aligned} \tag{10.2.129}$$

The magnitude of the total field at the pole is twice as strong as at the equator (most people think that intuitively it is the opposite)!

We can also write from the previous results:

$$\boxed{\mu_l=\frac{4\pi r^3 B}{\mu_0\sqrt{1+3\cos^2(\theta)}}} \tag{10.2.130}$$

also sometimes denoted by the letter m (yes... its obvious to refer the first letter of "magnetism").

✍**Example:**

Thus, we can have fun to calculate the magnetic moment of the Earth at the geomagnetic equator. What gives, knowing that the Earth's geomagnetic field at equator is in average equal to 32 [μT] (Earth's magnetic field intensity is roughly between $25,000$

- $65,000$ [nT] (i.e. 0.25 to 65 [Gauss]):

$$\mu_l=\frac{4\pi r^3 B}{\mu_0\sqrt{1+3\cos^2(\theta)}}=\frac{4\pi(6371)^3 32\cdot 10^{-6}}{\mu\sqrt{1+3\cos^2\left(\dfrac{\pi}{2}\right)}}\cong 78\cdot 10^{21}\,[\mathrm{A}\cdot\mathrm{m}^2]=78\cdot 10^{21}\,[\mathrm{C}\cdot\mathrm{s}^{-1}\cdot\mathrm{m}^2] \tag{10.2.131}$$

For the fun we can convert that easily to how much mass of simply ionized moving iron it corresponds:

$$\begin{aligned}M_{\mathrm{Fe}}&\cong\frac{78\cdot 10^{21}}{e\cdot N_{\mathbf{Av}}}\cdot M_{\text{mol,Fe}}=\frac{78\cdot 10^{21}}{1.609\cdot 10^{-19}\cdot 6.022\cdot 10^{23}}\cdot 55.847\cdot 10^{-3}\\&\cong 4.51\cdot 10^{16}\,[\mathrm{Kg}]\end{aligned} \tag{10.2.132}$$

As measurements (Geophysical Journal International, Volume 84, Issue 3, March 1986, Pages 561–579, https://doi.org/10.1111/j.1365-246X.1986.tb04371.x) give that the density of iron at the inner core-outer core boundary pressure is close to $1,300$ $[\mathrm{kg}\cdot\mathrm{m}^{-3}]$, the latter result give an Iron quantity corresponding to a moving volume of:

$$V_{\mathrm{Fe}}=\frac{4.51\cdot 10^{16}}{1,300}\cong 3.47\cdot 10^{13}\,[\mathrm{m}^3] \tag{10.2.133}$$

Volume of simply ionized moving iron corresponding to a sphere of radius:

$$R_{\mathrm{Fe}}\cong\sqrt[3]{\frac{4}{3}\frac{3.47\cdot 10^{13}}{\pi}}\cong 20\,[\mathrm{km}] \tag{10.2.134}$$

So it's not even that big considering the dimensions of Earth in comparison and especially in comparison to the whole inner core that has a radius estimated thanks to seismology techniques at $1,220$ kilometres...!

We can also estimated the magnetic field intensity at the surface of Earth's core. As the radius of Earth's core based on seismology is estimated to be equal at $3,484$ [km] and Earth's radius $6,371$ [km] we then have knowing (as proved above) that the magnetic field of dipole decrease as $1/r^3$, we then have:

$$B_{\text{Earth,core}}\cong 32\cdot 10^{-6}\frac{(6371\cdot 10^3)^3}{(3484\cdot 10^3)^3}\cong 196\,[\mu\mathrm{T}]=0.192\,[\mathrm{mT}] \tag{10.2.135}$$

Hence the magnetic field at Earth's core surface is approximately 6 times stronger at Earth's surface. Numerical models (see [29] and [100]) and theoretical consideration (see [510]) suggest an internal magnetic field of 1 to 4 [mT].

For the Earth (that is far from a perfect solid dipole at the opposite of Neutron Star), measurements give for the magnetic field amplitude:

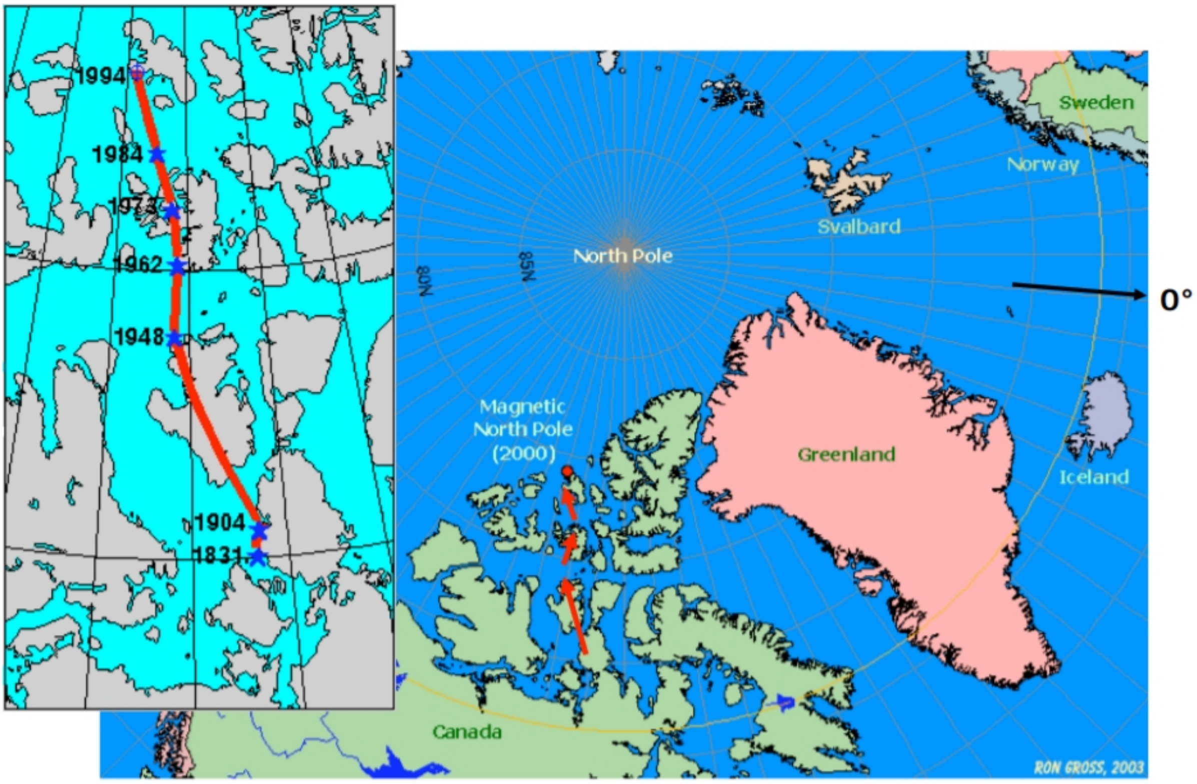
and furthermore the (main) magnetic north pole of Earth moves across the ages (this is named the "secular variation of Earth's magnetic north pole"):



A quite common question when dealing with such a topic is: Why does magnetism penetrate the huge majority of non-exotic (expected mu-metals and supra-conductors) so easily on thousand of kilometres like the magnetic field of Earth's inner core to Earth's surface!?

To answer this question we should reframe the question and ask: how do we prevent the penetration of magnetic fields in a solid in the first place? As we will see during our study of Maxwell equation, there are no magnetic monopoles (see page 4099) in nature, so the only possible way is to block the field is to run a current in the material which generates a field that counteracts the applied magnetic field.

If the only way for a material to to block an external magnetic field is through a current, we should think about how that current can be sustained in time. With the exception of superconductors, all materials have nonzero resistance. Therefore, the current needed to block penetration of magnetic fields will always decay in time. Thus, in general, there is no way to screen static magnetic fields in a material with non-zero resistance.

On the other hand, for alternating magnetic fields, most metals block magnetic fields just fine (provided they are thick compared to the skin depth) and the magnetic field does not penetrate except in an exponentially suppressed fashion. The key point here is Faraday's law (see page 4259) which tells us that we need a changing magnetic field to generate a current.

10.2.4.1 Magnetic torque

We have just introduced earlier the dipolar magnetic moment $\vec{\mu}_l$. For a magnet, the magnetic moment (denoted μ) is indirectly defined a quantity that determines the torque it will experience in an external magnetic field such that by definition:

$$\boxed{\vec{\tau}=\vec{\mu}\times\vec{B}} \quad (10.2.136)$$

Thus, if a magnetic dipole (or a bar magnet) is placed in a uniform magnetic field in oblique orientation, it experiences no force but experiences a torque. This torque tends to align the dipole moment along the direction of magnetic field!

We also have that a magnetic dipole moment may be defined as the torque acting on a magnetic dipole placed perpendicular to a uniform magnetic field of unit strength as in this case we have $\vec{\tau}=\vec{\mu}$.

In the magnetic pole representation of a material, a magnetic material can be identified as two magnetic poles some distance apart. The magnetic moment of a material bar is then given by the product of the "magnetic pole strength" denoted q_m and the distance between the poles L. Then for a magnetic bar where $\vec{n}$ is the unitary vector collinear to the magnet bar length, we have experimentally:

$$\vec{\tau}=\vec{\mu}\times\vec{B}=(q_m L\vec{n})\times\vec{B} \quad (10.2.137)$$

That is in scalar form:

$$\boxed{\tau=q_m LB\sin(\theta)} \quad (10.2.138)$$

This is the famous relation of the torque for a magnetic bar in a uniform constant magnetic field having two poles of magnetic strength q_m and $-q_m$:

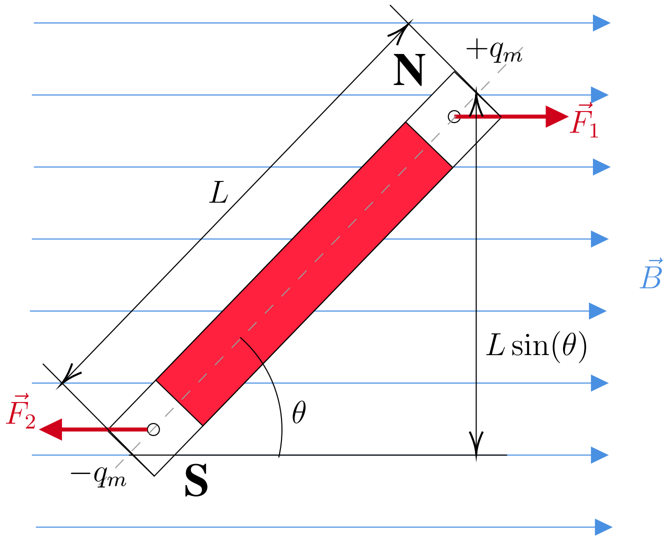


Figure 10.48: **Torque on a bar magnet in a uniform magnetic field**

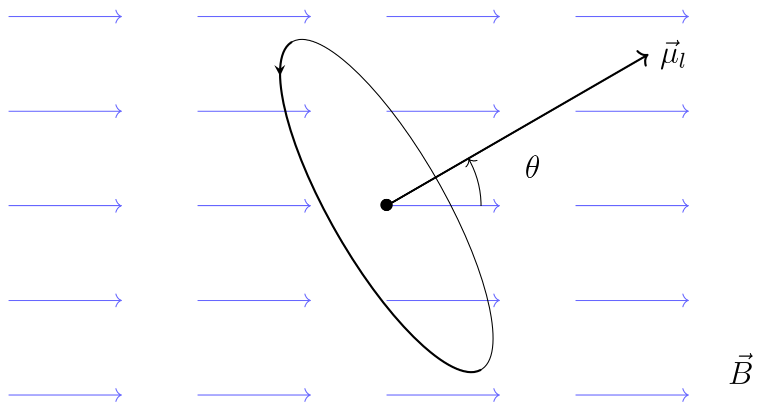
The lines of action of both forces $\vec{F}_1$ and $\vec{F}_2$ are different, therefore, these two forces form a couple (or torque) which tends to rotate the magnet along the direction of magnetic field strength.

Thus, torque acting on the bar magnet is max, when it is placed perpendicular to the magnetic field.

Obviously the same applies for the dipolar magnetic moment $\vec{\mu}_l$:



The work done in rotating the dipole through a small angle $\mathrm{d}\theta$:

$$\mathrm{d}W = \tau \mathrm{d}\theta = \mu B \sin(\theta)\mathrm{d}\theta \tag{10.2.139}$$

If the dipole is rotated from $\theta = 0_1$ to $\theta = \theta_2$, total work done is given by:

$$W = \int\limits_{\theta_1}^{\theta_2} \mu B \sin(\theta)\mathrm{d}\theta = -\mu B \left(\cos(\theta_2) - \cos(\theta_1)\right) \tag{10.2.140}$$

If $\theta_1 = \pi/2$ and $\theta_2 = \theta$, then:

$$W = -\mu B \cos(\theta) \tag{10.2.141}$$

This work done is stored in the form of potential energy i.e:

$$E_p = -\mu B \cos(\theta) \tag{10.2.142}$$

We will see again this relation further below.

10.2.5 Lorentz law (Lorentz force)

In electrostatics, we calculated the force exerted by one or a collection of electric charges at rest (...) on a stationary or moving electric charge. The electric force was for recall written as following:

$$\vec{F}=q\vec{E}(\vec{r}) \tag{10.2.143}$$

In the most general case, where the acting electric charges are moving, the force they exert on a punctual electric charge q placed in a given point in space is the sum of two terms: one that is independent of the relative speed $\vec{v}$ of this electric charge, the other that depends on it. Here's how is written this relation:

$$\boxed{\vec{F}=q\left(\vec{E}+\vec{v}\times\vec{B}\right)} \tag{10.2.144}$$

that is the "Lorentz law" or "Lorentz force".

To prove this relation, we will put two assumptions, but first it is important to inform the reader that this proof requires not necessarily obvious mathematical tools (most reader will have to read the section of Analytical Mechanics and Wave Quantum Physics to understand it well):

H1. Given a non-relativistic point particle of mass m, of coordinates x_i with $i=1,2,3$ and velocity $\dot{x}_i$ still with $i=1,2,3$. We assume that it is subjected to a force $\vec{F}$ that satisfies Newton's equations:

$$m\ddot{\vec{x}}=\vec{F}(\vec{x},\vec{v},t) \tag{10.2.145}$$

with the following commutation relations (see sections of Analytical Mechanics page 3189 and Wave Quantum Physics page 4718):

$$\begin{gathered}[x_i,x_j]=0\\ m[x_i,v_j]=\mathrm{i}\hbar\delta_{ij}\end{gathered} \tag{10.2.146}$$

The reader must realize that the last relation is an assumption (hypothesis) and it is not equivalent to the commutation rules that we saw in the section of Wave Quantum Physics between positions and linear momentum!

H2. There exist fields $\vec{E}(\vec{x},t)$ and $\vec{B}(\vec{x},t)$, not depending on the speed, such that:

$$\vec{F}=q(\vec{E}+\vec{v}\times\vec{B}) \tag{10.2.147}$$

and which satisfy the Maxwell equations (see section Electrodynamics page 4095):

$$\begin{gathered}\vec{\nabla}\times\vec{E}=-\frac{\partial\vec{B}}{\partial t}\\ \vec{\nabla}\circ\vec{B}=0\end{gathered} \tag{10.2.148}$$

At a classical level, we express the commutation assumptions by using the Poisson correspondence commutation-brackets (see section Analytical Mechanics page 3189), that is:

$$\begin{gathered}\{x_i,x_j\}=0\\ m\{x_i,\dot{x}_j\}=\mathrm{i}\hbar\delta_{ij}\end{gathered} \tag{10.2.149}$$

with (recall):

$$\{A,B\}=\sum_{i=1}^{3}\left\{\frac{\partial A}{\partial x_i}\frac{\partial B}{\partial p_i}-\frac{\partial A}{\partial p_i}\frac{\partial B}{\partial x_i}\right\} \tag{10.2.150}$$

Now we define a vector potential $\vec{A}$ (see section Electrodynamics page 4057) such that:

$$p_j=m\dot{x}_j+qA_j \tag{10.2.151}$$

then the hypothesis of commutation ($\{x_i,p_j\}=\delta_{ij}$) can be written for $i\neq j$:

$$\{x_i,p_j\}=x_i(m\dot{x}_j+qA_j)-(m\dot{x}_j+qA_j)x_i=0=\{x_i,A_j\} \tag{10.2.152}$$

So we can say that $\vec{A}$ depends only on $\vec{x}$ and t and since it commutes identically to p_j.

Moreover, we know that classical mechanics admits a Lagrangian formulation (equivalent to Newton's equations) for which the equations of mechanics become (see section Analytical Mechanics page 3181):

$$\begin{aligned}p_j&=\frac{\partial L}{\partial \dot{x}_j}\\ \dot{p}_j&=\frac{\partial L}{\partial x_j}\end{aligned} \tag{10.2.153}$$

where L is the Lagrangian of the system. Therefore, with:

$$p_j=m\dot{x}_j+qA_j(\vec{x},t) \tag{10.2.154}$$

we can integrate the relation:

$$p_j=\frac{\partial L}{\partial \dot{x}_j} \tag{10.2.155}$$

and we get:

$$L=\frac{1}{2}m\dot{x}_j^2+q\left(\dot{x}_jA(\vec{x},t)-\phi(\vec{x},t)\right) \tag{10.2.156}$$

Just as the electric scalar potential ϕ is a potential energy per unit charge, the magnetic vector potential $\vec{A}$ is potential energy per unit length element of current (but current has a direction, so the magnetic vector potential has to have three components, that's why it's a vector too...) that is [J$\cdot$m^{-1}A^{-1}]. It is an old tradition sometimes to use a derivate unit name the "Weber" such that:

$$1\,[\mathrm{J}\cdot\mathrm{m}^{-1}\mathrm{A}^{-1}]=1\,[\mathrm{W}\cdot\mathrm{m}^{-1}] \tag{10.2.157}$$

The "$-$" sign of the constant of integration of the vector potential is justified to be consistent with what we will see during our study of gauge theory (see section Electrodynamics page 4115).

The second Lagrange equation $p_j = m\dot{x}_j + qA_j(\vec{x},t)$ gives us then:

$$\dot{p}_j = m\ddot{x}_j + q\dot{A}_j = \frac{\partial L}{\partial x_j} \tag{10.2.158}$$

By developing a little bit:

$$m\ddot{x}_j = \dot{p}_j - q\dot{A}_j \tag{10.2.159}$$

and:

$$\dot{p}_j = \frac{\partial L}{\partial x_j} = \frac{\partial}{\partial x_j}\left(\frac{1}{2}m\dot{x}_j^2 + q\left(\dot{x}_j A(\vec{x},t) - \phi(\vec{x},t)\right)\right) \tag{10.2.160}$$

For the set of all coordinates, this gives under condensed form and using the tools of vector analysis:

$$\boxed{m\ddot{\vec{x}} = q\left(-\vec{\nabla}\cdot\phi - \frac{\partial\vec{A}}{\partial t} + \dot{\vec{x}}\times\left(\vec{\nabla}\times\vec{A}\right)\right)} \tag{10.2.161}$$

So what must be absolutely noticed here is that it is the potential vector that appear in the Lagrangian and not the magnetic field!!! Therefore it's the potential vector that is at the origin of the variation of energy of a particle in an electromagnetic field and not the magnetic field!!!!!!!!

Therefore:

$$m\ddot{\vec{x}} = \vec{F} = q\left(\vec{E} + \dot{\vec{x}}\times\vec{B}\right) \tag{10.2.162}$$

or written differently:

$$\boxed{\vec{F} = q\left(\vec{E} + \vec{v}\times\vec{B}\right)} \tag{10.2.163}$$

We thus fall back well on the expression of the Lorentz force where $\vec{E}$ and $\vec{B}$ are given by:

$$\begin{aligned}\vec{E} &= -\vec{\nabla}\cdot\phi - \frac{\partial\vec{A}}{\partial t}\\ \vec{B} &= \vec{\nabla}\times\vec{A}\end{aligned} \tag{10.2.164}$$

as we will see it in gauges theory. Certainly the proof is far from being obvious, but is possible.

Many engineer have tested this result in school laboratory and know very well the following image (purple light is emitted along the electron path, due to the electrons colliding with gas molecules in the bulb and not because of bremsstrahlung that we will discuss later):

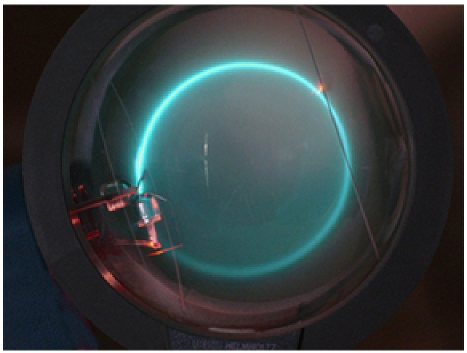


Figure 10.49: Beam of electrons moving in a circle, due to the presence of a magnetic field

You can also see this happening in photographs taken of charged particle tracks through a device known as the Wilson bubble chamber (we will come back on that one the section of Wave Quantum Physics as this detection procedure seems to be incompatible with Heisenberg's inequalities!):

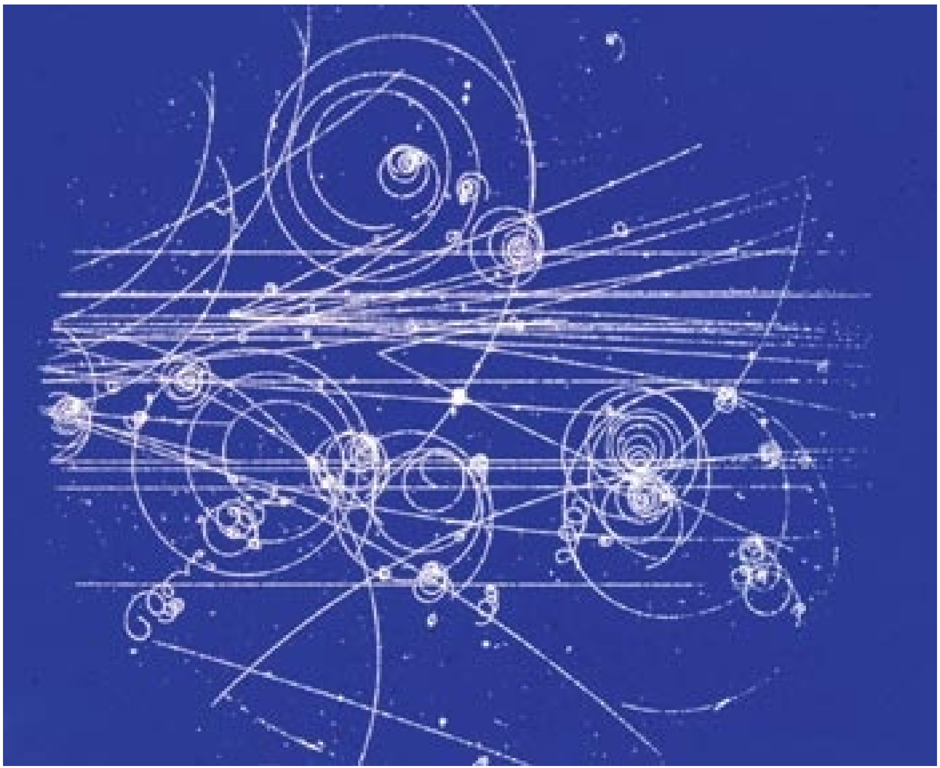

Figure 10.50: Bubble chamber (source: CERN)

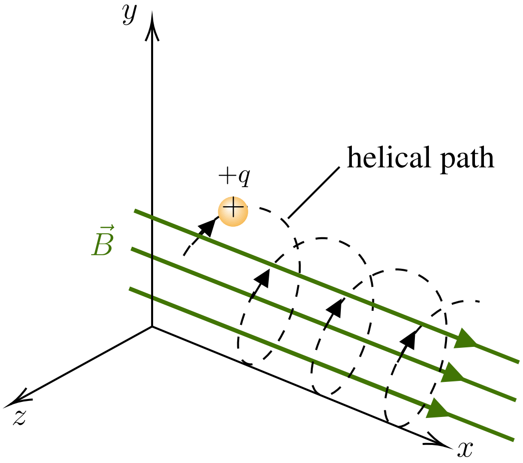
In principle, this is still how physicists frequently determine charge to mass ratios of particles produced in particle physics experiments.

If a charged particle moves in a uniform magnetic field with its velocity at some arbitrary angle with respect to $\vec{B}$, its path is a helix as we will prove it further below (see page 4071):



Spiralling tracks as visible in the figure above are a common feature of bubble chamber pictures, and they are caused by electrons e^- (or positrons e^+, which - key point - have the same mass).

What a spiral tells us is that an electron loses energy at a considerable rate as it travels through a bubble chamber liquid. All other charged particles, unless they collide with a nucleus, very gradually slow down - get more curved - as they lose energy by ionisation (making bubbles in the bubble chamber).

Electrons are able to lose energy more quickly by another process known as "bremsstrahlung" (braking radiation). This process, which is a consequence of the fact that all accelerated charges radiate, is important for electrons because they have small masses. We will study mathematically this phenomenon in the section of Electrodynamics.

10.2.5.1 Magnetic Vector Potential

To get some experience with the magnetic vector potential, let us look first at what it is for a uniform magnetic field $\vec{B}_0$. This is calculation that will be useful during our study of Quantum Physics.

Taking our z-axis in the direction of $\vec{B}_0$, we must have:

$$\begin{aligned} B_x &= \frac{\partial A_z}{\partial y} - \frac{\partial A_y}{\partial z} = 0 \\ B_y &= \frac{\partial A_x}{\partial z} - \frac{\partial A_z}{\partial x} = 0 \\ B_z &= \frac{\partial A_y}{\partial x} - \frac{\partial A_x}{\partial y} = B_0 \end{aligned} \tag{10.2.165}$$

By inspection, we see that one possible solution of these equations is:

$$A_y = xB_0 \qquad A_x = 0 \qquad A_z = 0 \tag{10.2.166}$$

Or we could equally well take:

$$A_x = -yB_0 \qquad A_y = 0 \qquad A_z = 0 \tag{10.2.167}$$

Still another solution is a linear combination of the two:

$$A_x = -\frac{1}{2}yB_0 \qquad A_y = \frac{1}{2}xB_0 \qquad A_z = 0 \tag{10.2.168}$$

It is clear that for any particular field $\vec{B}$, the vector potential $\vec{A}$ is not unique; there are many possibilities.

The third solution, more general, shows that $\vec{A}$ is perpendicular to the z-axis in this special examples.

So there are actually (infinitely) many vector fields $\vec{A}$ whose curl will equal an arbitrary magnetic flux density $\vec{B}$. In other words, given some vector field $\vec{B}$, the solution $\vec{A}$ to the differential equation $\vec{\nabla} \times \vec{A} = \vec{B}$ is not unique!

To completely (i.e. uniquely) specify a vector field, we need to specify both its divergence and its curl and as we will see it in the section of Electrodynamics the divergence can satisfy the following gauge equation:

$$\vec{\nabla} \circ \vec{A} = 0 \tag{10.2.169}$$

Therefore finally we can write among other relations that we will also prove in the section of Electrodynamics that:

$$\boxed{\begin{aligned} &\vec{\nabla} \times \vec{A} = \vec{B} \\ &\vec{\nabla} \circ \vec{A} = 0 \end{aligned}} \tag{10.2.170}$$

Otherwise the vector potential for a uniform field can also be obtained in another way. The circulation of $\vec{A}$ on any closed loop Γ can be related to the surface integral of $\vec{\nabla}\times\vec{A}$ by Stokes' theorem (see section Vector Calculus page 1889):

$$\oint_{\Gamma}\vec{A}\circ\mathrm{d}\vec{r}=\int(\vec{\nabla}\times\vec{A})\circ\mathrm{d}\vec{S} \tag{10.2.171}$$

But the integral on the right is equal to the flux of $\vec{B}$ through the loop, so:

$$\oint_{\Gamma}\vec{A}\circ\mathrm{d}\vec{r}=\int\vec{B}\circ\mathrm{d}\vec{S} \tag{10.2.172}$$

So the circulation of $\vec{A}$ around any loop is equal to the flux of $\vec{B}$ through the loop. If we take a circular loop, of radius r in a plane perpendicular to a uniform field $\vec{B}$, the flux is just:

$$\Phi=\int\vec{B}\circ\mathrm{d}\vec{S}=\int\|\vec{B}\|\cdot\|\vec{n}\|\cos(\theta)\mathrm{d}\vec{S}=B\int\mathrm{d}S=B\pi r^2 \tag{10.2.173}$$

Let us see another way to derive that result. We want to try one of the possibilities for the vector potential to be:

$$\vec{A}=\frac{\vec{B}\times\vec{r}}{2} \tag{10.2.174}$$

It can be seen that:

$$\nabla\times\vec{A}=\frac{1}{2}\nabla\times(\vec{B}\times\vec{r})=\frac{1}{2}[\vec{B}(\vec{\nabla}\cdot\vec{r})-\vec{r}(\vec{\nabla}\cdot\vec{B})+(\vec{r}\cdot\vec{\nabla})\vec{B}-(\vec{B}\cdot\vec{\nabla})\vec{r}] \tag{10.2.175}$$

The first term gives $3\vec{B}$ since the $\vec{\nabla}\circ\vec{r}=3$. The second term is zero because $\vec{\nabla}\circ\vec{B}=0$. The third and the fourth terms are calculated as follows:

$$(\vec{r}\circ\vec{\nabla})\vec{B}=\left(x\frac{\partial}{\partial x}+y\frac{\partial}{\partial y}+z\frac{\partial}{\partial z}\right)\left(\vec{i}B_x+\vec{j}B_y+\vec{k}B_z\right)=\vec{0} \tag{10.2.176}$$

because the field is uniform.

$$\begin{aligned}(\vec{B}\circ\vec{\nabla})\vec{r}&=\left(B_x\frac{\partial}{\partial x}+B_y\frac{\partial}{\partial y}+B_z\frac{\partial}{\partial z}\right)(\vec{i}x+\vec{j}y+\vec{k}z)\\&=\vec{i}B_x+\vec{j}B_y+\vec{k}B_z=\vec{B}\end{aligned} \tag{10.2.177}$$

Adding all the four terms, result follows. It can be seen that the Coulomb gauge condition is satisfied. The divergence of the vector potential is given by:

$$\vec{\nabla}\circ\vec{A}=\frac{1}{2}\vec{\nabla}\circ(\vec{B}\times\vec{r})=\frac{1}{2}[\vec{r}\circ(\vec{\nabla}\times\vec{B})-\vec{B}\circ(\vec{\nabla}\times\vec{r})]=0 \tag{10.2.178}$$

because the first term vanishes as the field is uniform while the second term vanishes because the curl of position vector is zero. Thus the expression satisfies Coulomb gauge condition. If the magnetic field is along the z direction, we can take either of the following expressions for the vector potential components:

$$\begin{aligned}\vec{A}&=\left(-\frac{By}{2},\frac{Bx}{2},0\right)\\\vec{A}&=(-By,0,0)\end{aligned} \tag{10.2.179}$$

Both these expressions are valid expressions for the vector potential and they differ by gradient of a scalar field. It can be checked that if we add a term $\vec{\nabla}(\psi)$ to the first term where:

$$\psi = -\frac{Bxy}{2} \tag{10.2.180}$$

we get the second expression.

Now let us consider another interesting example. For an infinite wire along the z axis, the magnetic field, using cylindrical coordinates, is (see page 4026):

$$\vec{B} = \frac{I\mu_0}{2\pi r}\vec{u}_\phi \tag{10.2.181}$$

where r is the distance from the axis of the wire. We want to know the expression of the corresponding magnetic vector potential.

We know that the magnetic field has cylindrical symmetry and is directed along the circumferential direction and must satisfy:

$$\vec{B} = \frac{\mu_0 I}{2\pi r}\vec{u}_\phi = \nabla \times \vec{A} \tag{10.2.182}$$

Thus the curl of the vector potential only has ϕ component:

$$B_\phi = (\nabla \times \vec{A})_\phi = \frac{\partial A_r}{\partial z} - \frac{\partial A_z}{\partial r} = \frac{\mu_0 I}{2\pi r} \tag{10.2.183}$$

By symmetry, since the wire is infinite, the derivative with respect to z must be zero and we have:

$$-\frac{\partial A_z}{\partial r} = \frac{\mu_0 I}{2\pi r} \tag{10.2.184}$$

which gives:

$$\vec{A}(\vec{r}) = -\frac{\mu_0}{2\pi} I \ln(r)\vec{u}_z + \vec{\nabla}(\psi) \tag{10.2.185}$$

where we have explicitly added gradient of an arbitrary scalar field.

Now suppose we look inside the wire, taking the wire's radius to be R. At a distance r from the axis, only current within that radius contributes to the field, so we get from Ampère's law (see page 4011) using a circular loop within the wire (see page 4026):

$$\vec{B} = \frac{\mu_0 r I}{2\pi R^2}\vec{u}_\phi \tag{10.2.186}$$

Using exactly the same method as earlier we then get:

$$\vec{A}(\vec{r}) = -\frac{\mu_0 r^2 I}{4\pi R^2}\vec{u}_\phi + \vec{\nabla}(\psi) \tag{10.2.187}$$

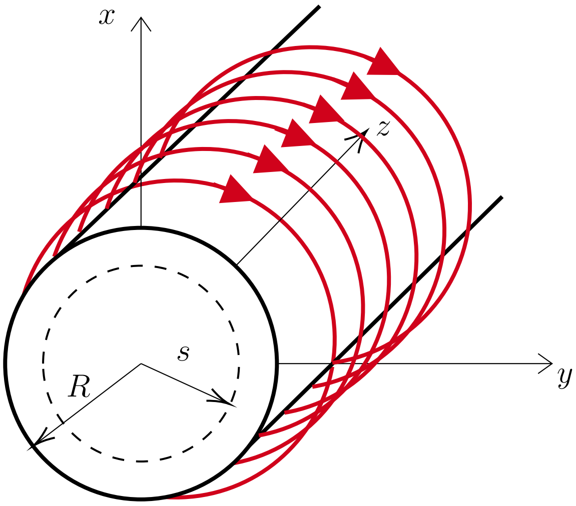
Again, we get $\vec{\nabla} \circ \vec{A} = 0$ and $\vec{\nabla} \times \vec{A} = \vec{B}$, so it looks like we're done.

Now let us move to another case! We know that the field inside a solenoid is along its axis (z direction) and is zero outside. If we take a circular path of radius s centered along its axis, the flux through the circular area is (see page 4014):

$$\Phi_B = \int \vec{B} \circ \mathrm{d}\vec{S} = \pi s^2 B = \pi \mu_0 n I s^2 \qquad (10.2.188)$$

The line integral of the vector potential is:

$$\oint\limits_{\Gamma} \vec{A} \circ \mathrm{d}\vec{s} = \int \vec{B} \circ \mathrm{d}\vec{S} = \pi \mu_0 n I s^2 \qquad (10.2.189)$$



The vector potential is thus given by for $s < R$:

$$\vec{A} = \mu_0 n I \frac{s}{2} \vec{u}_\phi \qquad (10.2.190)$$

Though the field outside is zero, the vector potential does not vanish outside the solenoid! This is because, if we take a circle of radius $s > R$, the flux through the circular area is:

$$\pi R^2 B = \pi R^2 \mu_0 n I \qquad (10.2.191)$$

flux being contributed only from inside the solenoid. Thus for $s > R$ as:

$$\oint\limits_{\Gamma} \vec{A} \circ \mathrm{d}\vec{s} = \int \vec{B} \circ \mathrm{d}\vec{S} = \pi \mu_0 n I R^2 \qquad (10.2.192)$$

We then get:

$$A \oint\limits_{\Gamma} \mathrm{d}s = A 2\pi s = \pi \mu_0 n I R^2 \qquad (10.2.193)$$

Hence:

$$\vec{A} = \mu_0 n I \frac{R^2}{2s} \vec{u}_\phi \qquad (10.2.194)$$

which falls off as inverse of distance from the axis.

Now an obvious question is if does vector potential have any physical significance?

It may be seen from the above example that the vector potential remains non-zero outside the solenoid even though the magnetic field itself has become zero. It turns out that the vector potential is not just a mathematical artefact but has physical reality!!!

If you are familiar with the Young's double slit experiment (see section Wave Optics page 4509) done with a beam of coherent light. The experiment is not really restricted to light wave but can be performed with matter wave such as a beam of electrons. We learn from quantum theory that like light exhibits dual behaviour, that of wave as well as particles known as photon, a wavelength is associated with material particles as well. This is known as "de Broglie wavelength" (see section Wave Quantum Physics page 4749) and is given by the ratio of the Planck's constant to the momentum of the particle.

The experiment is performed with an electron beam in place of light. What is done is to put a small solenoid just beyond the slits between the slits and the screen. Initially the solenoid does not carry any current and its dimensions are small enough so that it does not disturb the interference pattern produced on the screen because of the phase difference between electron waves arriving at the screen from the slits.

The current in the solenoid is switched on. The solenoid is of very small dimensions so that most of the electron beam passes outside the solenoid. Since the magnetic field outside is zero, the electron beams does not experience any force due to the magnetic field and should reach the screen undeflected. This should not then affect the interference pattern. However, what is found is that the pattern on the screen shifts suggesting a change in the phase relationship. It can be shown in quantum mechanics that the agent responsible for this phase change is the vector potential which is non-zero outside the solenoid though the magnetic field is zero.

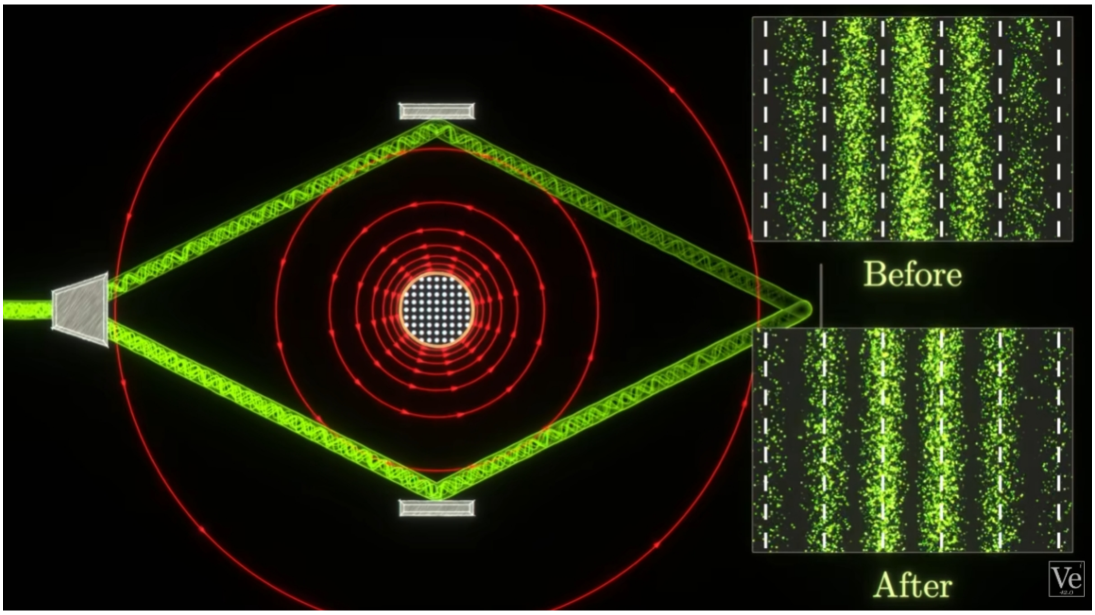


Figure 10.51: Illustrated concept of the Y. Aharonov and D. Bohm experiment (source: Vertisium)

The result is quite counter-intuitive because some people cannot accept that a particle can be influence by a potential in the absence of any force (that was the case of Niels Bohr)

For detailed experimental evidence see the papers [10] and [542].

10.2.5.2 Work of Magnetic Field

Let us stop a moment on the expression of the Lorentz force. We see with this relation that a stationary (or not) electric charge in an electric field will experience a force that will give him the necessary impulsion to make vary its kinetic energy (zero or non-zero at the start). This fact is however not valid for the magnetic field. Indeed, when we put a stationary electric charge in a magnetic field, this latter will not be influenced by magnetic field strength and therefore will not see its kinetic energy vary. If the electric charge has a non-zero initial velocity, it follows that the magnetic field will change the components of the velocity vector but not its norm!!! So, we used to say that "the magnetic field does not work" (in the sense that the magnetic field is not make move an electric charge that is initially at rest or change the norm of its speed). Let's see how we can prove mathematically that the magnetic field does not work.

Proof 10.2.2. We know that for an electric charged particle immersed in a magnetic field, we have:

$$\vec{F}=q\vec{v}\times\vec{B}=m\vec{a}=m\frac{\mathrm{d}\vec{v}}{\mathrm{d}t} \tag{10.2.195}$$

hence:

$$\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}=\frac{q}{m}\vec{v}\times\vec{B} \tag{10.2.196}$$

and let us express the temporal variation of the kinetic energy:

$$\frac{\mathrm{d}}{\mathrm{d}t}E_c=\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{1}{2}mv^2\right)=\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{1}{2}m\vec{v}\circ\vec{v}\right)=m\vec{v}\circ\frac{\mathrm{d}\vec{v}}{\mathrm{d}t} \tag{10.2.197}$$

and substituting in it the derivative of the speed by prior-previous relation, we get:

$$\frac{\mathrm{d}}{\mathrm{d}t}E_c=m\vec{v}\circ\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}=m\vec{v}\circ\left(\frac{q}{m}\vec{v}\times\vec{B}\right)=q\underbrace{\vec{v}\circ(\vec{v}\circ\vec{B})}_{\vec{v}\times\vec{v}\perp\vec{v}}=q\cdot 0=0 \tag{10.2.198}$$

The kinetic energy of the particle therefore does indeed not change because the magnetic field is conservative in the special case of stationary magnetic (and hence electric) fields.

This result also mean obvious that $\nabla\vec{F}=\vec{0}$. But if fact as we will prove it in the section of Electrodynamic this is a special case!! Indeed we will prove in the section of Electrokinetics the Faraday's induction law:

$$\vec{\nabla}\times\vec{E}=-\frac{\partial\vec{B}}{\partial t} \tag{10.2.199}$$

Therefore it is immediate that $\nabla\vec{F}$ will not be null anymore (and hence $\vec{F}$) if $\vec{B}$ is not static.

■ Q.E.D.

Now, if we are interested only in the second term of this relation, we can get to prove the "Laplace's force law"!

So we have considering only the second term of the Lorentz law:

$$\mathrm{d}\vec{F}=\mathrm{d}q\vec{v}\times\vec{B}=\rho\mathrm{d}V\vec{v}\times\vec{B}=\rho\mathrm{d}l\mathrm{d}S\vec{v}\times\vec{B} \tag{10.2.200}$$

where ρ is the volumetric electric charge density. If $\vec{v}$ and $\mathrm{d}\vec{l}$ are supposed parallels we can write that:

$$\mathrm{d}\vec{F}=\rho v\mathrm{d}S\mathrm{d}\vec{l}\times\vec{B} \tag{10.2.201}$$

A current density allows us to calculate the inertial speed of the electric charge carriers in a conductor. The number of conduction electrons in a wire is equal to:

$$nAl=\rho Al \tag{10.2.202}$$

where n is the number of conduction electrons per unit volume and Al the volume of the wire (and therefore A is the area of the section of the conductor).

A quantity of electric charges $q=\rho Al$ pass trough the surface section a wire in a time t given by:

$$t=\frac{l}{v} \tag{10.2.203}$$

The intensity of current I being defined by:

$$I=\frac{q}{t}=\frac{\rho Al}{\dfrac{l}{v}}=\rho Av \tag{10.2.204}$$

we get that:

$$v=\frac{J}{\rho} \tag{10.2.205}$$

From:

$$\mathrm{d}\vec{F}=\rho v\mathrm{d}S\mathrm{d}\vec{l}\times\vec{B} \tag{10.2.206}$$

We can now draw that:

$$\mathrm{d}\vec{F}=J\mathrm{d}S\mathrm{d}\vec{l}\times\vec{B} \tag{10.2.207}$$

Finally, we find that:

$$\boxed{\vec{F}=I\vec{l}\times\vec{B}=q\vec{v}\times\vec{B}} \tag{10.2.208}$$

which is the "Laplace's force law" or "Lorentz force" and therefore is derived from the Lorentz law.

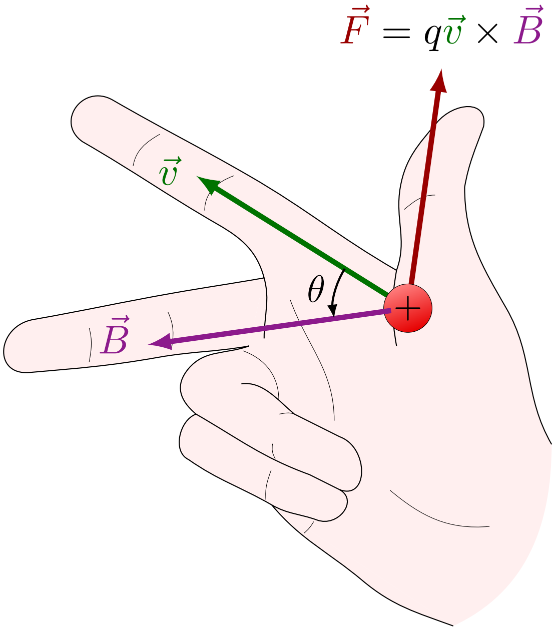

Figure 10.52: **Laplace's force right-handed rule (author: Izaadk Neutelings)**

We then deduce the units of the magnetic field (force per unit current and unit length of the source):

$$[\mathrm{N}\cdot\mathrm{m}^{-1}\cdot\mathrm{A}^{-1}]=[\mathrm{kg}\cdot\mathrm{s}^{-2}\cdot\mathrm{A}^{-1}]=[\mathrm{kg}\cdot\mathrm{s}^{-2}\cdot\mathrm{s}\cdot\mathrm{C}^{-1}]=[\mathrm{kg}\cdot\mathrm{s}^{-1}\cdot\mathrm{C}^{-1}]=[\mathrm{T}] \tag{10.2.209}$$

where T is a commonly tolerated unit in use named the "Tesla" in honour of Nikola Tesla one of the greatest spirit of all time with Albert Einstein. Therefore this unit implicitly contains the Coulomb unit which is then at the origin of the magnetic field! Knowing finally explicitly the units of the magnetic field, we can determine the units of the magnetic permeability constant by taking back the relation:

$$B=\frac{\mu_0 I}{2\pi r} \tag{10.2.210}$$

We have therefore for the units of the constant magnetic permeability:

$$[\mathrm{T}\cdot\mathrm{m}\cdot\mathrm{A}^{-1}]=[\mathrm{N}\cdot\mathrm{m}^{-1}\cdot\mathrm{A}^{-1}]=[\mathrm{kg}\cdot\mathrm{m}\cdot\mathrm{s}^{-2}\cdot\mathrm{A}^{-1}] \tag{10.2.211}$$

Remark

The magnitude of Earth's magnetic field at its surface ranges according to measurements from 25 to 65 $[\mu\mathrm{T}]$. Measurements done in Switzerland by the Biel Technical University the strength of the magnetic fields generated by electric trains changes constantly as the railroad car travels along, and is greatly dependent on the way the railroad car is advancing or braking, the magnetic fields were between 0.1 and 3 $[\mu\mathrm{T}]$.

So we see that it has for units a force by square current intensity. In SI units the permeability has (sadly) for units the "henry" per meter:

$$\frac{\mathrm{H}}{m}=\frac{\mathrm{kg}\cdot\mathrm{m}}{\mathrm{s}\cdot\mathrm{A}}$$

Having done this, let us see some important cases of application of the Lorentz law:

10.2.5.3 Classical Hall effect

Previously, we have studied the action of a magnetic induction on a wire-like circuit having for purpose to find the expression of the magnetic forces applied to the same area of this circuit. Now let us turn our attention to the conductivity electrons themselves, placing us in the case of the figure below:

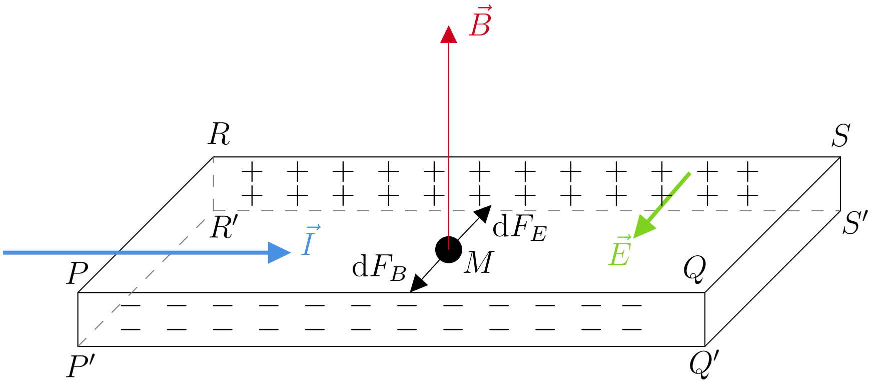

Figure 10.53: **DC current through a metallic ribbon for the study of classical Hall effect**

where a metallic ribbon is traversed by a continuous current $\vec{I}$. The vector of current density $\vec{J}$ is constant and parallel to the long sides $\overline{PQ}$ or $\overline{RS}$ of the ribbon.

Let us imagine then that the ribbon is immersed in a uniform magnetic field perpendicular to the planes PQ and RS (following the z-axis). The mobile electric charges of volumetric density ρ contained in a volume element $\mathrm{d}V$ is therefore subject to the magnetic force:

$$\mathrm{d}\vec{F}=\rho\mathrm{d}V\vec{v}\times\vec{B}=\vec{J}\times\vec{B}\mathrm{d}V \tag{10.2.212}$$

This force change the trajectories of mobile electrons and, during a transitional period, causing their accumulation on the front edge of the ribbon while an excess positive charge appears on the back edge.

This phenomenon produces an additional electric field parallel to $\overline{RP}$ which exerts on the mobile charges of volume $\mathrm{d}V$ an electric force:

$$\mathrm{d}\vec{F}=\rho\mathrm{d}V\vec{E} \tag{10.2.213}$$

The two forces are then opposing each other and the coulomb force tends to take back the electron paths in their initial position. A steady state is established gradually.

Remark

In fact, every time we talk about steady in physics, we lie a little bit. It is in fact just a stable equilibrium and in general, the system oscillates around its equilibrium position. After a while, a system like the conductor involved in our example shows negligible oscillations. Physics is sometimes also a matter of approximations...

When this state is reached, the current density is again parallel to $\overline{PQ}$ and the electric and magnetic forces above are vectorially opposed. So we have:

$$\vec{E}=-K(\vec{J}\times\vec{B}) \tag{10.2.214}$$

with:

$$K=\rho^{-1} \tag{10.2.215}$$

In some books, the cross product is made explicit in the form of its components such as:

$$E_y=\frac{J_x}{\rho}B_z \tag{10.2.216}$$

since the other components are zero (the current density is parallel to the ribbon and the magnetic field is perpendicular).

Now, as we have proved it in the section Electrokinetics we have:

$$\frac{J_x}{\rho}=v_x \tag{10.2.217}$$

therefore:

$$E_y=v_xB_z \tag{10.2.218}$$

We then define the "Hall coefficient" by:

$$R_H=\frac{E_y}{B_zJ_x} \tag{10.2.219}$$

R_H can be used at equilibrium for the measurement of J_x if we suppose $v_x=c^{te}$ and that the potential U (and therefore implicitly E_x) and external field B_z are known.

Notice that by construction we also have $R_H \propto \rho$ and this is used sometimes by engineer to determiner the density of electrical charge carriers in a new material sample.

Remark

We also tale of "Hall's resistance". It is simply the ratio of the Hall voltage on the current through the sample. It must not be confuse with the Hall resistance R_H.

In a two-dimensional semiconductor, the Hall effect is also measurable. By cons, at sufficiently low temperature, we observe a series of trays for the Hall resistance as a function of the magnetic field. These plates appear to specific resistance values, and this, independently of the sample used. This is the subject of the "quantum Hall effect" that we will not discuss in this chapter.

Under scalar form the relation of the "Hall effect", is written:

$$E=-KJB\sin(\alpha) \tag{10.2.220}$$

We can also express it by expliciting the potential difference that corresponds by definition to the electric field.

If l is the width of the ribbon, we have:

$$U=El \tag{10.2.221}$$

If e is its thickness, the current I that pass through it is equal to:

$$I = elJ \tag{10.2.222}$$

Given the relative positions of the various vectors, the relation expressing the Hall effect is equivalent to:

$$\frac{U}{l} = -K\frac{I}{el}B\sin(\alpha) \tag{10.2.223}$$

More aesthetically and in traditional form, the voltage of the Hall effect is given by:

$$U_H = k_H IB\sin(\alpha) \tag{10.2.224}$$

with:

$$\boxed{k_H = -\frac{1}{\rho e}} \tag{10.2.225}$$

which is the "Hall constant". It is inversely proportional to the density of the free electric charge carriers and in the context of metals, it is negative.

In other field of study such as the semiconductor, we write the Hall voltage in the following traditional form:

$$U_H = -\frac{1}{\rho e}IB\sin(\alpha) = -\frac{1}{qn}\frac{IB}{e}\sin(\alpha) = k_H\frac{IB}{e}\sin(\alpha) \tag{10.2.226}$$

where q is the electron charge, and n the traditional notation (sic!) of the carrier density within the study of semiconductors.

We then in the latter field the Hall constant which is defined by:

$$k_H = -\frac{1}{qn} \tag{10.2.227}$$

What has however made the reputation of the Hall effect, besides the fact that this result is enormously used to make magnetic fields sensors of all kinds (as Hall effect sensors operate without physical contact with the magnets), this is that for certain types of semiconductor this Hall constant is positive!!!! This would mean with the standard models we have available to us until now, there would be positive charges that would generate the current... and at the time of the establishment of this experience for semi-conductors this was inexplicable. At the time of Edwin Herbert Hall this experiment was used to check whether it was positive or negative charges that were moving and Hall concluded by testing it on conductive metals that only the negative electricity where moving in the conductors.

Remark

The most well known Hall probe by the population is the speedometer on bikes (odometer), which operates on the basis of attaching a small magnet on one of the spokes of a wheel and whose passage in front of the Hall sensor produces a signal processed by the electronic odometer.

We will prove later that by using quantum theory in the context of semiconductors (see section Electrokinetics page 4279) positive charges may yet appear under certain conditions and cause a current!

10.2.5.4 Larmor radius

A very interesting case of laboratory study is the movement of a charge in a uniform magnetic field. For this study, consider a particle of mass m and electric charge q placed in a uniform magnetic field with an initial velocity $\vec{v}_0$.

We have following Lorentz' law:

$$\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}=\frac{q}{m}\vec{v}\times\vec{B} \tag{10.2.228}$$

We will take advantage of the fact that the magnetic force is zero in the direction of the magnetic field.

We'll break down the speed in two components, one parallel and one perpendicular to the magnetic field such as:

$$\vec{v}=\vec{v}_{\text{tg}}+\vec{v}_n \tag{10.2.229}$$

The equation of motion is then:

$$\frac{\mathrm{d}\vec{v}_{\text{tg}}}{\mathrm{d}t}=\vec{0} \qquad \frac{\mathrm{d}\vec{v}_n}{\mathrm{d}t}=\frac{q}{m}\vec{v}_n\times\vec{B}=\frac{q}{m}v_nB\sin(\alpha) \tag{10.2.230}$$

The trajectory remains rectilinear uniform in the direction of the magnetic field! In other words, if the speed of the charged particle was initially zero in the direction of the field (i.e. $\alpha=\pi/2$) then it will remain zero!

Let us now consider a Cartesian coordinate system with the Z axis is given by the direction of the magnetic field such that $\mathrm{d}v_z/\mathrm{d}t=0$. The equation of motion is therefore written only on two components, since:

$$\begin{pmatrix}\dfrac{\mathrm{d}v_x}{\mathrm{d}t}\\ \dfrac{\mathrm{d}v_y}{\mathrm{d}t}\\ \dfrac{\mathrm{d}v_z}{\mathrm{d}t}\end{pmatrix}=\begin{pmatrix}\dfrac{\mathrm{d}v_x}{\mathrm{d}t}\\ \dfrac{\mathrm{d}v_y}{\mathrm{d}t}\\ 0\end{pmatrix}=\frac{q}{m}\begin{pmatrix}v_x\\ v_y\\ v_z\end{pmatrix}\times\begin{pmatrix}B_x\\ B_y\\ B_z\end{pmatrix}=\frac{q}{m}\begin{pmatrix}v_x\\ v_y\\ v_z\end{pmatrix}\times\begin{pmatrix}0\\ 0\\ B\end{pmatrix}=\frac{q}{m}\begin{pmatrix}v_yB\\ -v_xB\\ 0\end{pmatrix} \tag{10.2.231}$$

hence:

$$\frac{\mathrm{d}v_x}{\mathrm{d}t}=\frac{qB}{m}v_y=\omega_{\text{gs}}v_y \qquad \frac{\mathrm{d}v_y}{\mathrm{d}t}=-\frac{qB}{m}v_x=-\omega_{\text{gs}}v_x \tag{10.2.232}$$

A very simple special solution to these two differential equations in non relativistic framework is obviously:

$$v_x=v_0\cos(\omega t) \qquad v_y=-v_0\sin(\omega t) \tag{10.2.233}$$

So where we choose an initial speed following the x-axis. By integrating, we get:

$$x=\frac{v_0}{\omega}\sin(\omega t) \qquad y=\frac{v_0}{\omega}\cos(\omega t) \tag{10.2.234}$$

where the integration constants were chosen as zero (arbitrary choice). The trajectory is thus a circle of radius:

$$\boxed{R_L=\frac{mv_0}{qB}} \tag{10.2.235}$$

perpendicular to the magnetic field and named "Larmor radius", described with the pulsation:

$$\omega_{\text{gs}}=\frac{qB}{m} \tag{10.2.236}$$

named "gyro-synchrotron pulsation". This circle is travelled in the conventional positive direction for negative charges.

Remark

The movement is circular only if the particle, initially, therefore has no speed in the direction of the magnetic field. If it has one, it will keep it (the magnetic field has no action in that direction).

The problem of such a configuration to build an accelerator is that if we increase the energy of the particle (by adding a synchronized electric field on the gyro-synchrotron pulsation and collinear to the movement), its speed increases and the radius Larmor also. But the "cyclotron" which is based on this system has a limited radius since it is difficult to maintain a constant magnetic field over a large area:

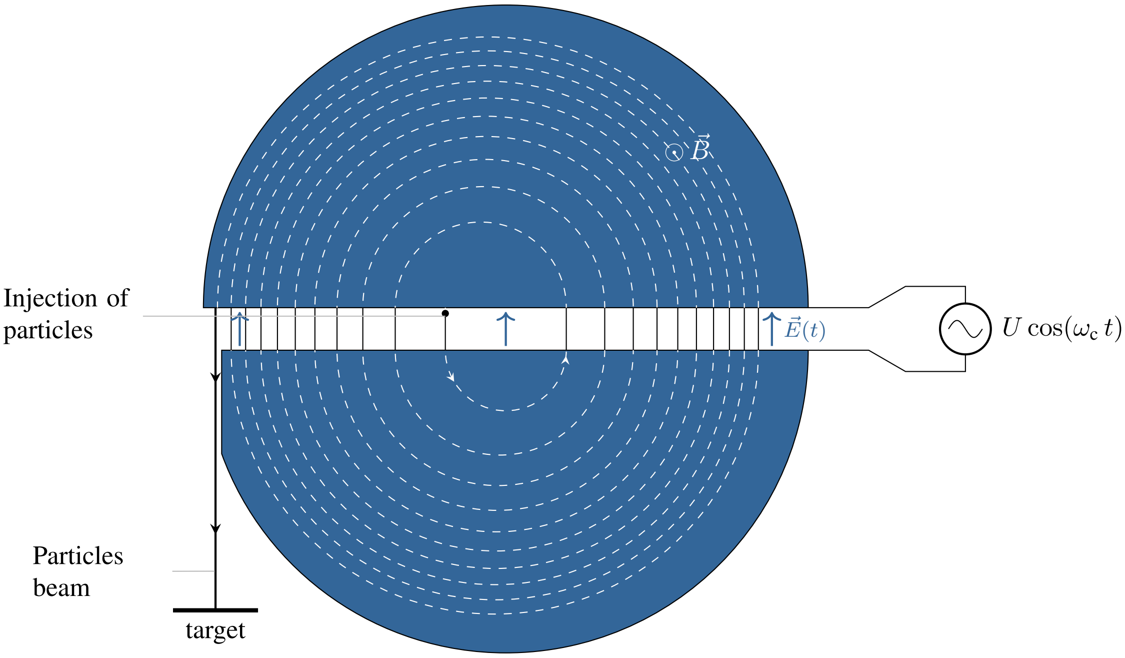

Figure 10.54: **Cyclotron principle (source: `http://femto-physique.fr`, author: Jimmy Roussel)**

Even more difficult, in the relativistic case, the pulse is then written with the Fitzgerald-Lorentz factor (see section Special Relativity page 5739):

$$\omega_{\text{gs}}=\frac{qB}{\gamma m} \tag{10.2.237}$$

We then see that we need to adjust the pulse of the electric field to the pulse of rotation when the sped increase: the accelerator is then now a "synchrotron".

To solve the problem of increasing radius, whereas we use a "Synchrotron" consisting of a single vacuum tube having straight sections containing the accelerating cavities and curved sections equipped with magnets creating at each instant the magnetic field adapted to the particle velocity. This technique, that it is easy to talk about but very difficult to put into practice, is the most used today. The CERN LHC is part of the family of synchrotrons.

From this relation, it is easy to have the kinetic energy of the particle:

$$E_c=\frac{1}{2}mv_0^2=\frac{1}{2}m\left(\frac{q}{m}BR_L\right)^2=\frac{1}{2}\frac{q^2}{m}(BR_L)^2 \tag{10.2.238}$$

As the kinetic energy if often acquired thanks to electric potential difference (when the technique is used with atoms or molecules they have to be ionized before), we have:

$$E_c=qU=\frac{1}{2}\frac{q^2}{m}(BR_L)^2 \tag{10.2.239}$$

Therefore after rearranging we have the famous relations named the "mass spectrometer equation" (also used for isotopic mass spectroscopy in nuclear physics):

$$\boxed{R_L=\frac{1}{B}\sqrt{\frac{2mU}{q}}\Leftrightarrow\frac{m}{q}=\frac{B^2R_L^2}{2U}} \tag{10.2.240}$$

It is based on this relation that works the "Dempster mass spectrometers". It is using this technique that researchers discovered in 11920 (holocene calendar) that atoms of the same chemical element does not necessarily have the same mass. The different varieties of atoms of the same chemical element, varieties that differ in mass, are the "isotopes" (see section Nuclear Physics page 5024):

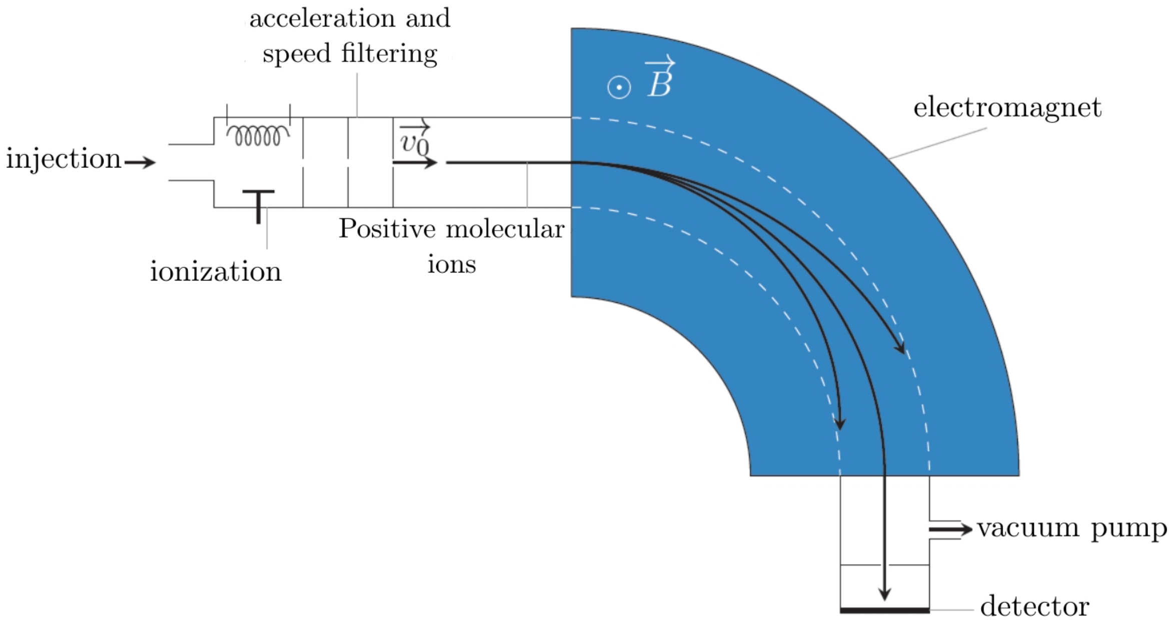

Figure 10.55: **Dempster mass spectrometers principle (source: `http://femto-physique.fr`, author: Jimmy Roussel)**

The Larmor radius is the greatest distance that a particle can travel in the transverse direction before being deflected from its path. This corresponds to a kind of trapping distance. Unless it receive additional kinetic energy, a charged particle is thus trapped in a magnetic field.

It is interesting to notice that more the kinetic energy of a particle is high (large mass or large transverse speed) and the Larmor radius is big. Conversely, the higher the magnetic field and the smaller is the Larmor radius (hence the fact we need hug magnetic field at CERN to keep high speed particles into a circular trajectory).

Let us consider now the case where $\alpha \neq \pi/2$, i.e. :

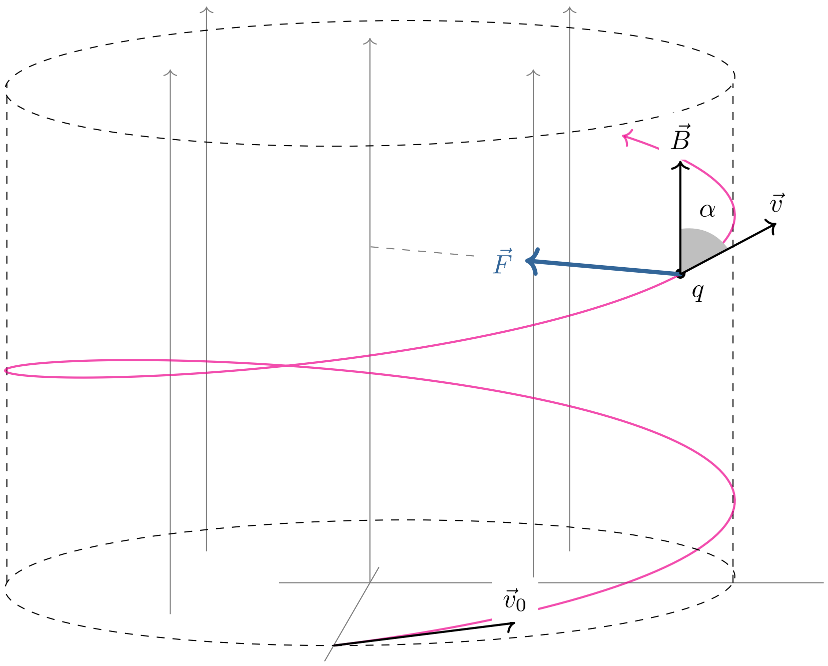

Figure 10.56: **Helical path of charge particle in a uniform constant magnetic field (author: Jimmy Roussel)**

Therefore is straightforward that Larmor radius we have obtained earlier is in fact special case of:

$$R_L = \frac{mv_n \sin(\alpha)}{qB} \tag{10.2.241}$$

The time needed to complete one revolution is obtained by definition of average velocity as:

$$\begin{aligned} v &= \frac{\Delta x}{\Delta t} \\ v_n &= \frac{2\pi R_L}{T} \\ \Rightarrow T &= \frac{2\pi R_L}{v_n} = \frac{2\pi\left(\dfrac{mv_n \sin(\alpha)}{qB}\right)}{v\sin(\theta)} = \frac{2\pi}{qB}m \end{aligned} \tag{10.2.242}$$

This period is also named the "cyclotron period" and its frequency is the reciprocal of the period with formula:

$$f = \frac{1}{T} = \frac{qB}{2\pi m} \tag{10.2.243}$$

The distance travelled parallel to the magnetic field B in one revolution is named the "pitch of the helical path" and is obtained as:

$$p = v_{\text{tg}} T = (v\cos(\theta)) \left(\frac{2\pi m}{qB}\right) \tag{10.2.244}$$

Thus, the formula for the pitch of the helix is:

$$p = \frac{2\pi m v \cos(\theta)}{qB} \tag{10.2.245}$$

To summarize so far:

- A helical path is formed when a charged particle enters with an angle of θ other than 90° into a uniform magnetic field. In the case of $\theta = 90^\circ$, a circular motion is generated.
- If the charged particle's velocity has components parallel and perpendicular to the uniform magnetic field then it moves in a helical path.
- In the parallel case, there is no force on the charged particle but in the perpendicular one, there is a centripetal acceleration toward the center.

We will come back on these concepts in the section Electrodynamics, where after studying the Maxwell equations, we will make some developments for the betatron type accelerator.

Remark

Confining the plasma in a tokamak is based on this property that charged particles have to describe a helical path around a magnetic field line. Hence the need to use a torus... in the simplest case.

To close this subject, and following the comment of a reader, let us develop a little more in detail the solution of the both differential equations seen previously:

$$\frac{\mathrm{d}v_x}{\mathrm{d}t} = \frac{qB}{m} v_y = \omega_{\text{gs}} v_y \qquad \frac{\mathrm{d}v_y}{\mathrm{d}t} = -\frac{qB}{m} v_x = -\omega_{\text{gs}} v_x \tag{10.2.246}$$

simplifying the notation, they become:

$$\begin{aligned} \ddot{x} &= \omega \dot{y} \\ \ddot{y} &= -\omega \dot{x} \\ \ddot{z} &= 0 \end{aligned} \tag{10.2.247}$$

and we will take as initial conditions:

$$\begin{aligned} x(0) &= 0 \quad & \dot{x}(0) &= v_{0x} \\ y(0) &= 0 \quad & \dot{y}(0) &= v_{0y} \\ z(0) &= 0 \quad & \dot{z}(0) &= v_{0z} \end{aligned} \tag{10.2.248}$$

The trick is to put:

$$\begin{aligned} X &= \dot{x} \\ Y &= \dot{y} \end{aligned} \tag{10.2.249}$$

The system of differential equations the becomes (we drop the Z component):

$$\begin{aligned} \dot{X} &= \omega Y \\ \dot{Y} &= -\omega X \end{aligned} \tag{10.2.250}$$

and therefore:

$$\ddot{X} = \omega\dot{Y} = \omega(-\omega X) = -\omega^2 X \Rightarrow \ddot{X} + \omega^2 X = 0 \tag{10.2.251}$$

And by doing the same for Y, we get:

$$\begin{aligned} \ddot{X} + \omega^2 X = 0 \\ \ddot{Y} + \omega^2 Y = 0 \end{aligned} \tag{10.2.252}$$

The both differential being identical it is sufficient to solve one to have the other solutions. The roots of the characteristic equation are (see section Differential and Integral Calculus page 1611):

$$K_{1,2} = \frac{-0 \pm \sqrt{0^2 - 4\omega^2}}{2} = \omega\sqrt{-1} = \mathrm{i}\omega \tag{10.2.253}$$

Since the discriminant is negative (the expression that is for recall under the root), then we have(see section Differential and Integral Calculus page 1609) the homogeneous solution is then:

$$X_h = e^{\alpha t}(A'\cos(\beta t) + B'\sin(\beta t)) = e^{0t}(A'\cos(\omega t) + B'\sin(\omega t)) \tag{10.2.254}$$

Hence:

$$X_h = A'\cos(\omega t) + B'\sin(\omega t) \tag{10.2.255}$$

And as there is no second member to our two differential equations, the homogeneous solution is then the general solution. Therefore:

$$X_G = X_h = A'\cos(\omega t) + B'\sin(\omega t) \tag{10.2.256}$$

and same:

$$Y_G = Y_h = C'\cos(\omega t) + D'\sin(\omega t) \tag{10.2.257}$$

Since we have put $X = \dot{x}$, $Y = \dot{y}$ and that we have $\ddot{x} = \omega\dot{y}$, then it comes:

$$\ddot{x} = \omega\dot{y} \Leftrightarrow \dot{X} = \omega Y \tag{10.2.258}$$

Thus explicitly:

$$-A'\omega\sin(\omega t) + B'\omega\cos(\omega t) = \omega(C'\cos(\omega t) + D'\sin(\omega t)) \tag{10.2.259}$$

Since this equation must be valid for all time t, let us consider the case where $t=0$, the equation is reduced to:

$$B'=C' \tag{10.2.260}$$

By doing the same for Y (always with $t=0$), we get:

$$D'=-A' \tag{10.2.261}$$

Taking into account the initial conditions for speed, we get:

$$\begin{aligned}\dot{x}(0)=X(0)=A'=-D'=v_{0x}\\ \dot{y}(0)=Y(0)=B'=C'=v_{0y}\end{aligned} \tag{10.2.262}$$

So:

$$\begin{aligned}X(t)=\dot{x}(t)=v_{0x}\cos(\omega t)+v_{0y}\sin(\omega t)\\ Y(t)=\dot{y}(t)=v_{0y}\cos(\omega t)-v_{0x}\sin(\omega t)\end{aligned} \tag{10.2.263}$$

Remark

By putting v_{0y} to be zero, we fall back on the simple special solution we proposed above with respect to speed.

To continue, we take the primitive to find the position coordinates. It comes then:

$$\begin{aligned}x(t)=\frac{v_{0x}}{\omega}\sin(\omega t)-\frac{v_{0y}}{\omega}\cos(\omega t)+c_x^{te}\\ y(t)=\frac{v_{0y}}{\omega}\sin(\omega t)+\frac{v_{0x}}{\omega}\cos(\omega t)+c_y^{te}\end{aligned} \tag{10.2.264}$$

For the initial conditions:

$$x(0)=0 \qquad y(0)=0 \tag{10.2.265}$$

to be satisfied, we see pretty quickly that we must have:

$$c_x^{te}=\frac{v_{0y}}{\omega} \qquad c_y^{te}=-\frac{v_{0x}}{\omega} \tag{10.2.266}$$

Thus finally:

$$\begin{aligned}x(t)=\frac{v_{0x}}{\omega}\sin(\omega t)-\frac{v_{0y}}{\omega}\cos(\omega t)+\frac{v_{0y}}{\omega}=\frac{1}{\omega}(v_{0x}\sin(\omega t)-v_{0y}\cos(\omega t)+v_{0y})\\ y(t)=\frac{v_{0y}}{\omega}\sin(\omega t)+\frac{v_{0x}}{\omega}\cos(\omega t)-\frac{v_{0x}}{\omega}=\frac{1}{\omega}(v_{0y}\sin(\omega t)+v_{0x}\cos(\omega t)-v_{0x})\end{aligned} \tag{10.2.267}$$

So if we take the Y component of the velocity to be zero, we have:

$$\begin{aligned}x(t)=\frac{v_{0x}}{\omega}\sin(\omega t)\\ y(t)=\frac{v_{0x}}{\omega}\cos(\omega t)-\frac{v_{0x}}{\omega}\end{aligned} \tag{10.2.268}$$

Which isn't anymore the path of a circle because of the initial conditions chosen for this development. To fall back on the circular path it require the initial condition on Y to be:

$$y(0)=\frac{v_{0x}}{\omega} \tag{10.2.269}$$

Trapped particles in magnetic fields are found in the Van Allen radiation belts around Earth, which are part of Earth's magnetic field. These belts were discovered by James Van Allen while trying to measure the flux of cosmic rays on Earth (high-energy particles that come from outside the solar system) to see whether this was similar to the flux measured on Earth. Van Allen found that due to the contribution of particles trapped in Earth's magnetic field, the flux was much higher on Earth than in outer space. Aurorae, like the famous aurora borealis (northern lights) in the Northern Hemisphere, are beautiful displays of light emitted as ions recombine with electrons entering the atmosphere as they spiral along magnetic field lines. Aurorae have also been observed on other planets, such as Jupiter and Saturn.

Inner van Allen belt

Figure 10.57: Van Allen radiation belts around Earth (source: OpenStax)

Notice that if instead of the relation established earlier:

$$\begin{aligned}\ddot{x}&=\omega\dot{y}\\ \ddot{y}&=-\omega\dot{x}\\ \ddot{z}&=0\end{aligned}\qquad(10.2.270)$$

we add a proportional friction force term ($\vec{F}=-h\vec{v}$) like it is the case in a bubble chamber particle detector, we get:

$$\begin{aligned}\ddot{x}&=\omega\dot{y}-\frac{h}{m}\dot{x}\\ \ddot{y}&=-\omega\dot{x}-\frac{h}{m}\dot{y}\\ \ddot{z}&=0\end{aligned}\qquad(10.2.271)$$

We can write this system in matrix form (and we put $\tau=h/m$):

$$\begin{pmatrix}\ddot{x}\\ \ddot{y}\end{pmatrix}=\begin{bmatrix}-\frac{1}{\tau} & \omega\\ -\omega & -\frac{1}{\tau}\end{bmatrix}\begin{pmatrix}\dot{x}\\ \dot{y}\end{pmatrix}\qquad(10.2.272)$$

We are looking for the eigenvalues λ of the matrix. Its characteristic polynomial is written:

$$\begin{vmatrix} -\frac{1}{\tau}-\lambda & \omega \\ -\omega & -\frac{1}{\tau}-\lambda \end{vmatrix} = \left(-\frac{1}{\tau}-\lambda\right)^2+\omega^2=0 \tag{10.2.273}$$

The roots are: $\lambda_{1,2}=-\frac{1}{\tau}\pm\mathrm{i}\omega$. For $\lambda_1=-\frac{1}{\tau}+\mathrm{i}\omega$, the eigenvectors are:

$$\begin{bmatrix} -\mathrm{i}\omega & \omega \\ -\omega & -\mathrm{i}\omega \end{bmatrix} \cdot \begin{pmatrix} c_{11} \\ c_{12} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \Rightarrow \begin{pmatrix} c_{11} \\ c_{12} \end{pmatrix} = \begin{pmatrix} 1 \\ \mathrm{i} \end{pmatrix} \tag{10.2.274}$$

We put $\xi=\dot{X}$, hence:

$$\dot{\xi}=\begin{bmatrix} -\frac{1}{\tau} & \omega \\ -\omega & -\frac{1}{\tau} \end{bmatrix}\xi \tag{10.2.275}$$

Let us put :

$$\tilde{\xi}(t)=\mathrm{e}^{-\frac{t}{\tau}}\begin{pmatrix} \cos(\omega t)+\mathrm{i}\sin(\omega t) \\ -\sin(\omega t)+\mathrm{i}\cos(\omega t) \end{pmatrix} \tag{10.2.276}$$

A linear combination gives the solutions for ξ :

$$\xi(t)=C_1\mathrm{e}^{-\frac{t}{\tau}}\begin{pmatrix} \cos(\omega t) \\ -\sin(\omega t) \end{pmatrix}+C_2\mathrm{e}^{-\frac{t}{\tau}}\begin{pmatrix} \sin(\omega t) \\ \cos(\omega t) \end{pmatrix} \tag{10.2.277}$$

By integrating, with respect to t:

$$\begin{aligned} X &= \int \xi(t)\mathrm{d}t \\ &= C_1\frac{\mathrm{e}^{-\frac{1}{\tau}t}}{\frac{1}{\tau^2}+\omega^2}\begin{pmatrix} -\frac{1}{\tau}\cos\omega t+\omega\sin\omega t \\ \frac{1}{\tau}\sin\omega t+\omega\cos\omega t \end{pmatrix}+C_2\frac{\mathrm{e}^{-\frac{1}{\tau}t}}{\frac{1}{\tau^2}+\omega^2}\begin{pmatrix} -\frac{1}{\tau}\sin\omega t-\omega\cos\omega t \\ -\frac{1}{\tau}\cos\omega t+\omega\sin\omega t \end{pmatrix}+\begin{pmatrix} C_3 \\ C_4 \end{pmatrix} \end{aligned} \tag{10.2.278}$$

With the following initial conditions $x(0)=0, y(0)=0, \dot{x}(0)=v_{0,x}, \dot{y}(0)=v_{0,y}$, we get finally:

$$\begin{aligned} x(t) &= \frac{\tau}{1+\omega^2\tau^2}\left(-v_{0,x}\mathrm{e}^{-\frac{t}{\tau}}(\cos(\omega t)-\omega\tau\sin(\omega t))-v_{0,y}\mathrm{e}^{-\frac{t}{\tau}}(\sin(\omega t)+\omega\tau\cos(\omega t))+v_{0,x}+\omega\tau v_{0,y}\right) \\ y(t) &= \frac{\tau}{1+\omega^2\tau^2}\left(v_{0,x}\mathrm{e}^{-\frac{t}{\tau}}(\sin(\omega t)+\omega\tau\cos(\omega t))+v_{0,y}\mathrm{e}^{-\frac{t}{\tau}}(-\cos(\omega t)+\omega\tau\sin(\omega t))+v_{0,y}-\omega\tau v_{0,x}\right) \end{aligned} \tag{10.2.279}$$

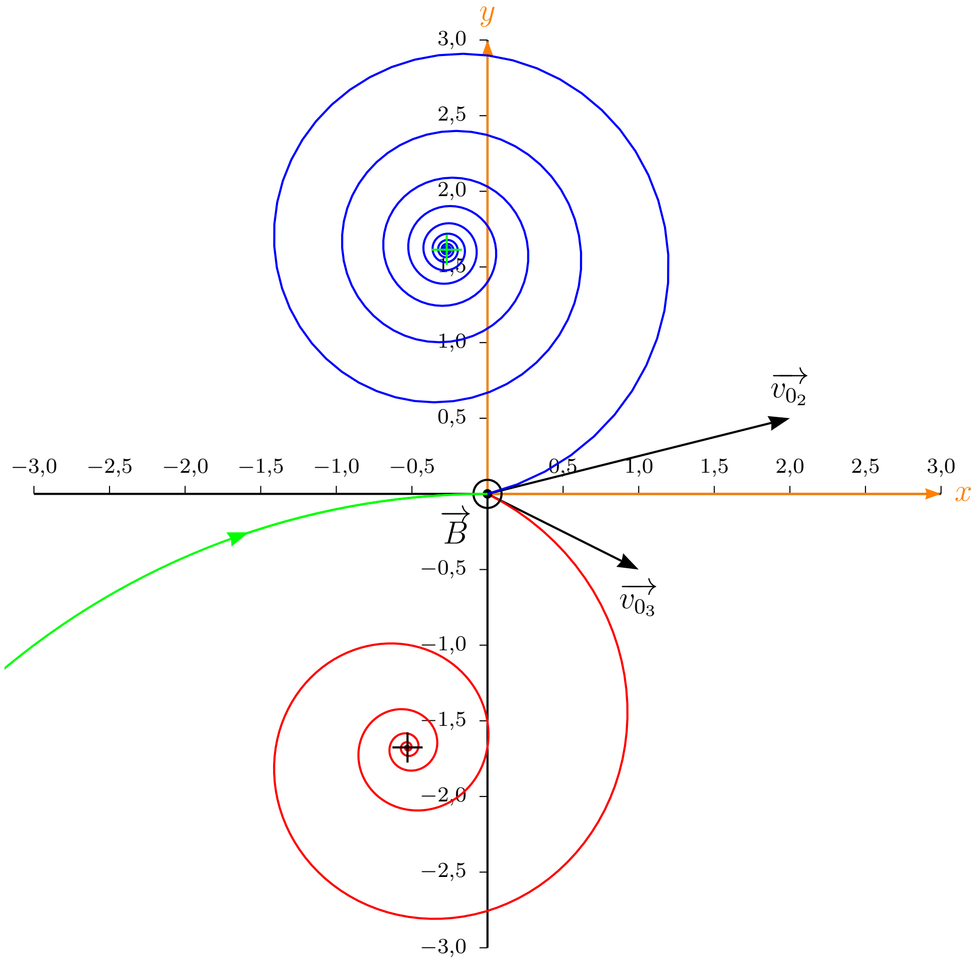

Figure 10.58: Bubble chamber helicoidal path

We can easily determine the asymptotic point! We put $t \to \infty$, therefore $\mathrm{e}^{-\frac{t}{\tau}} \to 0$:

$$\begin{aligned} x_{\infty} &= \frac{\tau}{1+\omega^2\tau^2}\left(v_{0,x}+\omega\tau v_{0,y}\right) \\ y_{\infty} &= \frac{\tau}{1+\omega^2\tau^2}\left(v_{0,y}-\omega\tau v_{0,x}\right) \end{aligned} \tag{10.2.280}$$

Now still in increasing difficulty, let us consider the case where we take into account also a movement in the z direction. We start from the general relation":

$$m\frac{\mathrm{d}\vec{v}}{\mathrm{d}t} = q\vec{v}\times\vec{B}-\lambda\vec{v} \tag{10.2.281}$$

Explicitly:

$$m\left(\ddot{x}\vec{e}_x+\ddot{y}\vec{e}_y+\ddot{z}\vec{e}_z\right) = q\left(\dot{x}\vec{e}_x+\dot{y}\vec{e}_y+\dot{z}\vec{e}_z\right)\wedge B\vec{e}_z-\lambda\left(\dot{x}\vec{e}_x+\dot{y}\vec{e}_y+\dot{z}\vec{e}_z\right) \tag{10.2.282}$$

Hence by projecting on the three axis:

$$\begin{aligned} m\ddot{x} &= qB\dot{y}-\lambda\dot{x} \\ m\ddot{y} &= -qB\dot{x}-\lambda\dot{y} \\ m\ddot{z} &= -\lambda\dot{z} \end{aligned} \tag{10.2.283}$$

Let us put $\omega_c = qB/m$ (the classic cyclotron pulsation) and $\tau = m/\lambda$ (time constant characteristic of energy losses), we arrive at:

$$\begin{gathered}\ddot{x} = \omega_c \dot{y} - \frac{1}{\tau}\dot{x}\\ \ddot{y} = -\omega_c \dot{x} - \frac{1}{\tau}\dot{y}\\ \ddot{z} = -\frac{1}{\tau}\dot{z}\end{gathered} \tag{10.2.284}$$

The third equation (in $\dot{z}$) is easily solved and gives with the initial conditions $\dot{z} = v_{0,z}$ and $z = 0$ at $t = 0$:

$$\dot{z} = v_{0,z} e^{-\frac{t}{T}} \quad \text{hence} \quad z = \tau v_{0,z}\left(1 - e^{-\frac{t}{\tau}}\right) \tag{10.2.285}$$

To solve the other two first equations we use a trick. We add the both of them but by multiplying the first one by $\cdot 1$ and the second one by $\cdot$i:

$$\begin{gathered}\ddot{x} = \omega_c \dot{y} - \frac{1}{\tau}\dot{x}\\ \mathrm{i}\ddot{y} = -\mathrm{i}\omega_c \dot{x} - \frac{\mathrm{i}}{\tau}\dot{y}\end{gathered} \tag{10.2.286}$$

The sum of the both gives:

$$(\ddot{x} + \mathrm{i}\ddot{y}) = \omega_c(\dot{y} - \mathrm{i}\dot{x}) - \frac{1}{\tau}(\dot{x} + \mathrm{i}\dot{y}) \tag{10.2.287}$$

If we rearrange this last relation a little bit, we get:

$$(\ddot{x} + \mathrm{i}\ddot{y}) = -\mathrm{i}\omega_c(\dot{x} + \mathrm{i}\dot{y}) - \frac{1}{\tau}(\dot{x} + \mathrm{i}\dot{y}) \tag{10.2.288}$$

Now we introduce a new variable $\xi = x + \mathrm{i}y$. Therefore:

$$\ddot{\xi} = -\mathrm{i}\omega_c \dot{\xi} - \frac{1}{\tau}\dot{\xi} \tag{10.2.289}$$

Or rearranging:

$$\ddot{\xi} = -\left(\frac{1}{\tau} + \mathrm{i}\omega_c\right)\dot{\xi} \tag{10.2.290}$$

For this equation, in fact in $\dot{\xi}$, the initial conditions at $t = 0$ are $x = y = 0$ therefore $\xi = 0$, $\dot{x} = v_0$, $\dot{y} = 0$ so $\dot{\xi} = v_0$, hence:

$$\dot{\xi} = v_0 e^{-\left(\frac{1}{\tau} + \mathrm{i}\omega_c\right)t} \tag{10.2.291}$$

Therefore we get immediately:

$$\xi = \frac{v_0}{\frac{1}{\tau} + \mathrm{i}\omega_c}\left(1 - e^{-\left(\frac{1}{\tau} + \mathrm{i}\omega_c\right)t}\right) \tag{10.2.292}$$

Using the Euler's formula (see section Numbers page 251), let us put:

$$\frac{1}{\tau}+\mathrm{i}\omega_c=\frac{1}{\tau^*}e^{\mathrm{i}\varphi} \tag{10.2.293}$$

with by construction:

$$\frac{1}{\tau^{*2}}=\frac{1}{\tau^2}+\omega_c^2 \tag{10.2.294}$$

and:

$$\tan(\varphi)=\tau\omega_c \tag{10.2.295}$$

Therefore:

$$\xi=\tau^*v_0e^{-\mathrm{i}\varphi}\left(1-e^{-\left(\frac{1}{\tau}+\mathrm{i}\omega_c\right)t}\right)=\tau^*v_0\left(e^{-\mathrm{i}\varphi}-e^{-\frac{t}{\tau}}e^{-\mathrm{i}(\omega_ct+\varphi)}\right) \tag{10.2.296}$$

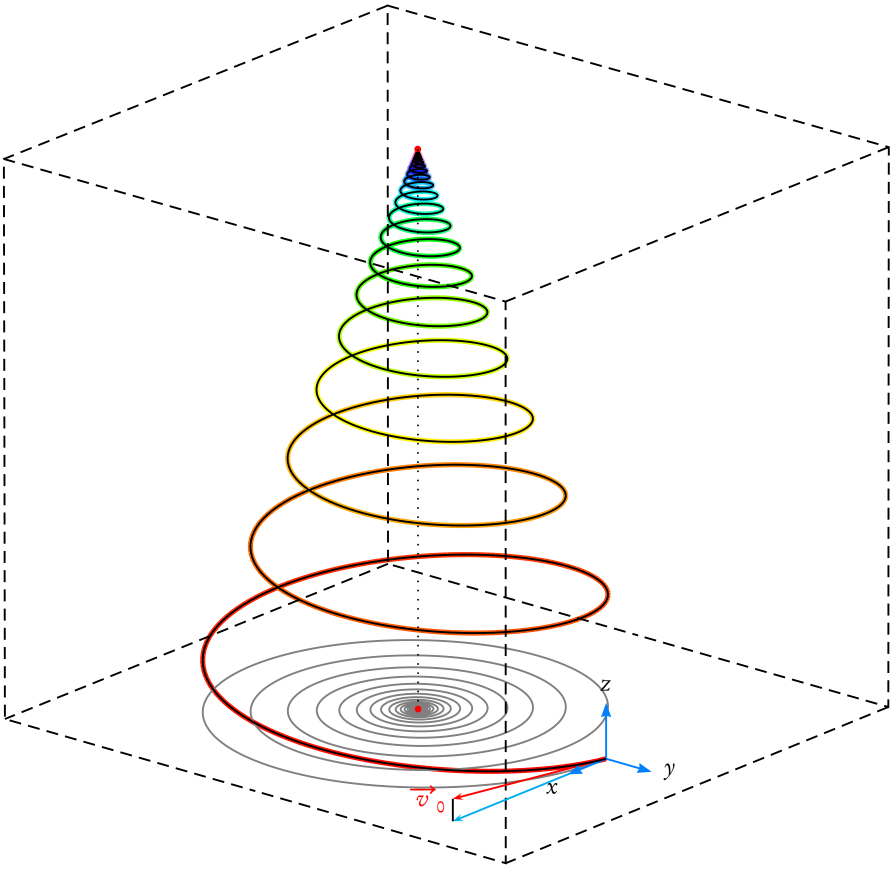
And finally:

$$\begin{aligned}x&=\Re(\xi)=\tau^*v_0\left[\cos(\varphi)-e^{-\frac{t}{\tau}}\cos\left(\omega_ct+\varphi\right)\right]\\y&=\Im(\xi)=\tau^*v_0\left[-\sin(\varphi)+e^{-\frac{t}{\tau}}\sin\left(\omega_ct+\varphi\right)\right]\end{aligned} \tag{10.2.297}$$

Therefore all three components are given by:

$$\begin{aligned}x&=\tau^*v_0\left[\cos(\varphi)-e^{-\frac{t}{\tau}}\cos\left(\omega_ct+\varphi\right)\right]\\y&=\tau^*v_0\left[-\sin(\varphi)+e^{-\frac{t}{\tau}}\sin\left(\omega_ct+\varphi\right)\right]\\z&=\tau v_{0,z}\left(1-e^{-\frac{t}{\tau}}\right)\end{aligned} \tag{10.2.298}$$

Here is the shape of the trajectory in perspective, for arbitrary values of the constants:



After about 7τ, the limit is reached and the charge has stopped at the coordinate point $x_\infty = \tau^* v_0 \cos(\varphi), y_\infty = -\tau^* v_0 \sin(\varphi), z_\infty = \tau v_{0,z}$.

10.2.5.5 Energy of a magnetic dipole

Thanks to the fact that we now have the units of the magnetic field and those of the magnetic permeability constant and the Lorentz law, we will now be able to determine by dimensional analysis and intuition the total energy of a static (oriented!) magnetic dipole which will be very useful for us for the theory of paramagnetism developed further below.

Let us consider for this a rigid magnet in the form of cylinder of length L and of negligible radius that can be regarded as a north / south dipole (a "bar magnet") immersed in a constant and homogeneous magnetic field in the plane perpendicular to the axis of rotation of the dipole:

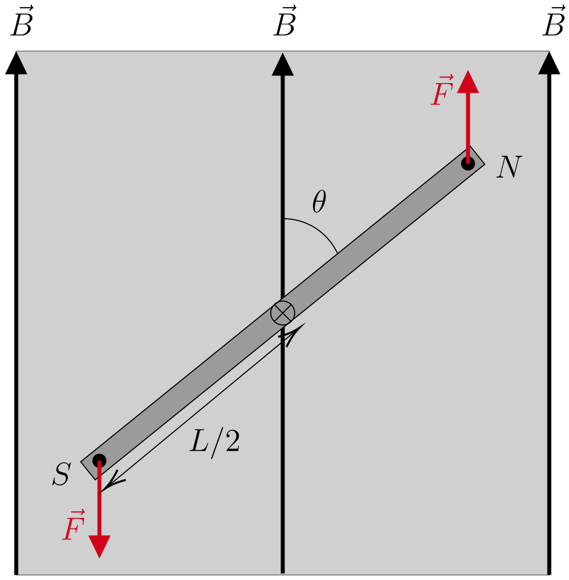


Figure 10.59: **Schematic diagram for the study of the static magnetic dipole**

The experience shows that when the dipole is collinear with the magnetic field, it does not move. It follows that the force on one end depends in proportion to the sine of the angle with the magnetic field such that:

$$\vec{F}\propto\vec{B}\sin(\theta) \tag{10.2.299}$$

At the dimension level we have so fare:

$$[\mathrm{kg}\cdot\mathrm{m}\cdot\mathrm{s}^{-2}]=[\mathrm{kg}\cdot\mathrm{s}^{-2}\cdot\mathrm{A}^{-1}] \tag{10.2.300}$$

We would have to get rid of Amps [A] by already making intervene at least obviously what characterizes a magnetic dipole... and we have already determined earlier above: its magnetic moment μ_l which units are for recall:

$$[\mathrm{A}\cdot\mathrm{m}^{-2}] \tag{10.2.301}$$

It seems quite natural enough to write to go a little further:

$$\vec{F}\propto\mu_l\vec{B}\sin(\theta) \tag{10.2.302}$$

This now gives at the dimensional level:

$$[\mathrm{kg}\cdot\mathrm{m}\cdot\mathrm{s}^{-2}]=[\mathrm{kg}\cdot\mathrm{s}^{-2}\cdot\mathrm{m}^{2}] \tag{10.2.303}$$

We then a unit of length in more. Then it seems quite natural to introduce the dipole length such that (the force should logically be equal at every point of the dipole so there is no reason to introduce here half of the dipole length!):

$$\vec{F}=\mu_l\vec{B}\sin(\theta)=\frac{\mu_l}{L}\vec{B}\sin(\theta) \quad (10.2.304)$$

Now to get back to the energy of the magnetic dipole, we consider that it is zero when the dipole is initially in a position perpendicular to the magnetic field. Using the common approximation as what infinitesimal movement of the two ends is given by for small angles:

$$\mathrm{d}l\cong\frac{L}{2}\mathrm{d}\theta \quad (10.2.305)$$

Thus, the elementary work (energy) to turn the dipole is (we multiply by two because we have to sum the two forces acting on each pole) by denoting by B the norm of the magnetic field:

$$\mathrm{d}E=2\left(2\frac{\mu_l}{L}B\sin(\theta)\right)\frac{L}{2}\mathrm{d}\theta=\mu_l B\sin(\theta)\mathrm{d}\theta \quad (10.2.306)$$

where we see that the dipole length is no longer involved. In fact we must not forget that it is in the magnetic dipole moment μ_l that we have the equivalent area of the dipole.

It comes by integration for a given final angle:

$$E=\mu_l B\int_{\pi/2}^{\theta}\sin(\theta)\mathrm{d}\theta=-\mu_l B\cos(\theta)\Big|_{\pi/2}^{\theta}=-\mu_l B\cos(\theta) \quad (10.2.307)$$

Therefore:

$$\boxed{E=-\vec{\mu}_l\circ\vec{B}} \quad (10.2.308)$$

Let us see now a classic and academic case that we can get from this result and that we will see again during our study of the spin in the section of Wave Quantum Physics.

So we have proved earlier above that an electric charged particle is deflected by a force given by the equation of the Lorentz' law:

$$\vec{F}=q\vec{v}\times\vec{B} \quad (10.2.309)$$

It follows that if the field has only a constant component in z and the speed only one component in x, this will cause a helical motion in the plane perpendicular to the field as we have already proved above in our study of the Larmor radius.

Let us consider now an electric charged particle launched at uniform speed along an x-axis between two poles of opposing magnets which generate a vertical and heterogeneous magnetic field and let us look only to the deflection along z of the trajectory of the particle.

From the perspective of the z-axis the particle can be considered in uniform acceleration (see section Classical Mechanics page 3224):

$$z=z_0+v_{0,z}t+\frac{1}{2}a_z t^2 \quad (10.2.310)$$

Since we assume that the initial position along z of the particle is midway between the two poles and that its initial velocity along the z-axis such as:

$$\begin{aligned}z_0&=0\\v_{0,z}&=0\end{aligned}\qquad(10.2.311)$$

Then we have:

$$z=\frac{1}{2}a_zt^2\qquad(10.2.312)$$

Since the magnetic field does not work (see proof earlier above) and that implies that the kinetic energy remains constant, we can write that the time is simply the ratio of the horizontal distance travelled by the particle by the speed module:

$$z=\frac{1}{2}a_z\left(\frac{L}{v}\right)^2=\frac{1}{2}a_zL^2\frac{1}{v^2}=\frac{1}{2}a_zL^2\left(\frac{m}{2E_c}\right)=\frac{mL^2}{4E_c}a_z\qquad(10.2.313)$$

Let us recall that we have proved just earlier above that the potential energy of a magnetic dipole was in a constant and homogeneous field given by:

$$E=-\vec{\mu}_l\circ\vec{B}\qquad(10.2.314)$$

Then in comes in our case:

$$E=-\mu_{lz}B_z\qquad(10.2.315)$$

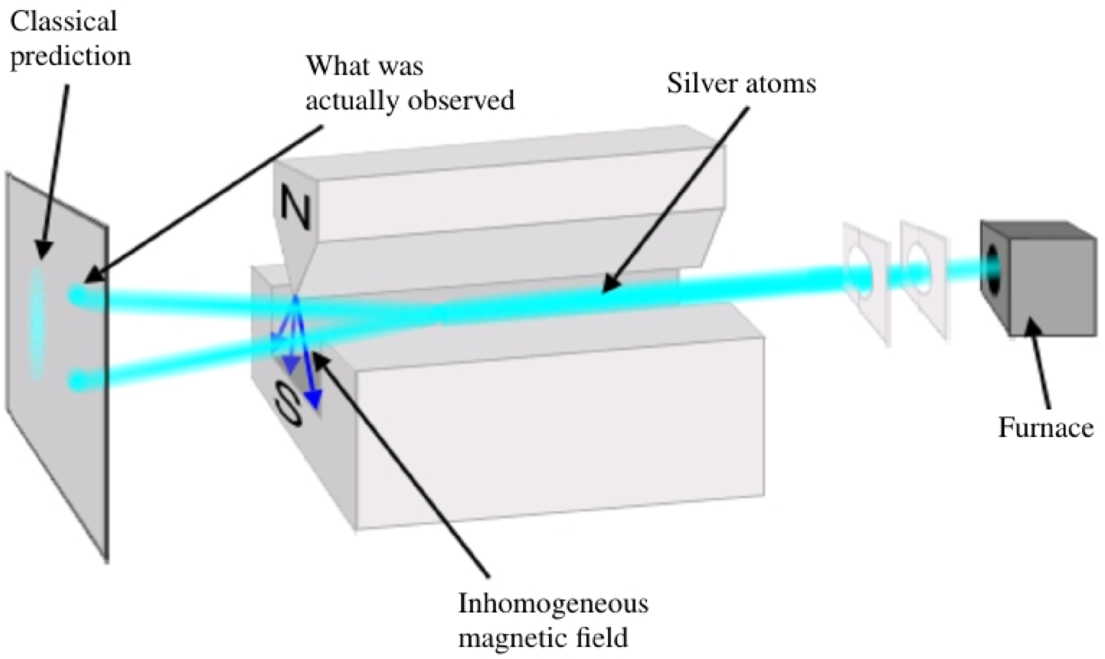
And as we can associate a force to a potential energy, it comes by assuming that the dipole magnetic moment is constant along the z-axis and the magnetic field is still somewhat a little bit inhomogeneous (happy mix of assumptions ... but we still do engineering physics in this textbook!):

$$F_z=-\frac{\partial E}{\partial z}\cong\mu_{lz}\frac{\partial B_z}{\partial z}=ma_z\qquad(10.2.316)$$

And finally:

$$z=\frac{mL^2}{4E_c}a_z=\frac{mL^2}{4E_c}\left(\frac{\mu_{lz}}{m}\frac{\partial B_z}{\partial z}\right)=\frac{\mu_{lz}L^2}{4E_c}\frac{\partial B_z}{\partial z}\qquad(10.2.317)$$

So we see in any case that z can take a continuous spectrum of values that depends on the magnetic dipole moment of the particle. Now, as we shall see in the section of Wave Quantum Physics and Relativistic Quantum Physics during our study of quantum operators and especially that of the orbital angular momentum and of spin, an experiment named "Stern-Gerlach experiment" has shown that this was not the case for some particles or atoms for which the z are clearly discrete, what classical physics seemed unable to explain!!!!



Classical prediction
What was actually observed
Silver atoms
N
S
Furnace
Inhomogeneous magnetic field

Figure 10.60: **Stern-Gerlarch experiment principle and result (source: Wikipedia, source: JohnDC†)**

Stern and Gerlach were astonished by what they saw. Not only were these "free" electrons deflected by the magnetic field, the pattern of their deflection was itself totally unexpected and mysterious. They found that the beam separated into two distinct parts. The basic experimental set-up is shown below.

This pointed to two things. First, the "free" electrons must have some kind of built-in magnetic moment because they are interacting with the magnetic field. Second, this magnetic moment is no ordinary dipole moment - the electrons are not acting like tiny little magnetic spheres shooting through the magnetic field.

10.2.6 Langevin treatment of Diamagnetism and Paramagnetism

We have define earlier what were diamagnetic and paramagnetic materials. In 11905 (holocene calendar) Langevin proposed after trial and error the theories of diamagnetism and paramagnetism (in 11906 - according to holocene calendar - Pierre Weiss proposed the theory of ferromagnetism) under some strong and simplified assumptions but that still work quite well to explain some material behaviours. We will see here what are the developments used to explained these behaviours.

10.2.6.1 Langevin model of diamagnetism

The purpose of this model is be able to explain the negative magnetism that is opposed to the magnetic excitation such that we can observe it in practice. This model is rough relatively to the quantum model but it is interesting for two main reasons: the first is that it already gives enough concepts to the reader to start the study of this subject if not familiar with quantum theory, the second being that it is a good training model (in the academic sense) because it shows how trials and successive approximations can lead to something relatively acceptable in practical perspective.

Remark

This model has its place in the section Magnetostatics because the excitation field used in the model is assumed to be constant!

For this, we consider the classical model of Langevin (the quantum model giving the same result as we will see in the corresponding section), where the electron is regarded as travelling a circular orbit of radius r and then can be assimilated to an electric current in a loop producing an electromotive force (see section Electrokinetics page 4253):

$$e=-\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}=-\frac{\mathrm{d}(BS)}{\mathrm{d}t}=-\frac{\mathrm{d}(\mu_0 HS)}{\mathrm{d}t}=-\mu_0 S\frac{\mathrm{d}H}{\mathrm{d}t}=-\mu_0\pi r^2\frac{\mathrm{d}H}{\mathrm{d}t} \tag{10.2.318}$$

that we can assimilate to an electric field such that (see section Electrokinetics page 4256):

$$e=\oint\limits_{\text{orbit}} E_m\mathrm{d}l=E_m 2\pi r=-\mu_0\pi r^2\frac{\mathrm{d}H}{\mathrm{d}t} \tag{10.2.319}$$

Therefore it comes:

$$E_m=-\frac{\mu_0 r}{2}\frac{\mathrm{d}H}{\mathrm{d}t} \tag{10.2.320}$$

We then have by denoting m_e the rest mass of the electron and q_e its electric charge:

$$\frac{\mathrm{d}v}{\mathrm{d}t}=a=\frac{q_e E_m}{m_e}=-\frac{q_e}{m_e}\frac{\mu_0 r}{2}\frac{\mathrm{d}H}{\mathrm{d}t} \tag{10.2.321}$$

hence:

$$\Delta v=-\frac{q_e\mu_0 r}{2m_e}\Delta H=-\frac{q_e\mu_0 r}{2m_e}\left(H-\underbrace{H_0}_{=0}\right)=-\frac{-q_e\mu_0 r}{2m_e}H \tag{10.2.322}$$

The application of an external magnetic excitation will have for effect to change the magnetic dipole moment μ_l of quantity $\Delta\mu_l$. But, we have prove earlier above that the magnetic dipole moment was given by:

$$\mu_l=\frac{q\omega}{2}r^2=\frac{q\dfrac{v}{r}}{2}r^2=\frac{qr}{2}v \tag{10.2.323}$$

Then it comes for the electron:

$$\Delta\mu_l=\frac{q_e r}{2}\Delta v=\frac{q_e r}{2}\left(-\frac{q_e\mu_0 r}{2m_e}H\right)=-\frac{q_e^2\mu_0 r^2}{4m_e}H \tag{10.2.324}$$

Then, the very clever and rough trick (in the approximate sense of the term relatively to the experience and to the quantum model developed a few years later) is to take into consideration the fact that the electron in classical point of view can be considered as a point object that can move in a sphere of radius R given in the case of a mono-electronic atom and not just in a planar circular radius r perpendicular to the direction of the magnetic excitation field.

In this case, we then have of course:

$$x^2+y^2+z^2=R^2 \tag{10.2.325}$$

and we will consider that the three coordinates are independent and identically distributed random variables (so already the theoretical model is very rough but it's better than nothing...). Therefore, it follows that their expectation is equal such as:

$$\mathrm{E}(x^2+y^2+z^2)=\mathrm{E}(R^2) \tag{10.2.326}$$

Using the property of linearity of the expected mean (see section Statistics page 571) and the notation used by the physicist, it is then written:

$$\langle x^2\rangle+\langle y^2\rangle+\langle z^2\rangle=\langle R^2\rangle \tag{10.2.327}$$

and as the coordinates are considered like random variables identically distributed, we also have:

$$\langle x^2\rangle=\langle y^2\rangle=\langle z^2\rangle \tag{10.2.328}$$

It follows immediately that:

$$\langle x^2\rangle=\langle y^2\rangle=\langle z^2\rangle=\frac{\langle R^2\rangle}{3} \tag{10.2.329}$$

And so if we are interested only to the average disk radius containing all orbits perpendicular to the direction of the magnetic excitation field directed along the z-axis, then it comes:

$$\langle x^2\rangle+\langle y^2\rangle=\frac{2}{3}\langle R^2\rangle \tag{10.2.330}$$

Therefore, finally, for an electron in all possible orbits of a limited sphere:

$$\langle\Delta\mu_l\rangle=-\frac{q_e^2\mu_0\langle r^2\rangle}{4m_e}H=-\frac{q_e^2\mu_0\dfrac{2}{3}\langle R^2\rangle}{4m_e}H=-\frac{q_e^2\mu_0\langle R^2\rangle}{6m_e}H \tag{10.2.331}$$

where $\langle R^2\rangle$ can be explicitly calculated with the quantum model (with wave functions to be precise!).

For an atom containing Z electrons, we will do the rough assumption that a simple sum of the effects is valid ...:

$$\langle\Delta\mu_l\rangle=\sum_{i=1}^{Z}-\frac{q_e^2\mu\langle R_i^2\rangle}{6m_e}H=-\frac{q_e^2\mu_0H}{6m_e}\sum_{i=1}^{Z}\langle R_i^2\rangle \tag{10.2.332}$$

From a macroscopic point of view, the number of atoms in a unit volume will be the ratio of the density of the material divided by the atomic weight of the element in question multiplied by Avogadro's number:

$$n=N_{\text{A}}\frac{\rho}{m_A} \tag{10.2.333}$$

It comes then by unit volume:

$$\langle\Delta\mu_l\rangle=-n\frac{q_e^2\mu_0H}{6m_e}\sum_{i=1}^{Z}\langle R_i^2\rangle=-H\frac{nq_e^2\mu_0}{6m_e}\sum_{i=1}^{Z}\langle R_i^2\rangle=H\chi_d \tag{10.2.334}$$

and it is this result that is assimilated to the magnetic susceptibility as it's written in the form of the "Langevin's diamagnetic susceptibility relation":

$$\boxed{\chi_d=-\frac{q_e^2n\mu_0}{6m_e}\sum_{i=1}^{z}\langle R_i^2\rangle} \tag{10.2.335}$$

At unit level, we have well:

$$\chi_d=\frac{[\text{C}^2][\text{m}^{-3}][\text{kg}\cdot\text{m}\cdot\text{s}^{-2}\cdot\text{A}^{-2}]}{[\text{kg}]}[\text{m}^2]=[\text{C}^2][\text{s}^{-2}\cdot\text{A}^{-2}]=[\text{C}^2][\text{s}^{-2}\cdot\text{s}^2\cdot\text{C}^{-2}]=[-] \tag{10.2.336}$$

So it is a coefficient without units as expected.... and it is because this coefficient is negative that we assimilate this model to diamagnetism (by definition). The reader will have perhaps noticed that if the magnetic excitation is zero, the susceptibility is also zero... which is an expected minimum behaviour of the theoretical model. But by cons this latter does not depend on the temperature (the influence thereof is anyway almost negligible in standard laboratory temperature range).

The agreement experiment / theory is excellent for spherically symmetric elements in the order of $\pm 10\%$ error. For non-spherical elements the error often reaches 50% with respect to the experience.

10.2.6.2 Langevin model of paramagnetism

Langevin tried (with varying degrees of success here too) to explain the paramagnetism with the same underlying ideas, but however by opting for a completely different mathematical approach to ensure a positive outcome... (do it yourself physicist way of life...). What Langevin also knew it is that paramagnetism highly dependent on the temperature according to experimental studies of ferromagnetic materials, it was therefore necessary to choose an approach emphasizing the temperature and at the time there were no $10,000$ ways to do this! It follows that this model opens also the door to the theory of ferromagnetism!

As at the starting point at that time we naturally assumed the (Maxwell-)Boltzmann distribution proved in the section of Statistical Mechanics that describes for recall the distribution of detectable particles that do not interact with any constraints on the number of particles state... (at the time of Langevin there were only this model available...):

$$f_{\text{MB}}(E,T)=e^{-\frac{E}{kT}} \tag{10.2.337}$$

where as the reader maybe noticed it (see section Statistical Mechanics page 3554) the potential energy μ_i is taken to be zero, so that all energy is in the form of kinetic energy.

It is important to notice that the latter writing of the distribution function, as we have seen in the section Statistical Mechanics, ignores the normalization constant to make it a true probability density function (but we will obviously calculate that constant a little further below).

We have also proved just earlier that the magnetic potential energy of a dipole was given by:

$$E=-\vec{\mu}_l\circ\vec{B}=-\mu_l B\cos(\theta) \tag{10.2.338}$$

Now, let us recall that we have proved in the section of Geometric Shapes that the surface of a sphere element was given by:

$$\mathrm{d}S=R^2\sin(\theta)\mathrm{d}\theta\mathrm{d}\phi \tag{10.2.339}$$

It comes therefore (the reader may refer to the figure of the section of Geometric Shapes) that for a crown of the sphere defined by two parallel planes, which middle contains the origin of the sphere is then given by (if needed and on readers request we can draw another figure) :

$$\mathrm{d}S=R^2\sin(\theta)\frac{\mathrm{d}\theta}{2}2\pi=R^2\sin(\theta)\mathrm{d}\theta \tag{10.2.340}$$

Why are we talking about this? Well because a portion of the total number of magnetic dipoles included in an angle range $\mathrm{d}\theta$ is as we see above proportional to a surface element as:

$$\mathrm{d}\theta=\frac{\mathrm{d}S}{R^2\sin(\theta)} \tag{10.2.341}$$

We then have that this number is given by (to a given unknown constant factor K):

$$\mathrm{d}n\propto KR^2\sin(\theta)\mathrm{d}\theta e^{-E/kT}=KR^2\sin(\theta)\mathrm{d}\theta e^{\mu_l B\cos(\theta)/kT} \tag{10.2.342}$$

The corresponding proportion (so it is also a probability) over all angles, for a given angle, is then given after normalization obviously by:

$$P(\theta)=\frac{KR^2\sin(\theta)\mathrm{d}\theta e^{\mu_l B\cos(\theta)/kT}}{\int\limits_0^\pi KR^2\sin(\theta)\mathrm{d}\theta e^{\mu_l B\cos(\theta)/kT}\mathrm{d}\theta}=\frac{\sin(\theta)\mathrm{d}\theta e^{\mu_l B\cos(\theta)/kT}}{\int\limits_0^\pi \sin(\theta)\mathrm{d}\theta e^{\mu_l B\cos(\theta)/kT}\mathrm{d}\theta} \tag{10.2.343}$$

We saw during our study of the magnetic dipole moment that $\vec{\mu}_l$ contributes to the magnetic field. If we have a volumetric density of n magnetic dipoles, then we have a contribution of around $n\vec{\mu}_l$ if they are all oriented in the same direction. But if we project the vector of the magnetic moment on the direction of the magnetic field, the contribution of dipoles will then be written:

$$n\mu_l\cos(\theta) \tag{10.2.344}$$

but as there are many dipoles in different directions and that do many various angles with the field, then we have to take the average such that the contribution to the magnetic field is proportional to:

$$n\mu_l\langle\cos(\theta)\rangle \tag{10.2.345}$$

And using simply the properties of density statistical functions (see section Statistics page 633), the expected mean contribution is given by:

$$n\mu_l\langle\cos(\theta)\rangle=n\mu_l\int\limits_0^\pi\cos(\theta)P(\theta)\mathrm{d}\theta=n\mu_l\int\limits_0^\pi\cos(\theta)\frac{\sin(\theta)e^{\mu_l B\cos(\theta)/kT}}{\int\limits_0^\pi\sin(\theta)e^{-\mu_l B\cos(\theta)/kT}\mathrm{d}\theta} \tag{10.2.346}$$

and as the denominator is just a normalization constant, we can get it out of the first integral:

$$n\mu_l\langle\cos(\theta)\rangle=n\mu_l\frac{\int\limits_0^\pi\cos(\theta)\sin(\theta)e^{\mu_l B\cos(\theta)/kT}\mathrm{d}\theta}{\int\limits_0^\pi\sin(\theta)e^{\mu_l B\cos(\theta)/kT}\mathrm{d}\theta} \tag{10.2.347}$$

To integrate, let us do the little simplification of writing by putting:

$$\gamma=\frac{\mu_l B}{kT} \tag{10.2.348}$$

This gives us:

$$n\mu_l\langle\cos(\theta)\rangle=n\mu_l\frac{\int\limits_0^\pi\cos(\theta)\sin(\theta)e^{\gamma\cos(\theta)}\mathrm{d}\theta}{\int\limits_0^\pi\sin(\theta)e^{\gamma\cos(\theta)}\mathrm{d}\theta} \tag{10.2.349}$$

and let us put:

$$x=\cos(\theta) \tag{10.2.350}$$

Then we have:

$$\frac{\mathrm{d}x}{\mathrm{d}\theta}=-\sin(\theta)\Rightarrow \mathrm{d}\theta-\frac{\mathrm{d}x}{\sin(\theta)} \tag{10.2.351}$$

It comes then:

$$n\mu_{\langle}x\rangle=n\mu_l\frac{\displaystyle\int\limits_{+1}^{-1}xe^{\gamma x}\mathrm{d}x}{\displaystyle\int\limits_{+1}^{-1}e^{\gamma x}\mathrm{d}x} \tag{10.2.352}$$

The primitive numerator is known to us because it is part of the usual primitive proved in detail in the section of Differential and Integral Calculus! The integral in the denominator is trivial:

$$\begin{aligned}n\mu_l\langle x\rangle&=n\mu_l\frac{e^{\gamma x}\left(\dfrac{1}{\gamma}x-\dfrac{1}{\gamma^2}\right)\Bigg|_{+1}^{-1}}{\dfrac{1}{\gamma}e^{\gamma x}\Bigg|_{+1}^{-1}}=n\mu_l\frac{e^{-\gamma}\left(-1-\dfrac{1}{\gamma}\right)-e^{\gamma}\left(1-\dfrac{1}{\gamma}\right)}{e^{-\gamma}-e^{\gamma}}\\&=n\mu_l\frac{e^{\gamma}\left(1-\dfrac{1}{\gamma}\right)-e^{-\gamma}\left(-1-\dfrac{1}{\gamma}\right)}{e^{\gamma}-e^{-\gamma}}=n\mu_l\frac{e^{\gamma}+e^{-\gamma}-e^{\gamma}\dfrac{1}{\gamma}+e^{-\gamma}\dfrac{1}{\gamma}}{e^{\gamma}-e^{-\gamma}}\\&=n\mu_l\left[\frac{e^{\gamma}+e^{-\gamma}}{e^{\gamma}-e^{-\gamma}}-\frac{1}{\gamma}\frac{e^{\gamma}-e^{-\gamma}}{e^{\gamma}-e^{-\gamma}}\right]=n\mu_l\left(\frac{e^{\gamma}+e^{-\gamma}}{e^{\gamma}-e^{-\gamma}}-\frac{1}{\gamma}\right)=n\mu_l\left(\coth(\gamma)-\frac{1}{\gamma}\right)\end{aligned} \tag{10.2.353}$$

The function:

$$L(\gamma)=\coth(\gamma)-\frac{1}{\gamma} \tag{10.2.354}$$

is often named "Langevin's function" with for recall:

$$\gamma=\frac{\mu_l B}{kT} \tag{10.2.355}$$

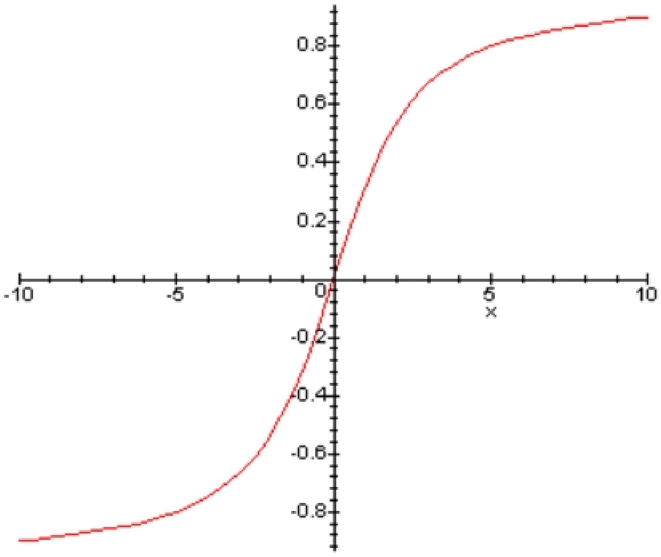


Figure 10.61: **Plot of Langevin's function in Maple™ 4.00b**

The Langevin function is equal 0 when its parameter is 0 and approaches 1 when its argument tends to infinity. So the system eventually saturate when the magnetic field increases, which corresponds to the experimental behaviour of paramagnetic materials. By cons the increase in temperature therefore decrease factor γ and makes the Langevin's function tend to 0 and has for effect to cancel the alignment of dipoles.

For small values of the parameter γ, the Langevin's function can be considered as linear as we see on the plot above. To simplify the expression, we'll calculate the Taylor approximation of the hyperbolic cotangent using detailed proved presented in the section of Sequences and Series and when the hyperbolic cotangent argument is to recall strictly less than 1 in absolute value:

$$\coth(\gamma) \cong \frac{1}{\gamma} + \frac{\gamma}{3} \tag{10.2.356}$$

Then we have:

$$L(\gamma) \cong \frac{\gamma}{3} = \frac{\mu_l B}{3kT} \tag{10.2.357}$$

We have therefore the magnetic field which is proportional to:

$$n\mu_0\langle x\rangle = n\mu_l L(\gamma) \cong n\mu_l \frac{\mu_l B}{3kT} = \frac{n\mu_l^3 B}{3kT} = \frac{n\mu_l^3 \mu_0 H}{3kT} = \frac{n\mu_l^2 \mu_0}{3kT} H \tag{10.2.358}$$

We see that the factor:

$$\frac{n\mu_l^2 \mu_0}{3kT} \tag{10.2.359}$$

is dimensionless. Indeed:

$$\frac{[\mathrm{m}^{-3}][\mathrm{A}\cdot\mathrm{m}^2]^2[\mathrm{kg}\cdot\mathrm{m}\cdot\mathrm{s}^{-2}\cdot\mathrm{A}^{-2}}{[\mathrm{m}^2\cdot\mathrm{kg}\cdot\mathrm{s}^{-2}\cdot\mathrm{K}^{-1}][\mathrm{K}]} = \frac{[\mathrm{m}^{-3}][\mathrm{A}^2\cdot\mathrm{m}^4][\mathrm{m}\cdot\mathrm{A}^{-2}]}{[\mathrm{m}^2]} = \frac{[\mathrm{m}^2]}{[\mathrm{m}^2]} = [-] \tag{10.2.360}$$

So we can consider it is the paramagnetic susceptibility and write the "Langevin's relation of the paramagnetic susceptibility":

$$\boxed{\chi_p \cong \frac{N\mu_l^2\mu_0}{3kT} = \frac{N\mu_l^2\mu_0}{3k}\frac{1}{T} = \frac{C}{T}} \tag{10.2.361}$$

better known under the name "Curie's law" and shows that the magnetic susceptibility is inversely proportional to the temperature (good but obviously this law becomes false at low temperatures and we must then derive empirically the Curie-Weiss law).

In physics and materials science, the "Curie temperature" T_C, or "Curie point", is the temperature above which certain materials lose their permanent magnetic properties, which can (in most cases) be replaced by induced magnetism.

Caution!! Keep in mind that's an oversimplified model! More realistic models based on quantum theory show that the magnetic susceptibility can increase or decrease in function of the temperature and pressure and therefore that the Curie temperature also varies quite strangely depending on the material property and the pressure following (see [472]):

$$\frac{T_\text{C}(p)}{T_\text{C}\left(P_0\right)} = \left[\exp\left(-\left(\frac{R\left(p, T_\text{C}(p)\right)}{R\left(p_0, T_\text{C}\left(p_0\right)\right)}-1\right)\right)\right]^{\frac{1}{n}} \tag{10.2.362}$$

As a little summary can always be useful here is one:

Property	**Diamagnetic**	**Paramagnetic**	**Ferromagnetic**
Magnetic induction	$B < B_0$	$B > B_0$	$B \gg B_0$
Susceptibility χ	$\chi < 0$	$\chi \geq 0$	$\chi \gg 0\,(10^2 - 10^3)$
Temperature dependence	No	$\chi_d = \dfrac{C}{T}$	$\chi_f = -\dfrac{C}{T - T_c}$
Relative permeability μ_r	$\mu_r < 1$	$\mu_r > 1$	$\mu_r \gg 1\,(10^2 - 10^3)$
Magnetising vector	Opposite to $\vec{H}$	In the direction of $\vec{H}$	In the direction of $\vec{H}$

Table 10.1: **Summary of common magnetic properties**

And here small numeric table of some Curie temperatures at room pressure:

Material	**Chemical Formula**	**Curie temp. [K]**	**Curie temp. [°C]**
Cobalt	Co	1388	1115
Iron	Fe	1043	770

10.3. Electrodynamics

Classical electrodynamics is a branch of theoretical physics that studies the interactions between electric charges and currents using an extension of the classical Newtonian model. The theory provides an excellent description of electromagnetic phenomena whenever the relevant length scales and field strengths are large enough that quantum mechanical effects are negligible. For small distances and low field strengths, such interactions are better described by quantum electrodynamics.

In this section we will build a set of equations that can sum up themselves our entire knowledge about electrostatics and magnetostatics. These equations, at the number of four, are named "Maxwell-Heaviside equations" (denomination that we will shorten as many other books under the name "Maxwell's equations") and will allow us to approach the branch of physics named "electrodynamics" and therefore electromagnetic waves (i.e.: light!).

Electrodynamics is a pillar of the electronic revolution! Without this theory: no radio, no phones or cell phones, no computers, no satellites, no satellites, no electric motor, we would still at the technological state of the late 119th century (holocene calendar) without it!

Remark

It is very important to understand what will follow! Some developments will be reused in the section of Special Relativity, Quantum Field Theory, etc. Furthermore, the reader should also read in parallel the section of Special Relativity to better understand the ins and outs of certain results and the provenance of some mathematical tools.

We assume before tackling mathematical models that everyone admits at the beginning of this third millennium than gamma rays, radio waves, microwaves, visible light (and not visible light) are electromagnetic waves (EM) of different frequencies:

10.3.1 Maxwell Equations

As already mentioned Maxwell's equations are a set of partial differential equations that form the foundation of classical electrodynamics, classical optics, and electric circuits and encompass the knowledge of almost all 119th century (holocene calendar) about the subject. These fields in turn underlie modern electrical and communications technologies. Maxwell's equations describe how electric and magnetic fields are generated and altered by each other and by charges and currents.

If there is a some gods (concept that remains to be proved beyond reasonable evidence) many people say that probably god (we don't know the god of what religion...) wrote the Maxwell Equations first and let there be light: and there was light!

10.3.1.1 First Maxwell Equation (constant electric flow)

Let us define $\vec{\mathcal{E}}$ a vectors field in space. Consider a closed surface S in this field. Then at each point (x, y, z) belonging to the surface corresponds a vector of the field:

In this case the Ostrogradsky's theorem gives us (see section Vector Calculus page 1882):

$$\Phi_{\mathcal{E}} = \oiint_S (\vec{\mathcal{E}} \circ \vec{n})\mathrm{d}S = \iiint_V (\vec{\nabla} \circ \vec{\mathcal{E}})\mathrm{d}V \qquad (10.3.1)$$

with V being the volume delimited by the closed surface S (so-named for recall "Gauss surface").

Remark

The Ostrogradsky theorem is verified since there is no singularities in the volume V!

Before continuing let us also recall that in the case of the Ostrogradsky theorem the normal vector $\vec{n}$ is conventionally directed outwardly from the surface.

In the particular case of an electric field, we get some very interesting results. Indeed, given a charge Q located relatively to a frame by the vector $\vec{r}_Q$. Then, we already saw in the section of Electrostatic that in every point in space, there is a field $\vec{E}$ such that:

$$\vec{E}(\vec{r})=\frac{KQ}{\|\vec{r}-\vec{r}_Q\|^3}(\vec{r}-\vec{r}_Q) \tag{10.3.2}$$

therefore:

$$\vec{E}(x,y,z)=\frac{KQ}{\left[(x-r_{Q_x})^2+(y-r_{Q_y})^2+(z-r_{Q_z})^2\right]^{3/2}}\begin{pmatrix}x-r_{Q_x}\\ y-r_{Q_y}\\ z-r_{Q_z}\end{pmatrix} \tag{10.3.3}$$

As we can see it, the field $\vec{E}$ has a singularity on $(r_{Q_x},r_{Q_y},r_{Q_z})$. Let us consider a Gauss surface such as the charge Q lies outside of this surface! Within the volume V delimited by the surface S the field $\vec{E}$ then has no singularities. So we can calculate the divergence (see section Vector Calculus page 1879) of $\vec{E}$:

$$\begin{aligned}\frac{\partial E_x}{\partial x}(x,y,z)&=\frac{KQ}{\left[(x-r_{Q_x})^2+(y-r_{Q_y})^2+(z-r_{Q_z})^2\right]^{3/2}}-\frac{3KQ(r-r_{Q_x})^2}{\left[(x-r_{Q_x})^2+(y-r_{Q_y})^2+(z-r_{Q_z})^2\right]^{5/2}}\\ \frac{\partial E_y}{\partial y}(x,y,z)&=\frac{KQ}{\left[(x-r_{Q_x})^2+(y-r_{Q_y})^2+(z-r_{Q_z})^2\right]^{3/2}}-\frac{3KQ(r-r_{Q_x})^2}{\left[(y-r_{Q_y})^2+(y-r_{Q_y})^2+(z-r_{Q_z})^2\right]^{5/2}}\\ \frac{\partial E_z}{\partial z}(x,y,z)&=\frac{KQ}{\left[(x-r_{Q_x})^2+(y-r_{Q_y})^2+(z-r_{Q_z})^2\right]^{3/2}}-\frac{3KQ(z-r_{Q_z})^2}{\left[(x-r_{Q_x})^2+(y-r_{Q_y})^2+(z-r_{Q_z})^2\right]^{5/2}}\end{aligned} \tag{10.3.4}$$

Therefore we get:

$$\text{div}(\vec{E})=\vec{\nabla}\circ\vec{E}=\frac{\partial E_x}{\partial x}+\frac{\partial E_y}{\partial y}+\frac{\partial E_z}{\partial z}=\frac{(3KQ-3KQ)\left[(x-r_{Q_x})^2+(y-r_{Q_y})^2+(z-r_{Q_z})^2\right]}{\left[(x-r_{Q_x})^2+(y-r_{Q_y})^2+(z-r_{Q_z})^2\right]^{5/2}} \tag{10.3.5}$$

So if we calculate the flow through this surface we find (see the section of Vector Calculus for a detailed description of the "nabla" operator represented by the symbol "del"):

$$\Phi_E=\iiint_V(\vec{\nabla}\circ\vec{E})\mathrm{d}V=0 \tag{10.3.6}$$

The flow is equal to zero!

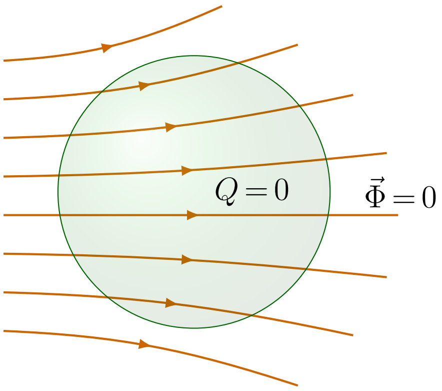
In the case where the charge Q is located inside the Gauss surface $\vec{\nabla}\circ\vec{E}$ is no longer defined on $(r_{Q_x},r_{Q_y},r_{Q_z})$ we have then:

$$\Phi_E=\iiint\limits_{V-B}(\vec{\nabla}\circ\vec{E})\mathrm{d}V+\Phi_B \tag{10.3.7}$$

With Φ_B being the flow $\vec{E}$ on a small ball B around the punctual charge Q.

In this case:

$$\Phi_E = \iiint\limits_{V-B} (\vec{\nabla} \circ \vec{E}) \mathrm{d}V = 0 \tag{10.3.8}$$



As the divergence is defined everywhere on $V-B$. So it remains:

$$\Phi_E = \Phi_B = \oiint_S \vec{E} \circ \mathrm{d}\vec{S} \tag{10.3.9}$$

But in the case of a sphere, it is quite easy to calculate:

$$\oiint_S \vec{E} \circ \mathrm{d}\vec{S} \tag{10.3.10}$$

We have:

$$\Phi_E = \oiint_S E \mathrm{d}S = E \oiint_S \mathrm{d}S = E \cdot S = 4\pi r^2 \left(\frac{1}{4\pi\varepsilon_0} \frac{Q}{r^2} \right) = \frac{Q}{\varepsilon_0} \tag{10.3.11}$$

hence the "first Maxwell equation" or "Gaussian law" (or "Gauss theorem") with a slightly condensed notation:

$$\boxed{\Phi_E = \oint_S \vec{E} \circ \mathrm{d}\vec{S} = \int\limits_V (\vec{\nabla} \circ \vec{E}) \mathrm{d}V = \frac{Q}{\varepsilon_0} \Leftrightarrow \vec{\nabla} \circ \vec{E} = \rho_Q \varepsilon_0^{-1}} \tag{10.3.12}$$

where ρ_Q is the charge density in Coulombs per m^3. On the left we have the integral form of the first Maxwell's (electro-magnetostatics) equation and its differential form on the right.

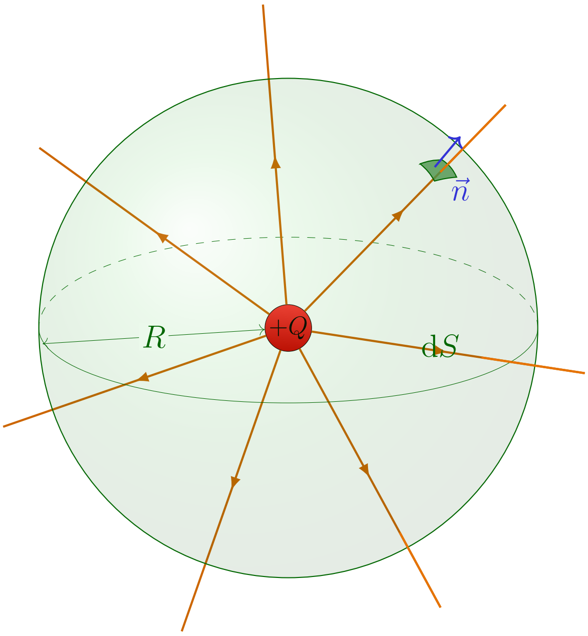


Figure 10.62: **Gauss law (author: Izaak Neutelings)**

This result suggests that the flow of the electric field through a closed surface (hence the circle on the integral) is equal to a given dimensional factor, to the total charge enclosed in the latter surface. Or in other words, the electrostatic field outside a charged sphere is identical to that of a point charge located at the spheres center.

Hence, the reader must keep in mind that the inverse square law applies to point sources. In Classical Electrodynamics there are not point sources (so quantum stuff is not the subject here!), so strictly speaking it never applies. In nature we have extended sources. If we are far away from the source, then it looks like a point source, so the inverse square law is a good approximation. Close to the source, the inverse square law doesn't apply unless the source happens to be perfectly spherical. Even in that case the law breaks down once we cross the surface and are inside the source.

Remark

The integral of the last relation is a line integral (thus evaluated on a curve)! In the field electrodynamics, line integrals apply very often on paths or closed surfaces hence the indication of a circle superimposed on the integral symbol and being named "circulation of the vector field".

If we now express this equation in terms of the electrical potential for which we have proved in the section Electrostatics that:

$$\vec{E}=-\vec{\nabla}\cdot U=-\overrightarrow{\text{grad}}(U) \tag{10.3.13}$$

We get:

$$\vec{\nabla}\circ(\vec{\nabla}\cdot U)=-\frac{\rho_Q}{\varepsilon_0} \tag{10.3.14}$$

We can write the above relation more aesthetically using the scalar Laplacian (see section Vector

Calculus page 1899) such that we get the relation:

$$\boxed{\Delta\cdot\varphi=-\frac{\rho_Q}{\varepsilon_0}} \tag{10.3.15}$$

named "Maxwell-Poisson equation".

10.3.1.2 Second Maxwell Equation (non-existence of magnetic monopole)

In the particular case of a magnetic field, we also get some very interesting results.

Indeed, given a current I located relatively by a reference frame by the vector $\vec{r}_I$. Then at each point $\vec{r}$ in space, we proved in the section Magnetostatics that there is a field $\vec{B}$ given by the Biot-Savart law (see page 4023) such that:

$$\vec{B}(\vec{r})=\underbrace{\frac{\mu_0}{4\pi}}_{=K}\frac{I\cdot\vec{l}\times(\vec{r}-\vec{r}_I)}{\|\vec{r}-\vec{r}_I\|^3} \tag{10.3.16}$$

Therefore:

$$\vec{B}(x,y,z)=\frac{KI}{[(x-r_{I_x})^2+(y-r_{I_y})^2+(z-r_{I_z})^2]^{3/2}}\begin{pmatrix}l_y(z-r_{I_z})-l_z(y-r_{I_y})\\ l_z(x-r_{I_x})-l_x(z-r_{I_z})\\ l_x(y-r_{I_y})-l_y(x-r_{I_x})\end{pmatrix} \tag{10.3.17}$$

As we can see it, the field $\vec{B}$ has a singularity on $(r_{I_x},r_{I_y},r_{I_z})$. Let us consider then a Gaussian surface such that the current I is outside this surface!

Within the volume V delimited by the surface S then field $\vec{B}$ has no singularities anymore. We can therefore calculate the divergence (see section Vector Calculus page 1879) of $\vec{B}$:

$$\begin{aligned}\frac{\partial B_x}{\partial x}(x,y,z)&=-\frac{3KI(x-r_{I_x})\left(l_y(z-r_{I_z})-l_z(y-r_{I_y})\right)}{[(x-r_{I_x})^2+(y-r_{I_y})^2+(z-r_{I_z})^2]^{3/2}}\\ \frac{\partial B_y}{\partial y}(x,y,z)&=-\frac{3KI(y-r_{I_y})\left(l_z(x-r_{I_x})-l_x(z-r_{I_z})\right)}{[(x-r_{I_x})^2+(y-r_{I_y})^2+(z-r_{I_z})^2]^{3/2}}\\ \frac{\partial B_z}{\partial z}(x,y,z)&=-\frac{3KI(z-r_{I_z})\left(l_x(y-r_{I_y})-l_y(x-r_{I_x})\right)}{[(x-r_{I_x})^2+(y-r_{I_y})^2+(z-r_{I_z})^2]^{3/2}}\end{aligned} \tag{10.3.18}$$

Therefore:

$$\mathrm{div}(\vec{B})=\vec{\nabla}\circ\vec{B}=\frac{\partial B_x}{\partial x}+\frac{\partial B_y}{\partial y}+\frac{\partial B_z}{\partial z}=0 \tag{10.3.19}$$

If we calculate the flow through this surface, we then find for the magnetic flux:

$$\Phi_B=\iiint_V(\vec{\nabla}\circ\vec{B})\mathrm{d}V=0 \tag{10.3.20}$$

The flow is equal to zero!

In the case where the current I is located within the Gauss surface, $\vec{\nabla}\circ\vec{B}$ is no longer defined in $(r_{I_x}, r_{I_y}, r_{I_z})$ we have then:

$$\Phi_B=\iiint\limits_{V-B'}(\vec{\nabla}\circ\vec{B})\mathrm{d}V+\Phi_{B'} \tag{10.3.21}$$

with $\Phi_{B'}$ being the flow of $\vec{B}$ on a small sphere B' surrounding partially the straight conductor carrying the current I. In this case:

$$\Phi_B=\iiint\limits_{V-B'}(\vec{\nabla}\circ\vec{B})\mathrm{d}V=0 \tag{10.3.22}$$

as the divergence is defined everywhere on $V-B'$. Therefore it remains only that:

$$\Phi_B=\Phi'_B=\oiint_S\vec{B}\circ\mathrm{d}\vec{S} \tag{10.3.23}$$

But in the case of a sphere, it is easy to calculate:

$$\oiint_S\vec{B}\circ\mathrm{d}\vec{S} \tag{10.3.24}$$

We then have the Gauss's law for the magnetic field:

$$\Phi_B=\oiint_S\vec{B}\circ\mathrm{d}\vec{S}=\oiint_S B\cdot\mathrm{d}S\cos(\phi)=0 \tag{10.3.25}$$

Indeed, in the case of the magnetic field, $\mathrm{d}\vec{S}$ and $\vec{B}$ are therefore perpendicular:

$$\varphi=\frac{\pi}{2}\Rightarrow\cos(\varphi)=0 \tag{10.3.26}$$

Remark

From which we can deduce that $\vec{B}\perp\vec{E}$!

Therefore, given a Gaussian surface in a magnetic field, then the magnetic flux through this surface is equal to:

$$\boxed{\Phi_B=\oiint_S\vec{B}\circ\mathrm{d}\vec{S}=\oiint_V(\vec{\nabla}\circ\vec{B})\mathrm{d}V=0\Leftrightarrow\vec{\nabla}\circ\vec{B}=0} \tag{10.3.27}$$

relation which is the "second Maxwell equation" or "Gauss law for magnetism" (also sometimes named "Gauss theorem for magnetism"). On the left we have the integral form of the fourth Maxwell's equation and its differential form on the right.

This second equation ($\vec{\nabla}\circ\vec{B}=0$) is equivalent to say that there is no "magnetic monopole" in nature, that is to say, at any positive pole, we have to find a negative one (from a magnet the field lines do not diverge). However, the second equation just add the idea (demonstrated by Dirac) that if it was possible to find a monopole in the Nature, it would be the point source of the magnetic field. We will see this a little further in detail below.

10.3.1.3 Third Maxwell Equation

We shall see in the section of Electrokinetics (because we need some concepts that we have not study yet), that the variation of the magnetic flux in time through a conductive loop induces a voltage in the loop given by the "Faraday's law" or "Lenz-Faraday's law":

$$\boxed{U(t)=-\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}} \tag{10.3.28}$$

and we have already proved in the section of Electrostatics that:

$$\Delta U=-\int \vec{E}\circ\mathrm{d}\vec{r}=-\int E\mathrm{d}r \tag{10.3.29}$$

where the last equality is valid only in the special case where the path is collinear to the electric field.

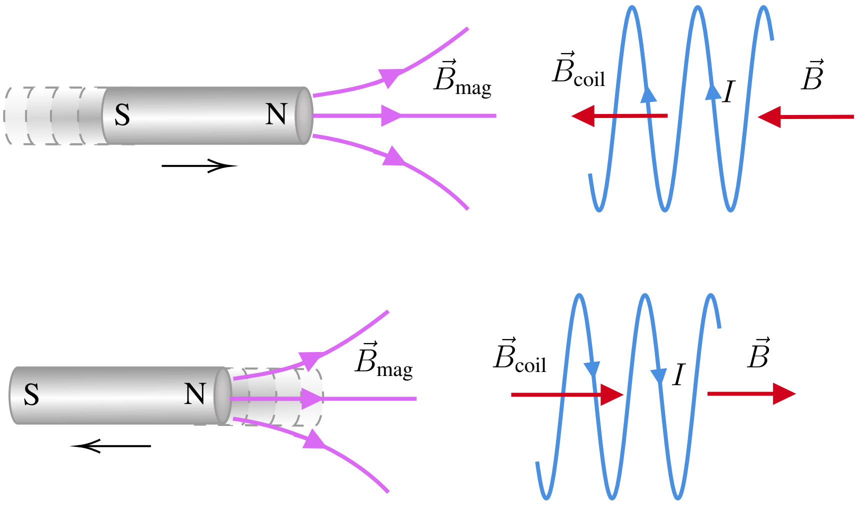

Figure 10.63: Lorenz law illustration

> **Remark**
>
> We will see in the section of Electrokinetics that it is not quite correct to denote the potential with U as above because in fact, Faraday's law expresses the electromotive force EMF (electromotive potential) denoted by e and this potential is not conservative unlike the electrostatic Coulomb potential (for which the integral over a closed path is zero as we have already proved it in the section of Electrostatics).

For an element $\mathrm{d}\vec{l}$ of a circuit Γ it comes:

$$U(t)=\int\limits_{\Gamma}\vec{E}\circ\mathrm{d}\vec{l} \tag{10.3.30}$$

the sign change is here justified by the Lenz law that said that the induced current (and magnetic flow associated with it) has such a direction that it opposes to the change in the flow through the circuit (see figure above).

If we develop this relation, using Stokes' theorem (see section Vector Calculus page 1889) which is for recall:

$$\oint_{\Gamma} \vec{f} \circ \mathrm{d}\vec{r} = \int_{S} (\vec{\nabla} \times \vec{f}) \circ \mathrm{d}\vec{S} \qquad (10.3.31)$$

Then we have:

$$U(t) = -\frac{\mathrm{d}\Phi_B}{\mathrm{d}t} = \oint_{\Gamma} \vec{E} \circ \mathrm{d}\vec{r} = \int_{S} (\vec{\nabla} \times \vec{E}) \circ \mathrm{d}\vec{S} \qquad (10.3.32)$$

Where, as we will see it in the section of Electrokinetics, the electric field above is not the simple Coulomb field but the sum of a Coulomb field and an electromotive field (implicitly generated by Biot-Savart force).

We then have:

$$-\frac{\mathrm{d}\Phi_B}{\mathrm{d}t} = -\frac{\mathrm{d}\displaystyle\int_{S} \vec{B} \circ \mathrm{d}\vec{S}}{\mathrm{d}t} = \int_{S} (\vec{\nabla} \times \vec{E}) \circ \mathrm{d}\vec{S} \qquad (10.3.33)$$

And if the surface element does not move in space and only the magnetic field varies with time, then we have:

$$-\frac{\mathrm{d}}{\mathrm{d}t} \int_{S} \vec{B} \circ \mathrm{d}\vec{S} = -\int_{S} \frac{\partial \vec{B}}{\partial t} \circ \mathrm{d}\vec{S} = \int_{S} (\vec{\nabla} \times \vec{E}) \circ \mathrm{d}\vec{S} \qquad (10.3.34)$$

Therefore:

$$\int_{S} \left(\vec{\nabla} \times \vec{E} + \frac{\partial B}{\partial t} \right) \circ \mathrm{d}\vec{S} = 0 \qquad (10.3.35)$$

A trivial solution is then to say that:

$$\vec{\nabla} \times \vec{E} + \frac{\partial B}{\partial t} = \vec{0} \qquad (10.3.36)$$

We then get finally:

$$\boxed{U(t) = -\frac{\mathrm{d}\Phi_B}{\mathrm{d}t} = \oint_{\Gamma} \vec{E} \circ \mathrm{d}\vec{l} \Leftrightarrow \vec{\nabla} \times \vec{E} = -\frac{\partial \vec{B}}{\partial t}} \qquad (10.3.37)$$

This is the "third Maxwell equation" or "Faraday-Maxwell law" sometimes still named "induction law". On the left we have therefore the integral form of the third Maxwell's equation and its differential form on the right.

The third equation therefore affirms that a variation of the magnetic field produces an electric field in a conductor loop. We then say that the term with the partial derivative of the magnetic field is the "magnetic coupling term". This equation is based on the Faraday's theory.

Remark

Often in the scientific literature, the potential $U(t)$ is simply denoted by a tiny u.

Faraday's law of induction is typically used by small portable devices such as below PEG (Personal Energy Generator) to charge portable electronic devices:

Figure 10.64: **Photo of a PEG (right) with a mobile phone (left)**

10.3.1.3.1 Betatron

Among the many examples of application of the third law that we will see in other sections of this textbook, there is one that is particularly nice because it is reminiscent of modern physics on a large scale (even if in reality we are very far).

Thanks to the Maxwell equations and the relations proved in the section Magnetostatics, we can make a small non-exhaustive theoretical study of the physical principle underlying one of the oldest non-linear particles accelerator.

One of the first non-linear methods that comes to mind is to accelerate a charged particle through magnetic induction. This type of accelerator is named a "betatron" (the idea is that it accelerates the electrons as fast as the one that appears in the beta decay...) and was conceptualized in the 11930s (holocene calendar).

The betatron is a particle accelerator that injects electrons into a vacuum torus (in white on the photo below) submitted to a magnetic field that will be considered here as homogeneous between the two magnets (in red in the photo below) to obtain intense X-rays or gamma rays useful in certain professional applications (medicine, analysis of structures, etc.). This accelerator is limited by the magnetic field that it can produce or support.

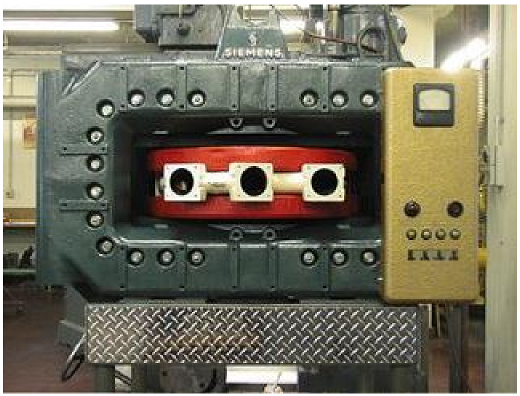

Figure 10.65: **Photo of a Betatron**

For this theoretical study, we will first use the result proved in the section Magnetostatics when we study the Larmor radius: an electron moving in a magnetic field will have a circular path which is perpendicular to the magnetic field.

Then we will also need the third Maxwell equation in the integral form:

$$U(t) = -\frac{\mathrm{d}\Phi_B}{\mathrm{d}t} = \int_\Gamma \vec{E} \circ \mathrm{d}\vec{l} \Leftrightarrow \vec{\nabla} \times \vec{E} = -\frac{\partial \vec{B}}{\partial t} \tag{10.3.38}$$

which - for recall - said that a change in the magnetic field produces an electric field in a conductor loop (or in a charged particle movement that can be assimilated to a conductor loop!!!!).

We have:

$$\int_\Gamma \vec{E} \circ \mathrm{d}\vec{L} = -\frac{\mathrm{d}\Phi_B}{\mathrm{d}t} = -\frac{\mathrm{d}}{\mathrm{d}t}\left(\oiint_S \vec{B} \circ \mathrm{d}\vec{S}\right) \tag{10.3.39}$$

and as the path is circular in the betatron as we have proved in our study of the Larmor radius in the section Magnetostatics, we have:

$$\int_\Gamma \vec{E} \circ \mathrm{d}\vec{l} = \int_\Gamma \|\vec{E}\| \cos(\alpha) \mathrm{d}l \tag{10.3.40}$$

Now, as the electric field is tangential to the circular path of the electrons and that they go in the opposite direction of that field (direction that is constant at any point of the path), we have since electrons travel in circles:

$$\int_\Gamma \vec{E} \circ \mathrm{d}\vec{l} = \int_\Gamma \|\vec{E}\| \cos(\alpha) \mathrm{d}l = \|\vec{E}\| \int_\Gamma \cos(\pi) \mathrm{d}l = -\|\vec{E}\| \int_\Gamma \mathrm{d}l = -2\pi R_L \|\vec{E}\| \tag{10.3.41}$$

But we also have:

$$-\frac{\mathrm{d}}{\mathrm{d}t}\left(\oiint_S \vec{B} \circ \mathrm{d}\vec{S}\right) = -\pi R_L^2 \frac{\mathrm{d}}{\mathrm{d}t}\|\vec{B}\| \tag{10.3.42}$$

Then it comes:

$$-2\pi R_L \|\vec{E}\| = -\pi R_L^2 \frac{\mathrm{d}}{\mathrm{d}t}\|\vec{B}\| \tag{10.3.43}$$

therefore:

$$\|\vec{E}\|=\frac{R_L}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|\vec{B}\| \tag{10.3.44}$$

We would like to calculate the kinetic energy that the negatively charged particle acquires after several rounds. This latter is equal to the work done by the electric field to move the load on the circular path (remember that the magnetic field don't do "work"!!!).

As we have proved in the section of Electrostatics, we have along an electric (constant) field line:

$$\Delta W=qE\Delta x \tag{10.3.45}$$

Therefore it comes as the charge travels N times the circumference of the betatron:

$$\Delta E_c=\Delta W=qE\Delta x=N2\pi R_L q\|\vec{E}\|=N2\pi R_L q\frac{R_L}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|\vec{B}\|=\pi NqR_L^2\frac{\mathrm{d}}{\mathrm{d}t}\|\vec{B}\| \tag{10.3.46}$$

✍**Example:**

Let us consider a sinusoidal magnetic field of magnitude $B_0=1\,[\text{T}]$ at a frequency of $f=50$ [Hz], therefore a period T of 20 [ms]. This means that in 5 [ms] the magnetic field passes from a maximum to a zero value.

Let us also consider that we have a betatron with a circular path of 1 [m] and the electron can remain approximately $480,000$ rounds on this circular trajectory with this specific radius without deviating too much (the equivalent of about $3,000$ [km] travelled). The electron is injected with an energy of 2 [MeV] in the vacuum torus (energy that is already very close to that of the speed of light!).

Let us first calculate the initial radius for the trajectory according to the relativistic Larmor radius. For this, first we need the speed corresponding to the energy of 2 [MeV]:

$$E_c=mc^2-m_0c^2=(\gamma-1)m_0c^2=\left(\frac{1}{\sqrt{1-\dfrac{v_0^2}{c^2}}}\right)m_0c^2 \tag{10.3.47}$$

After some elementary algebraic operations, we find:

$$v_0=299,407,509\cong 99.87\%\cdot c \tag{10.3.48}$$

Therefore the initial Larmor radius is equal to:

$$R_L=\frac{\gamma m_0v_0}{qB_0}=0.007\,[\text{m}] \tag{10.3.49}$$

We then for during all the time of the acceleration that will take the electron to a Larmor radius of 1 [m] a kinetic energy gain of:

$$\Delta E_c=\pi NqR_L^2\frac{\Delta\|\vec{B}\|}{\Delta t}\cong\pi 480,000\cdot 1.6\cdot 10^{-19}\cdot 1^2\cdot\frac{(1-0)}{(0.005-0)}=4.82548632\cdot 10^{-11}\,[\text{J}] \tag{10.3.50}$$

Which corresponds in electron volts to:

$$\Delta E_c \cong \frac{4.82548632 \cdot 10^{-11}}{1.6 \cdot 10^{-19}} \cong 300\,[\text{MeV}] \tag{10.3.51}$$

Hence the energy that was measured experimentally at that time. This energy also corresponds to a speed which is very close to that of light. Thus, with the same calculation as above, we get:

$$v_0 = 299,407,509 \cong 99.87\% \cdot c \tag{10.3.52}$$

speed reached only in a hundredths of a second!

Remark

Therefore in reality, the centrifugal (fictional) force increases gradually as the electron acquires kinetic energy (and therefore the speed). This force must be compensated by increasing the Lorentz force accordingly.

10.3.1.4 Fourth Maxwell Equation

The fourth Maxwell equation is in our point of view the most important one. It is a generalization of the Ampère's law which has already been presented in the section Magnetostatics and for which we got the circulation C_B of the magnetic field:

$$C_B = \int_{\Gamma} \vec{B} \circ \mathrm{d}\vec{l} = \mu_0 I \tag{10.3.53}$$

Remember that the third Maxwell's equation tells us that the variation of a magnetic field gives generated to an electric field. We can therefore assume that the converse may be probably true (need experimentation to be checked!).

A typical place where we can observe a variation of an electric field, for example, is the capacitor (see section Electrokinetics page 3997).

We know that:

$$I = \frac{\mathrm{d}Q}{\mathrm{d}t} \tag{10.3.54}$$

and that the electric field between two parallel planes, of surface S, bearing electric charges $Q_+ = -Q_-$, uniformly distributed is given by (see section Electrostatics page 3997):

$$E(x) = \frac{\sigma}{\varepsilon_0} = \frac{Q}{\varepsilon_0 S} \tag{10.3.55}$$

where σ is the surfacic density.

This result is independent of the distance l between the planes. The first Maxwell equation gives us:

$$\Delta U = -\int\limits_0^l E(x)\mathrm{d}x = -\frac{Q}{\varepsilon S}l \Rightarrow = |\Delta U| = \frac{Ql}{\varepsilon_0 S} \tag{10.3.56}$$

The capacity of a condensator is defined by (see section Electrostatics page 3997):

$$C = \frac{Q}{U} \tag{10.3.57}$$

we obtained in the particular case of plane and parallel capacitor that the capacity was equal to:

$$C = \frac{\varepsilon_0 S}{l} \tag{10.3.58}$$

Therefore it comes:

$$I = \frac{\mathrm{d}Q}{\mathrm{d}t} = \frac{\mathrm{d}Cu}{\mathrm{d}t} = C\frac{\mathrm{d}u}{\mathrm{d}t} \tag{10.3.59}$$

and using the fact that the electrostatic potential is the electric field multiplied by a distance that will be taken in this case as the distance D between the two planes of the capacitor, we have:

$$I = C\frac{\mathrm{d}(l\cdot E)}{\mathrm{d}t} = C\cdot E\frac{\mathrm{d}E}{\mathrm{d}t} = \varepsilon_0 S\frac{\mathrm{d}E}{\mathrm{d}t} \tag{10.3.60}$$

As the electric field may change with time, it is often customary to put a tiny i for the electric current variable (this is a tradition that we will see again the section Electrokinetics) and as between the two capacitor planes there only vacuum, then we speak of "displacement current", which is why the latter relation is often denoted as follows:

$$I_D = i_D = \varepsilon_0 S\frac{\mathrm{d}E}{\mathrm{d}t} \tag{10.3.61}$$

By expressing the above expression by using the surface current density, we get:

$$\vec{j}_D = \varepsilon_0\frac{\mathrm{d}\vec{E}}{\mathrm{d}t} \tag{10.3.62}$$

If the electric field is not uniform in space and thus depends on the spatial coordinates, we'll use the partial derivatives such as:

$$\vec{j}_D = \varepsilon_0\frac{\partial\vec{E}}{\partial t} \tag{10.3.63}$$

The displacement current generates a magnetic field calculable using Ampère's law:

$$C_B = \oint\limits_\Gamma \vec{B}\circ\mathrm{d}\vec{l} = \mu_0 I_D = \mu\iint\limits_\Sigma \vec{j}_D\circ\mathrm{d}\vec{S} = \mu_0\varepsilon_0\iint\limits_\Sigma \frac{\mathrm{d}\vec{E}}{\mathrm{d}t}\circ\mathrm{d}\vec{S} = \mu_0\varepsilon_0\frac{\mathrm{d}}{\mathrm{d}t}\iint\limits_\Sigma \vec{E}\circ\mathrm{d}\vec{S} \tag{10.3.64}$$

In all phenomena where we observe a charge displacement, we can assume that there is creation of a displacement current which is superimposed on the current flow because of capacitive effects in the material. We write therefore:

$$C_B = \oint\limits_\Gamma \vec{B}\circ\mathrm{d}\vec{l} = \mu_0 I_{\text{tot}} = \mu_0(I+I_D) = \mu_0\iint_\Sigma \vec{j}\circ\mathrm{d}\vec{S} + \mu_0\varepsilon_0\frac{\mathrm{d}}{\mathrm{d}t}\iint\limits_\Sigma \vec{E}\circ\mathrm{d}\vec{S} \tag{10.3.65}$$

where we have (recall of the section of Electrostatic and Magnetostatics):

$$\varepsilon=\varepsilon_0\varepsilon \qquad \text{and} \qquad \mu=\mu_0\mu_r \tag{10.3.66}$$

Furthermore, the Stokes theorem provides us that:

$$\int\limits_{\Gamma}\vec{H}\circ\mathrm{d}\vec{l}=\iint_{\Sigma}(\vec{\nabla}\times\vec{H})\circ\mathrm{d}\vec{S} \tag{10.3.67}$$

therefore:

$$\iint\limits_{\Sigma}\left(\vec{j}+\varepsilon\frac{\mathrm{d}\vec{E}}{\mathrm{d}t}\right)\circ\mathrm{d}\vec{S}=\iint_{\Sigma}(\vec{\nabla}\times\vec{H})\circ\mathrm{d}\vec{S} \tag{10.3.68}$$

and we get from this finally:

$$\boxed{\oint\limits_{\Gamma}\vec{B}\circ\mathrm{d}\vec{l}=\mu\iint\limits_{\Sigma}\vec{j}\circ\mathrm{d}\vec{S}+\mu\varepsilon\frac{\mathrm{d}}{\mathrm{d}t}\iint\limits_{\Sigma}\vec{E}\circ\mathrm{d}\vec{S}\Leftrightarrow\vec{\nabla}\times\vec{H}=\vec{j}+\varepsilon\frac{\partial\vec{E}}{\partial t}} \tag{10.3.69}$$

This is the "fourth Maxwell equation" or "Maxwell-Ampère equation". On the left we have the integral form of the fourth Maxwell's equation and its differential form on the right.

The fourth and last Maxwell equation combines the creation of a magnetic field to any variation of an electric field and / or the presence of an electric current (the presence of an electric current being a sufficient condition but not necessary in view of the second term). We then say that the term with the partial derivative of the electric field is the "term of electrical coupling".

To summarize a bit we have therefore the following four Maxwell equations in time domain[2] named "local forms of Maxwell's equations" in differential form (when the integrals are not indicated):

$$\boxed{\begin{array}{ll}\vec{\nabla}\circ\vec{E}=\dfrac{\rho_Q}{\varepsilon} & \vec{\nabla}\circ\vec{B}=0\\ \vec{\nabla}\times\vec{E}=-\dfrac{\partial\vec{B}}{\partial t} & \vec{\nabla}\times\vec{B}=\mu\vec{j}+\mu\varepsilon\dfrac{\partial\vec{E}}{\partial t}\end{array}} \tag{10.3.70}$$

In the case where $\mu_r,\varepsilon_r\neq 1$, that is to say if we do not work in vacuum but in the matter, we write the local Maxwell equations in the following form:

$$\boxed{\begin{array}{ll}\vec{\nabla}\circ\vec{D}=\rho_Q & \vec{\nabla}\circ\vec{B}=0\\ \vec{\nabla}\times\vec{E}=-\dfrac{\partial\vec{B}}{\partial t} & \vec{\nabla}\times\vec{H}=\vec{j}+\dfrac{\partial\vec{D}}{\partial t}\\ \vec{D}=\varepsilon\vec{E}=\varepsilon_0(1+\chi)\vec{E}=\varepsilon_0\varepsilon_r\vec{E} & \vec{B}=\mu\vec{H}=\mu_0(1+\chi_m)\vec{B}=\mu_0\mu_r\vec{B}\end{array}} \tag{10.3.71}$$

where $\vec{D}$ is (for recall) named the "displacement field" (also named "electric induction" or "electric flux density") and (for recall) $\vec{H}$ is the "magnetic excitation". We also have χ that is the "electric susceptibility" and χ_m the "magnetic susceptibility". Traditionally ε_r is named the "relative permittivity" and χ_r the "relative permeability".

---

[2] In some domains (like plasma physics) it is more useful to express the four equations in the "frequency domain" by taking the Fourier transform of both sides of each equality.

We often found the following notation:

$$\vec{D}=\varepsilon\vec{E}=\varepsilon_0(1+\chi)\vec{E}=\varepsilon_0\vec{E}+\varepsilon_0\chi\vec{E}=\varepsilon_0\vec{E}+\vec{P} \tag{10.3.72}$$

where $\vec{P}$ is named the "polarization density".

Caution!! $\vec{E}$ is a reaction of the vacuum to the field $\vec{D}$. This is due to the permittivity vacuum constant set in the integral (at least that's one way of seeing the thing...).

But in the vacuum and in the case where we consider an absence of charges, we get:

$$\boxed{\begin{array}{ll} \vec{\nabla}\circ\vec{E}=0 & \vec{\nabla}\circ\vec{B}=0 \\ \vec{\nabla}\times\vec{E}=-\dfrac{\partial\vec{B}}{\partial t} & \vec{\nabla}\times\vec{B}=\mu\varepsilon\dfrac{\partial\vec{E}}{\partial t} \end{array}} \tag{10.3.73}$$

This result is important because it expresses the possibility of the propagation of the electric and magnetic field even in the absence of sources!!! We will use these equations to determine the electromagnetic wave equations further below.

Remark

It is possible to express the Maxwell equations under relativistic form... but in reality, as we have already noticed, the equations are unchanged! Indeed, Maxwell's equations are already relativists. This is not surprising, because the vectors of electric and magnetic fields, the photons, travel at the speed of light. At this speed, relativity is the Queen and a correct theory could only be relativistic. However, we can express the latter equations using tensor mathematical notations (see below our demonstration of the tensor of the electromagnetic field). In this form the four equations become incredibly simple and compact (only one extremely short equation). Formulated in this way, the electric and magnetic fields are written as a single field named of course the "electromagnetic field". It is a tensor field as we shall see later.

In integral form the four Maxwell equations are written:

$$\boxed{\begin{array}{ll} \Phi_E=\oint\limits_{\Sigma}\vec{E}\circ\mathrm{d}\vec{S}=\oint\limits_{V}(\vec{\nabla}\circ\vec{E})\mathrm{d}V & \Phi_B=\oiint\limits_{\Sigma}\vec{B}\circ\mathrm{d}\vec{S}=\oiint\limits_{V}(\vec{\nabla}\circ\vec{B})\mathrm{d}V \\ U(t)=-\dfrac{\mathrm{d}\Phi_B}{\mathrm{d}t}=\oint\limits_{\Gamma}\vec{E}\circ\mathrm{d}\vec{l} & \oint\limits_{\Gamma}\vec{B}\circ\mathrm{d}\vec{l}=\mu\iint\limits_{\Sigma}\vec{j}\circ\mathrm{d}\vec{S}+\mu\varepsilon\dfrac{\mathrm{d}}{\mathrm{d}t}\vec{E}\circ\mathrm{d}\vec{S} \end{array}} \tag{10.3.74}$$

For information Maxwell himself didn't like electrodynamics the way he conceived it because he couldn't come up with an underlying mechanical model. Back then, the standard of beauty was a mechanical clockwork universe, but in Maxwell's theory electromagnetic fields just are - they are not made of anything else, no gears or notches, no fluids or valves. Maxwell was unhappy about his own theory because he thought that only « *when a physical phenomenon can* *be completely described as a change in the configuration and motion of a material system, the dynamical explanation of that phenomenon is said to be complete».* Maxwell tried for many years to explain electric and magnetic fields by something that would fit the mechanistic worldview. Alas, in vain.

> Caution!!! There is no principle of physics yet (in the beginning in the 121st century according to holocene calendar) that says physicals laws or constants have to be the same everywhere and always. Indeed, the reader must remember that the "laws" of physics are **descriptive**, not **imperative** and therefore they are some observed regularity in what we can observe experimentally with sufficiently wide occurrence or relevance! Asking whether the laws can change is no more and no less than asking whether regularities which have been observed up till now might not be quite as universal as was thought. The answer to that is: YES! This could drive the reader a bit mad. Indeed, how can we possibly do Science if the rules keep changing? But if you are a professional active scientist, you have to face up to that possibility - and you have a responsibility to check out if there is evidence beyond reasonable doubt about it! We will repeat this warning multiple times in this textbook as its seems that this is something necessary!

10.3.1.5 Magnetic Monopoles

Notice that opting for the natural measurement system where $c=1$, then we have to Maxwell's equations in vacuum:

$$\begin{aligned}\vec{\nabla}\circ\vec{E}=0 \qquad \vec{\nabla}\times\vec{B}-\frac{\partial\vec{E}}{\partial t}=\vec{0}\\ \vec{\nabla}\circ\vec{B}=0 \qquad \vec{\nabla}\times\vec{E}+\frac{\partial\vec{B}}{\partial t}=\vec{0}\end{aligned} \tag{10.3.75}$$

since as we prove it further below, in vacuum:

$$\varepsilon_0\mu_0=\frac{1}{c^2} \tag{10.3.76}$$

Then the transformation:

$$\vec{B}\mapsto\vec{E} \qquad \vec{E}\mapsto-\vec{B} \tag{10.3.77}$$

brings the second pair of preceding equations the first one!!!! This symmetry of Maxwell's equations is named "duality" and that's a clue that suggests that the electric and magnetic fields are only the unified parts of a whole.

Moreover, if we introduce the following complex field:

$$\vec{\mathcal{E}}=\vec{E}+\mathrm{i}\vec{B} \tag{10.3.78}$$

the duality (taking the real part only), then is written:

$$\left.\begin{aligned}\vec{B}\mapsto\vec{E}\\ \vec{E}\mapsto-\vec{B}\end{aligned}\right\}\vec{\mathcal{E}}\mapsto-\mathrm{i}\vec{\mathcal{E}} \tag{10.3.79}$$

the pair of Maxwell's equations indicated above is then reduced to (we use the property of linearity of the cross product) only one pair of equations which we must not forget to take only the real part:

$$\boxed{\vec{\nabla}\circ\vec{\mathcal{E}}=0 \qquad \vec{\nabla}\times\mathcal{E}=\mathrm{i}\frac{\vec{\mathcal{E}}}{\partial t}} \tag{10.3.80}$$

However, this symmetry does not extend to the Maxwell equations with sources expressed in the natural system by:

$$\begin{aligned}\vec{\nabla}\circ\vec{E}&=\rho_Q \qquad & \vec{\nabla}\times\vec{B}-\frac{\partial\vec{E}}{\partial t}&=\vec{j}\\ \vec{\nabla}\circ\vec{B}&=0 \qquad & \vec{\nabla}\times\vec{E}+\frac{\partial\vec{B}}{\partial t}&=\vec{0}\end{aligned} \tag{10.3.81}$$

but half of the time it does not work (make the substitution of $\vec{\mathcal{E}}$ you will see that you always get one of the equations on the pair that is consistent and the other not!). The trick then is to separate the two densities in their respective imaginary and real part (as we can see, generalize any physics theory to complex numbers always bring us to very interesting stuff as for maths!!!):

$$\begin{aligned}\rho_Q&=\rho_e+\mathrm{i}\rho_m\\ \vec{j}&=\vec{j}_e+\mathrm{i}\vec{j}_m\end{aligned} \tag{10.3.82}$$

We then get (always without forgetting to take the real parts and not forgetting that we are in natural units):

$$\begin{aligned}\vec{\nabla}\circ\vec{E}&=\rho_Q \qquad & \vec{\nabla}\times\vec{B}-\frac{\partial\vec{E}}{\partial t}&=\vec{j}_e\\ \vec{\nabla}\circ\vec{B}&=\rho_m \qquad & \vec{\nabla}\times\vec{E}+\frac{\partial\vec{B}}{\partial t}&=\vec{j}_m\end{aligned} \tag{10.3.83}$$

then we simply have to put $\rho_m=\vec{j}_m=0$. These equations are certainly charming but their generalization brings nothing new because no magnetic charge expressed as:

$$\vec{\nabla}\circ\vec{B}=\rho_m \tag{10.3.84}$$

and named "magnetic monopole" was observed to this date. In an experimental context, we say then that $\rho_Q,\vec{j}$ are real such that we have well:

$$\rho_m=\vec{j}_m=0 \tag{10.3.85}$$

The previous system rewritten as following is named "symmetrized Dirac-Maxwell equations" (in natural units):;

$$\begin{aligned}\vec{\nabla}\circ\vec{E}&=\rho_Q \qquad & \vec{\nabla}\circ\vec{B}&=\rho_m\\ \vec{\nabla}\times\vec{E}&=-\frac{\partial\vec{B}}{\partial t}-\vec{j} \qquad & \vec{\nabla}\times\vec{B}&=\vec{j}_e+\frac{\partial\vec{E}}{\partial t}\end{aligned} \tag{10.3.86}$$

To see if we have the right to write the relations above, remember first that if we take the divergence of the curl of the electric field, we know that this operation (see section Vector Calculus page 1911) is always equal to zero regardless of the function considered:

$$\vec{\nabla}\circ(\vec{\nabla}\times\vec{f})=0 \tag{10.3.87}$$

Then we have the following result:

$$\vec{\nabla}\circ(\vec{\nabla}\times\vec{E})=\vec{\nabla}\circ\left(-\frac{\partial\vec{B}}{\partial t}-\vec{j}_m\right)=0 \tag{10.3.88}$$

Hence:

$$-\frac{\partial(\vec{\nabla}\circ\vec{B})}{\partial t}-\vec{\nabla}\circ\vec{j}_m=0 \tag{10.3.89}$$

Therefore:

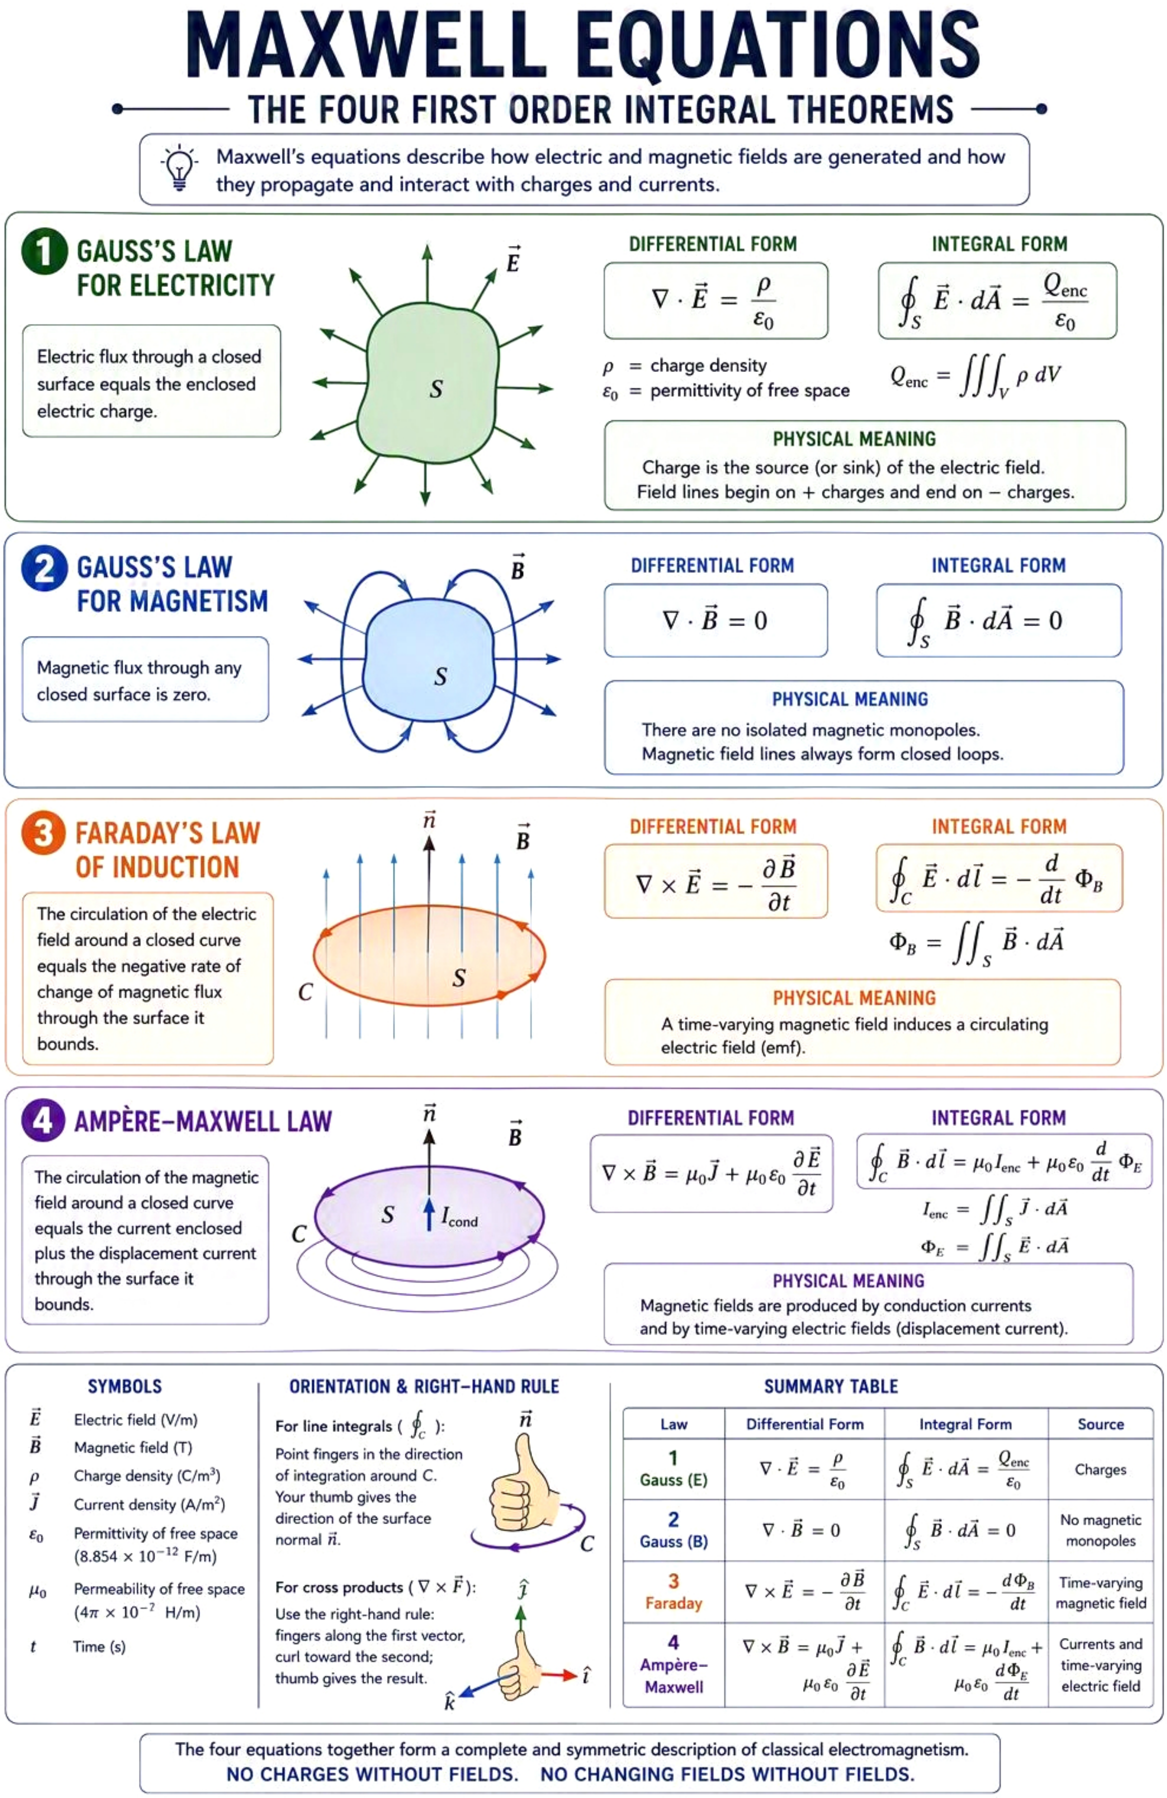
$$-\frac{\partial\rho_m}{\partial t}-\vec{\nabla}\circ\vec{j}_m=0 \tag{10.3.90}$$

Thus after rearrangement:

$$\vec{\nabla}\circ\vec{j}_m+\frac{\partial\rho_m}{\partial t}=0 \tag{10.3.91}$$

So is the fact of falling back on a continuity equation (identical in the form to the thermodynamics continuity equation, fluid mechanics continuity equation, electric field continuity equation or even that of the quantum probability continuity equation, etc.) that would have brought Dirac to complete the four Maxwell equations we have written just above.

Remember that current is the movement of charge. The continuity equation says that if charge is moving out of a differential volume (i.e. divergence of current density is positive) then the amount of charge within that volume is going to decrease, so the rate of change of charge density is negative. Therefore the continuity equation amounts to a conservation of charge.



MAXWELL EQUATIONS

THE FOUR FIRST ORDER INTEGRAL THEOREMS

Maxwell's equations describe how electric and magnetic fields are generated and how they propagate and interact with charges and currents.

1 GAUSS'S LAW FOR ELECTRICITY

Electric flux through a closed surface equals the enclosed electric charge.

DIFFERENTIAL FORM

$$\nabla \cdot \vec{E} = \frac{\rho}{\varepsilon_0}$$

ρ = charge density
ε_0 = permittivity of free space

INTEGRAL FORM

$$\oint_S \vec{E} \cdot d\vec{A} = \frac{Q_{\text{enc}}}{\varepsilon_0}$$

$$Q_{\text{enc}} = \iiint_V \rho \, dV$$

PHYSICAL MEANING

Charge is the source (or sink) of the electric field.
Field lines begin on + charges and end on − charges.

2 GAUSS'S LAW FOR MAGNETISM

Magnetic flux through any closed surface is zero.

DIFFERENTIAL FORM

$$\nabla \cdot \vec{B} = 0$$

INTEGRAL FORM

$$\oint_S \vec{B} \cdot d\vec{A} = 0$$

PHYSICAL MEANING

There are no isolated magnetic monopoles.
Magnetic field lines always form closed loops.

3 FARADAY'S LAW OF INDUCTION

The circulation of the electric field around a closed curve equals the negative rate of change of magnetic flux through the surface it bounds.

DIFFERENTIAL FORM

$$\nabla \times \vec{E} = -\frac{\partial \vec{B}}{\partial t}$$

INTEGRAL FORM

$$\oint_C \vec{E} \cdot d\vec{l} = -\frac{d}{dt}\Phi_B$$

$$\Phi_B = \iint_S \vec{B} \cdot d\vec{A}$$

PHYSICAL MEANING

A time-varying magnetic field induces a circulating electric field (emf).

4 AMPÈRE–MAXWELL LAW

The circulation of the magnetic field around a closed curve equals the current enclosed plus the displacement current through the surface it bounds.

DIFFERENTIAL FORM

$$\nabla \times \vec{B} = \mu_0 \vec{J} + \mu_0 \varepsilon_0 \frac{\partial \vec{E}}{\partial t}$$

INTEGRAL FORM

$$\oint_C \vec{B} \cdot d\vec{l} = \mu_0 I_{\text{enc}} + \mu_0 \varepsilon_0 \frac{d}{dt}\Phi_E$$

$$I_{\text{enc}} = \iint_S \vec{J} \cdot d\vec{A}$$

$$\Phi_E = \iint_S \vec{E} \cdot d\vec{A}$$

PHYSICAL MEANING

Magnetic fields are produced by conduction currents and by time-varying electric fields (displacement current).

SYMBOLS

$\vec{E}$	Electric field (V/m)
$\vec{B}$	Magnetic field (T)
ρ	Charge density (C/m^3)
$\vec{J}$	Current density (A/m^2)
ε_0	Permittivity of free space (8.854×10^{-12} F/m)
μ_0	Permeability of free space ($4\pi \times 10^{-7}$ H/m)
t	Time (s)

ORIENTATION & RIGHT–HAND RULE

For line integrals ($\oint_C$):

Point fingers in the direction of integration around C. Your thumb gives the direction of the surface normal $\vec{n}$.

For cross products ($\nabla \times \vec{F}$):

Use the right-hand rule: fingers along the first vector, curl toward the second; thumb gives the result.

SUMMARY TABLE

Law	Differential Form	Integral Form	Source
1 Gauss (E)	$\nabla \cdot \vec{E} = \frac{\rho}{\varepsilon_0}$	$\oint_S \vec{E} \cdot d\vec{A} = \frac{Q_{\text{enc}}}{\varepsilon_0}$	Charges
2 Gauss (B)	$\nabla \cdot \vec{B} = 0$	$\oint_S \vec{B} \cdot d\vec{A} = 0$	No magnetic monopoles
3 Faraday	$\nabla \times \vec{E} = -\frac{\partial \vec{B}}{\partial t}$	$\oint_C \vec{E} \cdot d\vec{l} = -\frac{d\Phi_B}{dt}$	Time-varying magnetic field
4 Ampère–Maxwell	$\nabla \times \vec{B} = \mu_0 \vec{J} + \mu_0 \varepsilon_0 \frac{\partial \vec{E}}{\partial t}$	$\oint_C \vec{B} \cdot d\vec{l} = \mu_0 I_{\text{enc}} + \mu_0 \varepsilon_0 \frac{d\Phi_E}{dt}$	Currents and time-varying electric field

The four equations together form a complete and symmetric description of classical electromagnetism.
NO CHARGES WITHOUT FIELDS. NO CHANGING FIELDS WITHOUT FIELDS.

10.3.2 Charge conservation equation

So we proved so far the four Maxwell's equations which are the foundations of classical electrodynamics.

The Maxwell's equations can be divided into two groups:

1. Equations without sources:

$$\vec{\nabla}\circ\vec{B}=0 \qquad \vec{\nabla}\times\vec{E}=-\frac{\partial\vec{B}}{\partial t} \tag{10.3.92}$$

2. Equations with sources[3] (in vacuum below):

$$\vec{\nabla}\circ\vec{E}=\frac{\rho_Q}{\varepsilon_0} \qquad \vec{\nabla}\times\vec{B}=\mu_0\vec{j}-\frac{1}{c^2}\frac{\partial\vec{E}}{\partial t} \tag{10.3.93}$$

Deriving the first equation with sources in respect to time:

$$\frac{\mathrm{d}(\vec{\nabla}\circ\vec{E})}{\mathrm{d}t}=\vec{\nabla}\circ\frac{\mathrm{d}\vec{E}}{\mathrm{d}t}=\frac{1}{\varepsilon_0}\frac{\mathrm{d}\rho_Q}{\mathrm{d}t} \tag{10.3.94}$$

by taking the divergence of the second we get:

$$\vec{\nabla}\circ(\vec{\nabla}\times\vec{B})=\mu_0\vec{\nabla}\circ\vec{j}+\frac{1}{c^2}\vec{\nabla}\circ\frac{\partial\vec{E}}{\partial t} \tag{10.3.95}$$

The divergence of a curl (rotational) is always zero as we have prove it in the section of Vector Calculus and therefore the last expression is zero. But since a reader asked us, we detail this result more explicitly simplifying a bit:

$$(\vec{\nabla}\circ\vec{\nabla})\times(\vec{\nabla}\circ\vec{B})=\mu_0\vec{\nabla}\circ\vec{j}+\frac{1}{c^2\varepsilon_0}\frac{\partial\rho_Q}{\partial_t} \tag{10.3.96}$$

but, $\vec{\nabla}\circ\vec{B}=0$ and therefore:

$$\mu_0\vec{\nabla}\circ\vec{j}+\frac{1}{c^2\varepsilon_0}\frac{\partial\rho_Q}{\partial t}=0 \tag{10.3.97}$$

After simplification and using natural units (see section Principia page 3124) we get:

$$\boxed{\vec{\nabla}\circ\vec{j}+\frac{\partial\rho_Q}{\partial t}=0} \tag{10.3.98}$$

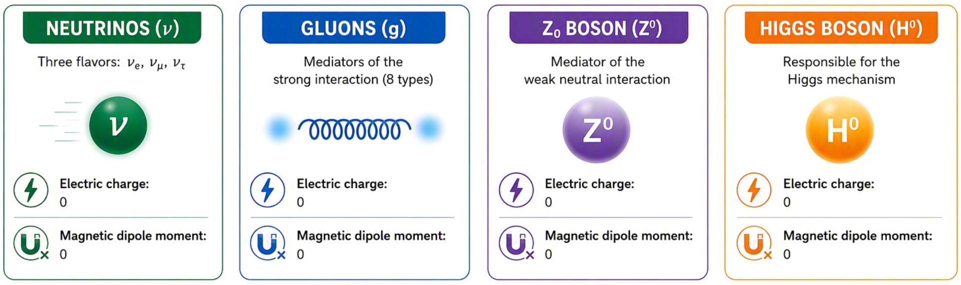
which is named the "charge conservation equation" or "equation of continuity" and said that in two near instants $t+\mathrm{d}t$, the variation $\mathrm{d}Q$ of the charge contained in a closed surface defining a system can only be exclusively attributed to a charge exchange with the outside.

This equation is very important because it involves in the study of relativity, the load is a translation invariant quantity.

---

[3] The fourth Maxwell equation as denoted here is sometimes named the "Oersted's law"

The reader has to know that not everything in the universe interacts with electric and magnetic fields. We have the neutrinos, the Z_0, the Higgs boson and the gluons that are electromagnetically inert particles:



NEUTRINOS (ν)
Three flavors: ν_e, ν_μ, ν_τ
ν
Electric charge: 0
Magnetic dipole moment: 0
GLUONS (g)
Mediators of the strong interaction (8 types)
Electric charge: 0
Magnetic dipole moment: 0
Z_0 BOSON (Z^0)
Mediator of the weak neutral interaction
Z^0
Electric charge: 0
Magnetic dipole moment: 0
HIGGS BOSON (H^0)
Responsible for the Higgs mechanism
H^0
Electric charge: 0
Magnetic dipole moment: 0

10.3.3 Gauge Theory

Before you start reading this subsection it is of primary importance for the reader to go for a ride in the Algebra chapter of this textbook, in which there is a section Vector Calculus where we prove some differential vector operators that are of first importance in physics and especially for gauge theory and where we also study their main properties.

What will follow is very important because besides the fact that we are going to naturally present a new vector field (the vector potential) which is essential in certain equations of relativistic quantum physics (see section of the same name page 4919) we will reuse this gauges approach in the section of Wave Quantum Physics where the consequences are much more important!

Given the known relation:

$$\vec{\nabla}\circ\vec{B}=0 \tag{10.3.99}$$

There exists by the properties of the divergence and curl (rotational) operators (see section Vector Calculus page 1866) a "vector potential $\vec{A}(\vec{r},t)$" such that:

$$\vec{B}=\vec{\nabla}\times\vec{A} \tag{10.3.100}$$

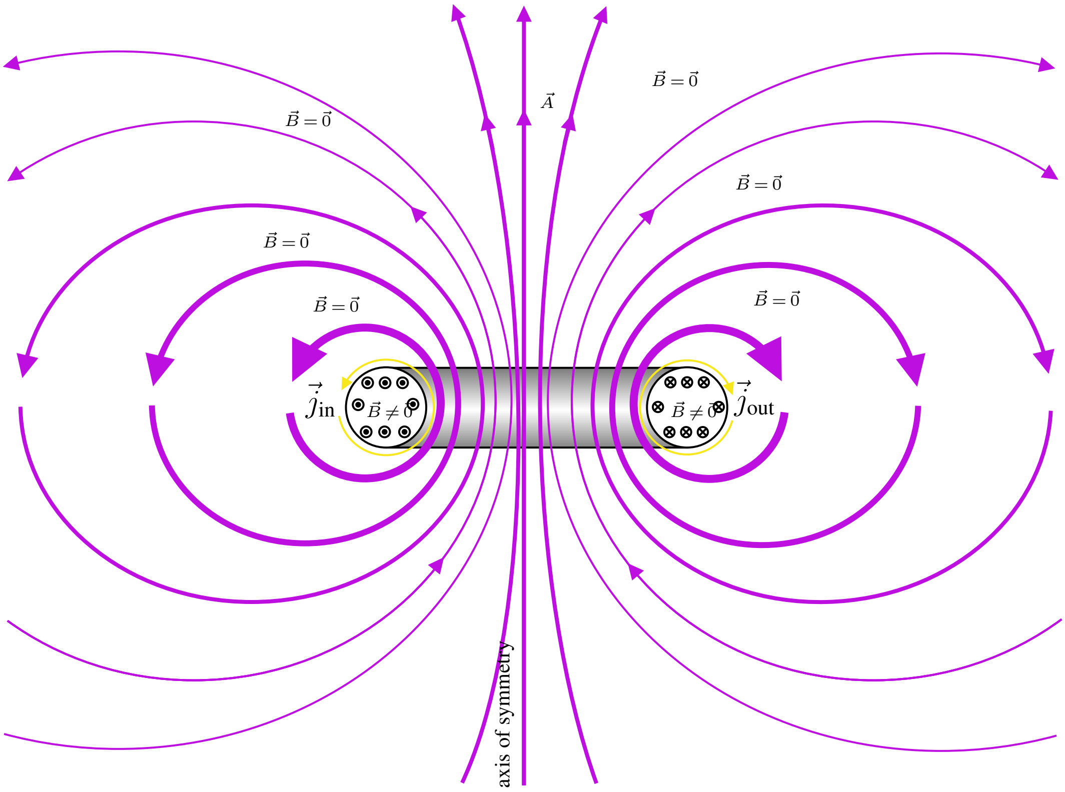
thus satisfying then (the divergence of the curl - rotational - of a vector field is always zero because it is a mathematical property proven in the section of Vector Calculus):

$$\vec{\nabla}\circ(\vec{\nabla}\times\vec{A})=0 \tag{10.3.101}$$

and in the context of magnetostatic named "magnetic potential".

Remark

The vector potential is therefore a potential... and a vector! Similarly as we have define a potential U which derivates from an electric field $\vec{E}$, we can thus define a potential $\vec{A}(\vec{r},t)$ for the field $\vec{B}$. But for technical reasons (coming from the expression of the curl - rotational - of $\vec{E}$ and of $\vec{B}$ in the Maxwell's equations), the potential vector $\vec{A}(\vec{r},t)$ is not that simple as U and can not be expressed as a simple scalar, we must use a vector potential.



$\vec{A}$
$\vec{B}=\vec{0}$
$\vec{B}=\vec{0}$
$\vec{B}=\vec{0}$
$\vec{B}=\vec{0}$
$\vec{B}=\vec{0}$
$\vec{B}=\vec{0}$
$\vec{j}_{\text{in}}$
$\vec{B}\neq\vec{0}$
$\vec{B}\neq\vec{0}$
$\vec{j}_{\text{out}}$
axis of symmetry

Figure 10.66: **Vector Magnetic Potential $\vec{A}$**

Thus, a depiction of the $\vec{A}$ field around a loop of $\vec{B}$ flow (as would be produced in a toroidal inductor) is qualitatively the same as the $\vec{B}$ field around a loop of current.

The reader will have notice that at the opposite of the electric potential they can be no magnetic field but still a magnetic potential.

If we take the relation $\vec{B}=\vec{\nabla}\times\vec{A}$ in the Maxwell equation $\vec{\nabla}\times\vec{E}=-\partial\vec{B}/\partial t$ we get:

$$\boxed{\vec{\nabla}\times\left(\vec{E}+\frac{\partial\vec{A}}{\partial t}\right)=\vec{0}} \tag{10.3.102}$$

We put now (the notation $\vec{F}$ has no relation with the Newtonian force!):

$$\boxed{\vec{\nabla}\times\left(\vec{E}+\frac{\partial\vec{A}}{\partial t}\right)=\vec{\nabla}\times\vec{F}=\vec{0}} \tag{10.3.103}$$

and we use the mathematical properties of the curl (rotational) and gradient operators to write a new relation (the "$-$" sign is an anticipation of what will follow):

$$\boxed{\vec{F}=-\vec{\nabla}\phi} \tag{10.3.104}$$

hence:

$$\boxed{\vec{E}=-\vec{\nabla}\phi-\frac{\partial\vec{A}}{\partial t}} \tag{10.3.105}$$

where $\phi(\vec{r},t)$ is a "scalar potential" that is well known to us as being the electric potential U.

Remarks

R1. The field $\vec{F}$ seems to obey the same properties as that of the gravitational field (Newton-Poisson law), but it seem to be only a curiosity (units and other mathematical properties are not equivalent).

R2. The reader probably easily see that if the vector potential is zero, then we fall back on (see section Electrostatic page 3977):

$$\vec{E}=-\vec{\nabla}\cdot\phi\equiv\vec{\nabla}\cdot\phi \tag{10.3.106}$$

which reinforces the assumptions of previous developments (and that's not ...)

In addition, the fields $\vec{E}$ and $\vec{B}$ remain unchanged if we do in the previous relations the following replacements (the terms cancel trivially):

$$\phi\rightarrow\phi'=\phi-\frac{\partial\psi}{\partial t}\qquad\vec{A}\rightarrow\vec{A}'=\vec{A}+\vec{\nabla}\psi \tag{10.3.107}$$

where ψ is an arbitrary function of $\vec{r}$ and t.

We name such a transformation a "gauge change". The freedom on the choice of potentials allow us to impose a constraint that we name "gauge constraint".

There are several ways of forming this constraint among which we distinguish two very common in physics!

Thus we will use either the "Lorentz gauge" by imposing:

$$\boxed{\vec{\nabla}\circ\vec{A}+\frac{1}{c^2}\frac{\partial\phi}{\partial t}=0} \tag{10.3.108}$$

or the "Coulomb gauge" by imposing:

$$\boxed{\vec{\nabla}\circ\vec{A}=0} \tag{10.3.109}$$

holds. Thus, ψ should satisfy:

$$\begin{gathered}\vec{\nabla}\circ\vec{A}'=\vec{\nabla}\circ\vec{A}+\vec{\nabla}\circ\vec{\nabla}\psi\Rightarrow\vec{\nabla}\circ\vec{A}'-\vec{\nabla}\circ\vec{\nabla}\psi=\vec{\nabla}\circ\vec{A}=0\\ \Rightarrow\vec{\nabla}\circ\vec{A}'=\vec{\nabla}\circ\vec{\nabla}\psi=\Delta\psi=f(\vec{r},t)\end{gathered} \tag{10.3.110}$$

The relation:

$$\boxed{\vec{\nabla}\circ\vec{A}'=\Delta\psi} \tag{10.3.111}$$

which is named "Poisson equation of the potential vector".

Similarly, to show that it is always possible to impose the Lorenz condition, we simply need to find ψ in the above equations:

$$\phi\rightarrow\phi'=\phi-\frac{\partial\psi}{\partial t}\qquad\vec{A}'\rightarrow\vec{A}+\vec{\nabla}\psi \tag{10.3.112}$$

such that the relation (Lorenz gauge):

$$\boxed{\vec{\nabla}\circ\vec{A}+\frac{1}{c^2}\frac{\partial\phi}{\partial t}=0} \tag{10.3.113}$$

is satisfied. Therefore, ψ must satisfy:

$$\begin{gathered}\vec{\nabla}\circ\vec{A}'+\frac{1}{c^2}\frac{\partial\phi'}{\partial t}=\vec{\nabla}\circ\vec{A}+\vec{\nabla}\circ\vec{\nabla}\psi+\frac{1}{c^2}\frac{\partial\phi}{\partial t}-\frac{1}{c^2}\frac{\partial^2\psi}{\partial t^2}=\vec{\nabla}\circ\vec{A}+\Delta\psi+\frac{1}{c^2}\frac{\partial\phi}{\partial t}-\frac{1}{c^2}\frac{\partial^2\psi}{\partial t^2}\\ \Rightarrow\vec{\nabla}\circ\vec{A}+\frac{1}{c^2}\frac{\partial\phi'}{\partial t}=\Delta\psi-\frac{1}{c^2}\frac{\partial^2\psi}{\partial t^2}\end{gathered} \tag{10.3.114}$$

Or in other words and in a more condensed manner:

$$\Box\psi=\frac{1}{c^2}\frac{\partial\phi'}{\partial t}+\vec{\nabla}\circ\vec{A}'=g(\vec{r},t) \tag{10.3.115}$$

where the operator:

$$\boxed{\Box=\frac{1}{c^2}\frac{\partial^2}{\partial t^2}-\Delta} \tag{10.3.116}$$

is by definition named the "Alembertian" (we will often encounter this term from now as well in the section of Electrodynamics and Wave Quantum Physics) that is also invariant under Lorentz transformation as we will prove it in the section of Special Relativity.

Reporting the equations:

$$\vec{B}=\vec{\nabla}\times\vec{A}\quad\text{and}\quad\vec{E}=-\vec{\nabla}\phi-\frac{\partial\vec{A}}{\partial t} \tag{10.3.117}$$

in the other two Maxwell equations in vacuum:

$$\vec{\nabla}\circ\vec{E}=\frac{\rho_Q}{\varepsilon_0}\quad\text{and}\quad\vec{\nabla}\times\vec{B}=\mu_0\vec{j}+\vec{1}c^2\frac{\partial\vec{B}}{\partial t} \tag{10.3.118}$$

we get, by making appear the Laplacian of a vector field $\Delta\vec{A}$ by on of the properties of the curl, gradient and divergence vector operators (see section Vector Calculus page 1911):

$$\vec{\nabla}\times(\vec{\nabla}\times\vec{A})=\vec{\nabla}(\vec{\nabla}\circ\vec{A})-\Delta\vec{A} \tag{10.3.119}$$

the following relations:

$$\boxed{\begin{gathered}-\Delta\phi=\frac{\rho_q}{\varepsilon_0}+\vec{\nabla}\circ\frac{\partial\vec{A}}{\partial t}\\ \Box\vec{A}=\mu_0\vec{j}-\vec{\nabla}\left(\vec{\nabla}\circ\vec{A}+\frac{1}{c^2}\frac{\partial\phi}{\partial t}\right)\end{gathered}} \tag{10.3.120}$$

the latter relation being named the "arbitrary gauge".

For the Lorenz gauge, these last two equation simplify to (feel free to contact us if you do not see how):

$$\boxed{\begin{aligned}-\Box\phi&=\frac{\rho_q}{\varepsilon_0}\\ \Box\vec{A}&=\mu_0\vec{j}\end{aligned}}\tag{10.3.121}$$

that we name "wave equations for electromagnetic potentials" in analogy with the wave equations of electric and magnetic fields that we will determine further below. For the Coulomb gauge, the same equations simplify to:

$$\boxed{\begin{aligned}-\Box\phi&=-\frac{\rho_q}{\varepsilon_0}\\ \Box\vec{A}&=\mu_0\vec{j}-\frac{1}{c^2}\vec{\nabla}\frac{\partial\phi}{\partial t}\end{aligned}}\tag{10.3.122}$$

knowing that $c^2=1/(\varepsilon_0\mu_0)$ we can write the two wave equations of electromagnetic potentials in the form:

$$\begin{aligned}-\Delta\phi&=\frac{\rho_q}{\varepsilon_0}=\mu_0c^2\rho_Q\\ \Box\vec{A}&=\mu_0\vec{j}\end{aligned}\tag{10.3.123}$$

Let us now put $A^0=\phi/c$ (to homogenize the units) such that we define a "four-vector potential" which allows us to write vectorially the two above relations in unified manner:

$$\boxed{\Box A^\alpha=(\phi/c,\mu_0\vec{j})=(m_0c\rho_Q,\mu_0\vec{j})=\mu_0(c\rho_Q,\vec{j})}\tag{10.3.124}$$

Remark

The fact that the Alembertian of the four-vector potential is expressed from the four-vector current which is contravariant (see section Special Relativity page 5646) bring us to put that the four-vector potential is itself contravariant!

Relation that we will we denote is a more condense form as follows:

$$\boxed{\Box A^\alpha=\mu_0j^\alpha}\tag{10.3.125}$$

where j^α is name "four-vector current".

Remark

We will see again this four-vector during our determination of the electromagnetic field tensor further below (except that we will be in natural units but this does not change the idea...).

The four-vector potential as defined above leads us to be able to write the (quadrivergence) Lorenz gauge by making use of tensor notation:

$$\begin{aligned}\vec{\nabla}\circ\vec{A}+\frac{1}{c^2}\frac{\partial\phi}{\partial t}&=\frac{1}{c^2}\frac{\partial}{\partial t}\phi+\partial_xA_x+\partial_yA_y+\partial_zA_z\\ &=\frac{1}{c}\frac{\partial}{\partial t}\frac{\phi}{c}+\partial_1A^1+\partial_2A^2+\partial_3A^3=\partial_0A^0+\partial_1A^1+\partial_2A^2+\partial_3A^3=0\end{aligned}\tag{10.3.126}$$

Which ultimately allows you to write the Lorenz gauge in the covariant form below:

$$\boxed{\partial_\alpha A^\alpha = 0} \tag{10.3.127}$$

It is therefore an equation of the form of the Klein-Gordon equation for a massless particle (see section Relativistic Quantum Physics page 4921). So we can say in a sense that the invariance of the electromagnetic gauge is connected to the fact that the mass of the photon is zero!

Remark

It is useful to notice that the fact that writing $\dfrac{1}{c}\dfrac{\partial}{\partial t} = \partial_0$ (with or without natural units where $c = 1$) is a notation that will also be adopted in our study of the Dirac equation (see section Relativistic Quantum Physics page 4938) or also in quantum field theory (except that there will be an imaginary part).

These notations finally lead us to be able to write:

$$\begin{aligned}\partial_\alpha(\Box A^\alpha) &= \partial_\alpha(\mu_0 j^\alpha)\\ \partial_\alpha A^\alpha &= \mu_0 \partial_\alpha j^\alpha = 0\end{aligned} \tag{10.3.128}$$

We obtain the continuity equation:

$$\boxed{\partial_\alpha j^\alpha = 0} \tag{10.3.129}$$

that is tensor equivalent form of the following relation (see prof earlier above):

$$\vec{\nabla} \circ \vec{j} + \frac{\partial \rho_Q}{\partial t} = 0 \tag{10.3.130}$$

To summarize roughly:

A given number of physical effects are modelized, depending on the case, by fields that can be scalar, vector, tensor, or spinor fields that we therefore name "gauges". A given number of physical phenomena seems to comply with conditions of say of "symmetry", vis-à-vis these gauges. This symmetry is expressed by what we therefore name a "gauge invariance".

For example, the field that modelize well the electromagnetic field is as we have seen it, a four-vectors field consisting of a scalar potential ϕ (whose gradient is the electric field $\vec{E}$) and a vector-potential $\vec{A}$ (whose curl is the magnetic field $\vec{B}$). It is this quadrivectoriel field that helps us to modelize the electromagnetic field that is named "gauge".

It turns out that we were getting exactly the same physical effects on a system of electric charged particles if we replace this gauge by another gauge by adding it a gauge constraint (typical example between the Lorenz gauge or Coulomb gauge as seen above). The invariance of the laws of physics when switching from a gauge to another is a "gauge invariance". In the case of the electromagnetic field, this gauge invariance turns expressing the electric charge conservation (as we have just proved it).

Mathematically, such gauges changes appear to be the result of the action of a symmetry group of infinite dimensions (transforming these into each other gauges) that we name the "gauge group" of the considered interaction (here the electromagnetic interaction).

For the gravitational field, for example (see section General Relativity page 5720), the gravitational interaction is modelled by a symmetric tensor field of rank 2 with a given signature. This metric field is distributed on a 4D variety modelling the space-time (for a naive and technical definition of "space-time" see the section of Special Relativity at page 5708). This is the gauge of the gravitational interaction. According to General Relativity (the equivalence principle) we do not change anything to the gravitational interaction if we change the system of space-time coordinates in which we express the metric. The portion of an expression of the metric to another by changing coordinate system is also a gauge change. The invariance of General Relativity gauge then expressed the possibility to change to a gauge to another without changing the geodesic followed by the testing particles falling freely in the gravitational field modelled by the metric field.

The invariance of General Relativity gauge is what we named "diffeomorphism invariance" (bijective change of coordinate system with some degree of regularity) and the General Relativity gauge group is the "diffeomorphisms group" of $\mathbb{R}^2$ (named the "soft group").

It should be noted also that the potential-vector $\vec{A}$ is perhaps not so virtual as it may seem. Indeed, it is possible to modify the trajectories of charged particles passing outside a cylindrical volume where there is a magnetic field $\vec{B}$ induced by an electric current (travelling in the winding of a solenoid where this field $\vec{B}$ is "trapped"). It is therefore possible to influence the particle trajectory circulating in an area where the magnetic field $\vec{B}$ is zero but where its vector potential equation is not!!!

Furthermore, we will use the results we just get here for our study of the Yang-Mills theory in our way to the electroweak unification (see the Standard Model in the section of Field Quantum Theory).

Remark

The well-known experiment that involves the vector potential is the Aharonov-Bohm experiment. The "Aharonov–Bohm effect", sometimes named the "Ehrenberg–Siday–Aharonov–Bohm effect", is a quantum mechanical phenomenon in which an electrically charged particle is affected by an electromagnetic potential $(U, \vec{A})$, despite being confined to a region in which both the magnetic field $\vec{B}$ and electric field $\vec{E}$ are zero. The underlying mechanism is the coupling of the electromagnetic potential with the complex phase of a charged particle's wave function, and the Aharonov–Bohm effect is accordingly illustrated by interference experiments.

10.3.3.1 Electromagnetic field tensor

In electromagnetism, the "electromagnetic tensor" or "electromagnetic field tensor" (sometimes named the "field strength tensor", "Faraday tensor" or "Maxwell bivector") is a mathematical object that describes the electromagnetic field in space-time of a physical system. The field tensor was first used after the 4-dimensional tensor formulation of special relativity was introduced by Hermann Minkowski. The tensor allows some physical laws to be written in a very concise form.

To determine the electromagnetic field tensor let us assume at first that the action (see section

Analytical Mechanics page 3161) of an electric charged particle in an electromagnetic field is given by (a priori empirical choice... but you'll see a little further):

$$\boxed{S_1=\int\left(q\vec{A}\circ\vec{v}-q\phi\right)\mathrm{d}t=\int L_1\mathrm{d}t}\tag{10.3.131}$$

Remark

The notation S_0 is reserved to the action of a free particle (see section Special Relativity page 5681).

The Lagrangian for an electric charged particle in an electromagnetic field is therefore the sum of the Lagrangian of the particle interacting with the electromagnetic field L_1 added to the Lagrangian of the free particle L_0 (see section Special Relativity page 5681):

$$\boxed{L=L_0+L_1=-m_0c^2\sqrt{1-\frac{v^2}{c^2}}+q\vec{A}\circ\vec{v}-q\phi}\tag{10.3.132}$$

Remark

This is therefore the Lagrangian of the interaction of the particle with the field added to the Lagrangian of the mass of the particle. Thus we see that it still missing the Lagrangian of the electromagnetic field itself in the case of absence of electric charges (named: "Lagrangian of the free field") but we will see it further below.

This is therefore (a priori) the Lagrangian of a charged particle in an electromagnetic field having for source a given quantity of electric charges in relative movement.

We will now prove that this Lagrangian is correct (the previous relation could be stated as a theorem)!

For this remember first that the general momentum is (see section Analytical Mechanics page 3180 and Special Relativity page 5681):

$$\vec{p}=\frac{\partial L}{\partial\vec{v}}=\frac{m_0\vec{v}}{\sqrt{1+\dfrac{v^2}{c^2}}}+q\vec{A}\tag{10.3.133}$$

To verify that we made the right choice of Lagrangian initially, we will obtain the equations of motion and ensure that they coincide with the Lorentz force. The Lagrange equations are in this case:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial\vec{v}}-\frac{\partial L}{\partial\vec{r}}=0&=\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{m_0\vec{v}}{\sqrt{1+\dfrac{v^2}{c^2}}}+q\vec{A}\right)-\frac{\partial}{\partial\vec{r}}\left(-m_0c\sqrt{1-\frac{v^2}{c^2}}+q\vec{A}\circ\vec{v}-q\phi\right)\\&=\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{m_0\vec{v}}{\sqrt{1+\dfrac{v^2}{c^2}}}\right)+q\dot{\vec{A}}-q\vec{\nabla}\cdot(\vec{A}\circ\vec{v})+q\vec{\nabla}\cdot\phi\end{aligned}\tag{10.3.134}$$

But we have:

$$\vec{F}=\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{m_0\vec{v}}{\sqrt{1+\dfrac{v^2}{c^2}}}\right) \tag{10.3.135}$$

and therefore:

$$\vec{F}=-q\dot{\vec{A}}+q\vec{\nabla}\cdot\left(\vec{A}\circ\vec{v}\right)-q\vec{\nabla}\cdot\phi \tag{10.3.136}$$

But we pointed out in the definition of the scalar potential that $\vec{E}=-\vec{\nabla}\cdot\phi$ hence:

$$\vec{F}=q\vec{E}+q\left(\vec{\nabla}\left(\vec{A}\circ\vec{v}\right)-\dot{\vec{A}}\right) \tag{10.3.137}$$

We should necessarily have by analogy with the Lorentz force:

$$\vec{\nabla}\cdot(\vec{A}\circ\vec{v})-\dot{\vec{A}}=\vec{v}\times\vec{B}=\vec{v}\times\left(\vec{v}\times\vec{A}\right) \tag{10.3.138}$$

So we need before proceeding to check that:

$$\vec{\nabla}\cdot\left(\vec{A}\circ\vec{v}\right)-\frac{\mathrm{d}\vec{A}}{\mathrm{d}t}=\vec{v}\times\left(\vec{\nabla}\times\vec{A}\right) \tag{10.3.139}$$

With:

$$\mathrm{d}\vec{A}=\frac{\partial\vec{A}}{\partial x}\mathrm{d}x+\frac{\partial\vec{A}}{\partial y}\mathrm{d}y+\frac{\partial\vec{A}}{\partial z}\mathrm{d}z\Rightarrow\frac{\mathrm{d}\vec{A}}{\mathrm{d}t}=\frac{\partial\vec{A}}{\partial x}\frac{\mathrm{d}x}{\mathrm{d}t}+\frac{\partial\vec{A}}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}t}+\frac{\partial\vec{A}}{\partial z}\frac{\mathrm{d}z}{\mathrm{d}t}=\frac{\partial\vec{A}}{\partial x}v_x+\frac{\partial\vec{A}}{\partial y}v_y+\frac{\partial\vec{A}}{\partial z}v_z \tag{10.3.140}$$

In components:

$$\frac{\mathrm{d}\vec{A}}{\mathrm{d}t}=\begin{pmatrix}v_x\partial_xA_x+v_y\partial_yA_x+v_z\partial_zA_x\\v_x\partial_xA_y+v_y\partial_yA_y+v_z\partial_zA_y\\v_x\partial_xA_z+v_y\partial_yA_z+v_z\partial_zA_z\end{pmatrix} \tag{10.3.141}$$

Therefore:

$$\begin{pmatrix}\dfrac{\partial}{\partial x}A_xv_x+\dfrac{\partial}{\partial x}A_yv_y+\dfrac{\partial}{\partial x}A_zv_z\\\dfrac{\partial}{\partial y}A_xv_x+\dfrac{\partial}{\partial y}A_yv_y+\dfrac{\partial}{\partial y}A_zv_z\\\dfrac{\partial}{\partial z}A_xv_x+\dfrac{\partial}{\partial z}A_yv_y+\dfrac{\partial}{\partial z}A_zv_z\end{pmatrix}-\dot{\vec{A}}=\vec{v}\times\begin{pmatrix}\partial_yA_z-\partial_zA_y\\\partial_zA_x-\partial_xA_z\\\partial_xA_y-\partial_yA_x\end{pmatrix} \tag{10.3.142}$$

That is:

$$\begin{pmatrix}v_x\partial_xA_x+v_y\partial_xA_y+v_z\partial_xA_z\\v_x\partial_yA_x+v_y\partial_yA_y+v_z\partial_yA_z\\v_x\partial_zA_x+v_y\partial_zA_y+v_z\partial_zA_z\end{pmatrix}=\begin{pmatrix}v_y(\partial_xA_y-\partial_xA_y)-v_z(\partial_zA_x-\partial_xA_z)\\v_z(\partial_yA_z-\partial_zA_y)-v_x(\partial_xA_y-\partial_yA_x)\\v_x(\partial_zA_x-\partial_xA_z)-v_y(\partial_yA_z-\partial_zA_y)\end{pmatrix}+\dot{\vec{A}} \tag{10.3.143}$$

Therefore, distributing the terms:

$$\begin{pmatrix}v_x\partial_xA_x+v_y\partial_xA_y+v_z\partial_xA_z\\v_x\partial_yA_x+v_y\partial_yA_y+v_z\partial_yA_z\\v_x\partial_zA_x+v_y\partial_zA_y+v_z\partial_zA_z\end{pmatrix}=\begin{pmatrix}v_y\partial_xA_y-v_y\partial_yA_x-v_z\partial_zA_x+v_z\partial_xA_z\\v_z\partial_yA_z-v_z\partial_zA_y-v_x\partial_xA_y+v_x\partial_yA_x\\v_x\partial_zA_x-v_x\partial_xA_z-v_y\partial_yA_z+v_y\partial_zA_y\end{pmatrix}+\dot{\vec{A}} \tag{10.3.144}$$

and as: And as:

$$\begin{aligned}&\begin{pmatrix}v_y\partial_x A_y - v_y\partial_y A_x - v_z\partial_z A_x + v_z\partial_x A_z\\ v_z\partial_y A_z - v_z\partial_z A_y - v_x\partial_x A_y + v_x\partial_y A_x\\ v_x\partial_z A_x - v_x\partial_x A_z - v_y\partial_y A_z + v_y\partial_z A_y\end{pmatrix} + \dot{\vec{A}}\\ &= \begin{pmatrix}v_y\partial_x A_y - \cancel{v_y\partial_y A_x} - \cancel{v_z\partial_z A_x} + v_z\partial_x A_z\\ v_z\partial_y A_z - \cancel{v_z\partial_z A_y} - \cancel{v_x\partial_x A_y} + v_x\partial_y A_x\\ v_x\partial_z A_x - \cancel{v_x\partial_x A_z} - \cancel{v_y\partial_y A_z} + v_y\partial_z A_y\end{pmatrix} + \begin{pmatrix}v_x\partial_x A_x + \cancel{v_y\partial_y A_x} + \cancel{v_z\partial_z A_x}\\ \cancel{v_x\partial_x A_y} + v_y\partial_y A_y + \cancel{v_z\partial_z A_y}\\ \cancel{v_x\partial_x A_z} + \cancel{v_y\partial_y A_z} + v_z\partial_z A_z\end{pmatrix}\\ &= \begin{pmatrix}v_y\partial_x A_y + v_z\partial_x A_z + v_x\partial_x A_x\\ v_z\partial_y A_z + v_x\partial_y A_x + v_y\partial_y A_y\\ v_x\partial_z A_x + v_y\partial_z A_y + v_z\partial_z A_z\end{pmatrix} = \begin{pmatrix}v_x\partial_x A_x + v_y\partial_x A_y + v_z\partial_x A_z\\ v_x\partial_y A_x + v_y\partial_y A_y + v_z\partial_y A_z\\ v_x\partial_z A_x + v_y\partial_z A_y + v_z\partial_z A_z\end{pmatrix}\end{aligned} \tag{10.3.145}$$

Therefore we have indeed the equality (yes i know written like this it looks stupid but don't forget the relation above we start from):

$$\begin{pmatrix}v_x\partial_x A_x + v_y\partial_x A_y + v_z\partial_x A_z\\ v_x\partial_y A_x + v_y\partial_y A_y + v_z\partial_y A_z\\ v_x\partial_z A_x + v_y\partial_z A_y + v_z\partial_z A_z\end{pmatrix} = \begin{pmatrix}v_x\partial_x A_x + v_y\partial_x A_y + v_z\partial_x A_z\\ v_x\partial_y A_x + v_y\partial_y A_y + v_z\partial_y A_z\\ v_x\partial_z A_x + v_y\partial_z A_y + v_z\partial_z A_z\end{pmatrix} \tag{10.3.146}$$

These developments thus confirm our initial hypothesis as what the action of the field can be written:

$$S_1 = \int \left(q\vec{A}\circ\vec{v} - q\phi\right)\mathrm{d}t = \int L_1 \mathrm{d}t \tag{10.3.147}$$

and that it expresses the interaction of a charged particle with a magnetic field (since it contains the Lorentz force!).

Here is a table with some interesting values based on Rayleigh criteria $\lambda = 550\,[nm]$:

Tool	**Diameter** D [m]	$\Delta\theta$ [rad]	$\Delta\theta$ [arcsec]	**Details on Moon**	**Details at** 200 [km]
Eye	0.0025	$2.7\cdot 10^{-4}$	55	103 [km]	53 [m]
	0.010	$6.7\cdot 10^{-5}$	13	25 [km]	13 [m]
Bincoular	0.050	$1.3\cdot 10^{-5}$	2.8	5 [km]	2.7 [m]
	0.10	$6.7\cdot 10^{-6}$	1.4	2.6 [km]	1.3 [m]
150 [mm] Telescope	0.15	$4.5\cdot 10^{-6}$	0.92	1.7 [km]	89 [cm]
	0.20	$3.4\cdot 10^{-6}$	0.69	1.3 [km]	67 [cm]
1 [m] Telescope	1.0	$6.7\cdot 10^{-7}$	0.14	260 [m]	13 [cm]
Hubble	2.4	$2.8\cdot 10^{-7}$	0.058	110 [m]	55 [mm]
James-Webb	6.5	$1.0\cdot 10^{-7}$	0.021	39 [m]	20 [mm]
VLT	8.0	$8.4\cdot 10^{-8}$	0.017	32 [m]	16 [mm]

Table 10.3: **Some typical power of resolution based on Rayleigh criteria**

So now we have proved that the "Lagrangian of the current-field interaction":

$$\boxed{L = -m_0c^2\sqrt{1-\frac{v^2}{c^2}} + q\vec{A}\circ\vec{v} - q\phi} \tag{10.3.148}$$

which we assumed empirically the shape earlier and that is finally well correct!

The action integral is then written:

$$S=\int_{t_1}^{t_2}\left(-m_0c^2\sqrt{1-\frac{v^2}{c^2}}+q\vec{A}\circ\vec{v}-q\phi\right)\mathrm{d}t \qquad (10.3.149)$$

Let us introduce the velocity $\vec{v}$ of the particle in the form $\vec{v}=\mathrm{d}\vec{r}/\mathrm{d}t$ and the integral is then written:

$$S=\int_{t_1}^{t_2}\left(-m_0c^2\sqrt{1-\frac{v^2}{c^2}}\mathrm{d}t+q\vec{A}\circ\mathrm{d}\vec{r}-q\phi\mathrm{d}t\right) \qquad (10.3.150)$$

Let us recall that we have proved in the section of Special Relativity the invariant:

$$\mathrm{d}s^2=c^2\mathrm{d}t^2-(\mathrm{d}x^2+\mathrm{d}y^2+\mathrm{d}z^2) \qquad (10.3.151)$$

and also:

$$\mathrm{d}s'^2=c^2\mathrm{d}t'^2-(\mathrm{d}x'^2+\mathrm{d}y'^2+\mathrm{d}z'^2) \qquad (10.3.152)$$

As the space-time intervals are invariants such as (see section Special Relativity page 5704):

$$c^2\mathrm{d}t'^2-(\mathrm{d}x'^2+\mathrm{d}y'^2+\mathrm{d}z'^2)=c^2\mathrm{d}t^2-(\mathrm{d}x^2+\mathrm{d}y^2+\mathrm{d}z^2) \qquad (10.3.153)$$

Let us introduce the velocity $\vec{v}$ of the particle in the form $\vec{v}=\mathrm{d}\vec{r}/\mathrm{d}t$ and the integral is then written:

$$S=\int_{t_1}^{t_2}\left(-m_0c^2\sqrt{1-\frac{v^2}{c^2}}\mathrm{d}t+q\vec{A}\circ\mathrm{d}\vec{r}-q\phi\mathrm{d}t\right) \qquad (10.3.154)$$

Let us recall that we have proved in the section of Special Relativity the invariant:

$$\mathrm{d}s^2=c^2\mathrm{d}t^2-(\mathrm{d}x^2+\mathrm{d}y^2+\mathrm{d}z^2) \qquad (10.3.155)$$

and also:

$$\mathrm{d}s'^2=c^2\mathrm{d}t'^2-(\mathrm{d}x'^2+\mathrm{d}y'^2+\mathrm{d}z'^2) \qquad (10.3.156)$$

As the space-time intervals are invariants such as (see section Special Relativity page 5704):

$$c^2\mathrm{d}t'^2-(\mathrm{d}x'^2+\mathrm{d}y'^2+\mathrm{d}z'^2)=c^2\mathrm{d}t^2-(\mathrm{d}x^2+\mathrm{d}y^2+\mathrm{d}z^2) \qquad (10.3.157)$$

If the repository O' is not in movement ($\mathrm{d}x'=\mathrm{d}y'=\mathrm{d}z'=0$), we have:

$$\mathrm{d}s^2=c^2\mathrm{d}t'^2=c^2\mathrm{d}t^2-(\mathrm{d}x^2+\mathrm{d}y^2+\mathrm{d}z^2) \qquad (10.3.158)$$

hence:

$$\mathrm{d}t'=\frac{\mathrm{d}s}{c}=\mathrm{d}t\sqrt{1-\frac{\mathrm{d}x^2+\mathrm{d}y^2+\mathrm{d}z^2}{c^2\mathrm{d}t^2}} \qquad (10.3.159)$$

which is also written as:

$$\frac{\mathrm{d}s}{c}=\mathrm{d}t\sqrt{1-\frac{v^2}{c^2}} \qquad (10.3.160)$$

Therefore:

$$S=\int_{t_1}^{t_2}\left(-m_c^2\sqrt{1-\frac{v^2}{c^2}}\mathrm{d}t+q\vec{A}\circ\mathrm{d}\vec{r}-q\phi\mathrm{d}t\right)=\int_{\alpha}^{\beta}(-m_0c\mathrm{d}s+q\vec{A}\circ\mathrm{d}\vec{r}-q\phi\mathrm{d}t) \qquad (10.3.161)$$

Now let us use of the contravariant four-vector potential (see above):

$$A^i=\left(\frac{\phi}{c},A_1,A_2,A_3\right)=\left(\frac{\phi}{c},\vec{A}\right) \qquad (10.3.162)$$

and the contravariant four-vector displacement (see section Special Relativity page 5639):

$$\mathrm{d}x^i=(c\mathrm{d}t,\mathrm{d}x_1,\mathrm{d}x_2,\mathrm{d}x_3)=(c\mathrm{d}t,\mathrm{d}\vec{x}) \qquad (10.3.163)$$

The expression of the action of an electric charged particle in an electromagnetic field and in a Minkowski metric η_{ij} (see sections of Special Relativity page 5705 and General Relativity page 5732) is finally reduced to the condensed expression:

$$\boxed{S=\int_{\alpha}^{\beta}-m_0c\mathrm{d}s-qA^i(\eta_{ij}\mathrm{d}x^j)=\int_{\alpha}^{\beta}-m_0c\mathrm{d}s-qA^i\mathrm{d}x_i} \qquad (10.3.164)$$

with therefore:

$$\mathrm{d}x_i=(c\mathrm{d}t,-\mathrm{d}x,-\mathrm{d}y,-\mathrm{d}z) \qquad (10.3.165)$$

without forgetting that here we use the metric $(+,-,-,-)$ (see sections of Special Relativity page 5705 and General Relativity page 5732).

Let us notice that the integral action in the absence of magnetic and electric field is then written:

$$S=-m_0c\int_{\alpha}^{\beta}\mathrm{d}s \qquad (10.3.166)$$

which corresponds well to what we have obtained in the section of Special Relativity for a free particle!

According to the principle of least action, the action integral has zero variation to the effective motion of the particle, therefore:

$$\delta S=-\left(\int_{\alpha}^{\beta}m_0c\mathrm{d}s+q\delta(A^i\mathrm{d}x_i)\right)=0 \qquad (10.3.167)$$

Remark

By the equality with zero, we can eliminate the minus sign before the integral.

Using the expression of the curvilinear abscissa (see section Special Relativity page 5705):

$$\mathrm{d}s^2=g_{ij}\mathrm{d}x^i\mathrm{d}x^j \tag{10.3.168}$$

for the Minkowski metric, we can write (remember that in the Euclidean metric only the terms of the diagonal where $i=j$ are non-zero):

$$\mathrm{d}s^2=\eta_{ij}\mathrm{d}x^j\mathrm{d}x^i=\mathrm{d}x_i\mathrm{d}x^i \tag{10.3.169}$$

Therefore:

$$\mathrm{d}s=\sqrt{\mathrm{d}x_i\mathrm{d}x^i}\Leftrightarrow\delta\mathrm{d}s=\frac{1}{2}\frac{\delta\mathrm{d}x_i\mathrm{d}x^i}{\sqrt{\mathrm{d}x_i\mathrm{d}x^i}}+\frac{1}{2}\frac{\mathrm{d}x_i\delta\mathrm{d}x^i}{\sqrt{\mathrm{d}x_i\mathrm{d}x^i}}=\frac{\mathrm{d}x^i\delta\mathrm{d}x_i}{\mathrm{d}s} \tag{10.3.170}$$

the preceding integral is then written:

$$\delta S=\int\limits_{\alpha}^{\beta}m_0c\delta\mathrm{d}s+q\delta(A^i\mathrm{d}x_i)=\int\limits_{\alpha}^{\beta}m_0c\frac{\mathrm{d}x^i\delta\mathrm{d}x_i}{\mathrm{d}x}+qA^i\delta\mathrm{d}x_i+q\delta A^i\mathrm{d}x_i \tag{10.3.171}$$

This gives using curvilinear components (see section Tensor Calculus page 1524):

$$\delta S=\int\limits_{\alpha}^{\beta}(m_0cu^i+qA^i)\delta\mathrm{d}x_i+\int\limits_{\alpha}^{\beta}q\delta A^i\mathrm{d}x_i \tag{10.3.172}$$

Let us integrate by parts (see section Differential and Integral Calculus page 1532) the first integral:

$$\delta S=(m_0cu^i+qA^i)\mathrm{d}x_i\Big|_{\alpha}^{\beta}-\int\limits_{\alpha}^{\beta}(m_0c\mathrm{d}u^i\delta x_i+q\mathrm{d}A^i\delta x_i)+\int\limits_{\alpha}^{\beta}q\delta A^i\mathrm{d}x_i \tag{10.3.173}$$

But as:

$$\delta x_i\Big|_{\alpha}=0\Rightarrow\mathrm{d}x_i\Big|_{\alpha}=0\qquad\text{and}\qquad\delta x_i\Big|_{\beta}=0\Rightarrow\mathrm{d}x_i\Big|_{\beta}=0 \tag{10.3.174}$$

Therefore:

$$\delta S=\int\limits_{\alpha}^{\beta}(-m_0c\mathrm{d}u^i\delta x_i-q\mathrm{d}A^i\delta x_i+q\delta A^i\mathrm{d}x_i) \tag{10.3.175}$$

with:

$$\delta A^i=\frac{\partial A^i}{\partial x^k}\delta x^k=\partial^k A^i\delta x^k\qquad\text{and}\qquad\mathrm{d}A^i=\frac{\partial A^i}{\partial x^k}\mathrm{d}x^k=\partial^k A^i\mathrm{d}x^k \tag{10.3.176}$$

can be written:

$$\begin{aligned}\delta S &= \int\limits_{\alpha}^{\beta} \left(-m_0 c \mathrm{d}u \delta x_i - q\partial^k A^i \mathrm{d}x^k \delta x_i + q\partial^k A^i \delta x^k \mathrm{d}x_i\right)\\ &= \int\limits_{\alpha}^{\beta} \left(-m_0 c\left(\frac{\mathrm{d}u^i}{\mathrm{d}s}\mathrm{d}s\right)\delta x_i - q\partial^k A^i (u^k \mathrm{d}s)\delta x_i + q\partial^k A^i \delta x^k (u_i \mathrm{d}s)\right)\\ &= \int\limits_{\alpha}^{\beta} \left(-m_0 c\left(\frac{\mathrm{d}u^i}{\mathrm{d}s}\mathrm{d}s\right)\delta x_i - q\partial^k A^i (u^k \mathrm{d}s)\delta x_i + q\partial^i A^k \delta x^i (u_k \mathrm{d}s)\right)\\ &= \int\limits_{\alpha}^{\beta} \left(-m_0 c\left(\frac{\mathrm{d}u^i}{\mathrm{d}s}\right) - q\partial^k A^i (u^k) + q\partial^i A^k (u_k)\right)\delta x_i \mathrm{d}s\\ &= \int\limits_{\alpha}^{\beta} \left(-m_0 c\left(\frac{\mathrm{d}u^i}{\mathrm{d}s}\right) + q(\partial^i A^k - \partial^k A^i)u^k\right)\delta x_i \mathrm{d}s\end{aligned} \tag{10.3.177}$$

The quantities δx_i being arbitrary, the expression in brackets is zero:

$$-m_0 c\left(\frac{\mathrm{d}u^i}{\mathrm{d}s}\right) + q(\partial^i A^k - \partial^k A^i)u^k = 0 \tag{10.3.178}$$

Let us put:

$$\boxed{F^{ik} = \partial^i A^k - \partial^k A^i} \tag{10.3.179}$$

The contravariant quantities F^{ik} form the contravariant components of what we named the "tensor of the electromagnetic field" or "Faraday's tensor" (hence the F...) or more commonly the "Maxwell tensor". We say then that F^{ik} the "curl of (the magnetic) potential".

The "equations of motion of a particle in an electromagnetic field" then take the form:

$$\boxed{m_0 c\frac{\mathrm{d}u^i}{\mathrm{d}s} - qF^{ik}u^k = 0} \tag{10.3.180}$$

that some physicists name the "geodesic corrected by a Lorentz force".

It is important not notice that the term:

$$F^{ik}u^k \tag{10.3.181}$$

corresponds obviously to the electric field seen by the observer!

Remark

The tensor of the electromagnetic field is invariant under the transformations:

$$A^i \rightarrow A^{i'} = A^i - \partial^i \alpha \tag{10.3.182}$$

Indeed:

$$F^{ik}=\partial^i(A^k-\partial^k\alpha)-\partial^k(A^i-\partial^i\alpha)=F^{ik}-\partial^i\partial^k\alpha+\partial^k\partial^i\alpha=F^{ik} \tag{10.3.183}$$

In Minkowski metric η_{ij} (we will need the tensor of the electromagnetic field in the section Special Relativity, hence the choice of this metric), we have however:

$$m_0c\frac{\eta_{ij}\mathrm{d}u^i}{\mathrm{d}s}-q\eta_{ij}(\partial^iA^k-\partial^kA^i)u^k=0 \tag{10.3.184}$$

Which gives:

$$m_0c\frac{\eta_{ij}\mathrm{d}u^i}{\mathrm{d}s}-q(\partial_jA^k-\partial^kA_j)u^k=0 \tag{10.3.185}$$

The term $\partial_jA^k-\partial^kA_j$ is often denoted F^{ik} (even if it is not more fully contravariant).

It remains to us to determine the contravariant components of the tensor F^{ik} (tensor which has the property of being antisymmetric such that $F^{ik}=-F^{ki}$ as we will see further below).

Let's start with the simplest. We assume as obvious that:

$$\begin{aligned}F^{00}&=\partial_0A^0-\partial^0A_0=0\\F^{11}&=\partial_1A^1-\partial^1A_1=0\\F^{22}&=\partial_2A^2-\partial^2A_2=0\\F^{33}&=\partial_3A^3-\partial^3A_3=0\end{aligned} \tag{10.3.186}$$

Then, remembering that $\vec{B}=\vec{\nabla}\times\vec{A}$:

$$\begin{pmatrix}B_x\\B_y\\B_y\end{pmatrix}=\begin{pmatrix}\partial_yA_z-\partial_zA_y\\\partial_zA_x-\partial_xA_z\\\partial_xA_y-\partial_yA_x\end{pmatrix}=\begin{pmatrix}\partial_2A_3-\partial_3A_2\\\partial_3A_1-\partial_1A_3\\\partial_1A_2-\partial_2A_1\end{pmatrix} \tag{10.3.187}$$

Hence (by choosing the Minkowski metric with signature $(+,-,-,-)$):

$$\begin{aligned}F^{21}=-F^{12}=\partial_2A^1-\partial^1A_2&=\frac{\partial}{-\partial y}A^1-\frac{\partial}{\partial x}(-A_2)=\frac{\partial}{\partial x}A_2-\frac{\partial}{\partial y}A^1=B_z\\F^{32}=-F^{23}=\partial_3A^2-\partial^2A_3&=\frac{\partial}{-\partial z}A^2-\frac{\partial}{\partial y}(-A_3)=\frac{\partial}{\partial y}A_3-\frac{\partial}{\partial z}A^2=B_x\\F^{13}=-F^{31}=\partial_1A^3-\partial^3A_1&=\frac{\partial}{-\partial x}A^3-\frac{\partial}{\partial z}(-A_1)=\frac{\partial}{\partial z}A_1-\frac{\partial}{\partial x}A^3=B_y\end{aligned} \tag{10.3.188}$$

Which gives us so far:

$$F^{ik}=\begin{bmatrix}F^{00}&F^{01}&F^{02}&F^{03}\\F^{10}&F^{11}&F^{12}&F^{13}\\F^{20}&F^{21}&F^{22}&F^{23}\\F^{30}&F^{31}&F^{32}&F^{33}\end{bmatrix} \tag{10.3.189}$$

Remark

Strictly speaking not to confuse the Faraday's tensor $F^{ik}=\partial^i A^k-\partial^k A^i$ with its matrix form, we should put the first term of the above equality between brackets $[F^{ik}]$ as we have already mention it in the section of Tensor Calculus!

Now, being known that $x_0=ct$ and $A_0=\phi/c$ the other components of the tensor F^{ki} are written taking into account that:

$$\vec{E}=-\vec{\nabla}\cdot\phi-\frac{\partial\vec{A}}{\partial t} \tag{10.3.190}$$

and therefore:

$$\frac{1}{c}\left(\frac{\partial\vec{A}}{\partial t}+\vec{\nabla}\cdot\phi\right)=\frac{\vec{E}}{c} \tag{10.3.191}$$

thus, with the partial contravariant derivatives according to the Minkowski metric:

$$\begin{aligned}F^{01}=-F^{10}=\partial_0 A^1-\partial^1 A_0=\frac{1}{c}\left(\frac{\partial A_1}{\partial t}-\frac{\partial\phi}{-\partial x}\right)=\frac{1}{c}\left(\frac{\partial A_1}{\partial t}+\frac{\partial\phi}{\partial x}\right)=-\frac{E_x}{c}\\F^{02}=-F^{20}=\partial_0 A^2-\partial^2 A_0=\frac{1}{c}\left(\frac{\partial A_2}{\partial t}-\frac{\partial\phi}{-\partial y}\right)=\frac{1}{c}\left(\frac{\partial A_2}{\partial t}+\frac{\partial\phi}{\partial y}\right)=-\frac{E_y}{c}\\F^{03}=-F^{30}=\partial_0 A^3-\partial^3 A_0=\frac{1}{c}\left(\frac{\partial A_3}{\partial t}-\frac{\partial\phi}{-\partial z}\right)=\frac{1}{c}\left(\frac{\partial A_3}{\partial t}+\frac{\partial\phi}{\partial z}\right)=-\frac{E_z}{c}\end{aligned} \tag{10.3.192}$$

Thus we have for the tensor of the electromagnetic field in contravariant components with and always with the Minkowski signature $(+,-,-,-)$:

$$F^{ik}=\begin{bmatrix}F^{00}&F^{01}&F^{02}&F^{03}\\F^{10}&F^{11}&F^{12}&F^{13}\\F^{20}&F^{21}&F^{22}&F^{23}\\F^{30}&F^{31}&F^{32}&F^{33}\end{bmatrix}=\begin{bmatrix}0&-\frac{E_x}{c}&-\frac{E_y}{c}&-\frac{E_z}{c}\\\frac{E_x}{c}&0&-B_z&B_y\\\frac{E_y}{c}&B_z&0&-B_x\\\frac{E_z}{c}&-B_y&B_x&0\end{bmatrix} \tag{10.3.193}$$

So that the equation of motion is finally:

$$\boxed{m_0c^2\frac{\mathrm{d}u^i}{\mathrm{d}s}-qF^{ik}u^k=0} \tag{10.3.194}$$

But as we will see it in the section of Special Relativity, the real tensor of the electromagnetic field is defined by (still in the metric $+,-,-,-$):

$$F^{\mu\nu}=cF^{ik}=\begin{bmatrix}0&-E_x&-E_y&-E_z\\E_x&0&-cB_z&cB_y\\E_y&cB_z&0&-cB_x\\E_z&-cB_y&B_x&0\end{bmatrix} \tag{10.3.195}$$

so that the Lorentz transformations are conform.

The expression in tensor form of the electromagnetic field clearly shows the unity of the electromagnetic field while generally the electric and magnetic fields are considered separately in classical theory.

But as in theoretical physics we often work in natural units (this is somewhat the "norm" ...), then we have in advanced graduate books:

$$\boxed{F^{\mu\nu}=\begin{bmatrix}0 & -E_x & -E_y & -E_z\\ E_x & 0 & -B_z & B_y\\ E_y & B_z & 0 & -B_x\\ E_z & -B_y & B_x & 0\end{bmatrix}} \tag{10.3.196}$$

Hence the equation of motion in natural units:

$$\boxed{m_0\frac{\mathrm{d}u^{\mu}}{\mathrm{d}s}-qF^{\mu\nu}u^{\nu}=0} \tag{10.3.197}$$

By denoting now the components of 1 to 4 instead of 0 to 3 (it is easier for students to find their way in the matrix) and without forgetting that the partial derivatives are covariant and adopting again the natural units such as $\mu=\varepsilon=1$ (verbatim $c=1$), the two Maxwell equations with source are written:

$$\begin{aligned}&\vec{\nabla}\circ\vec{E}=\frac{\rho_Q}{\varepsilon} && \xrightarrow{\text{natural units}}\vec{\nabla}\circ\vec{E}=\rho_Q\\ &\vec{\nabla}\times\vec{B}-\mu\varepsilon\frac{\mathrm{d}\vec{E}}{\mathrm{d}t}=\mu\vec{j} && \xrightarrow{\text{natural units}}\vec{\nabla}\times\vec{B}-\frac{\mathrm{d}\vec{E}}{\mathrm{d}t}=\vec{j}\end{aligned} \tag{10.3.198}$$

Using the tensor of the electromagnetic field, it remarkably appears that these two equations can be written as in the condensed tensor equation:

$$\boxed{\partial_{\mu}F^{\nu\mu}=j^{\nu}} \tag{10.3.199}$$

where j^{ν} is the "four-vector current" defined by (in natural units!):

$$j^{\nu}=(j^0,\vec{j})=(\rho_Q,\vec{j}) \tag{10.3.200}$$

Using the first definition of the Faraday's tensor (the one where the field components are divided by c) and taking as known (we will prove it later) that $c=1/\sqrt{\varepsilon_0\mu_0}$ we have in the SI system:

$$\partial_{\mu}F^{\nu\mu}=\mu_0 j^{\nu} \tag{10.3.201}$$

with:

$$j^{\nu}=(c\rho_Q,\vec{j}) \tag{10.3.202}$$

As we shall immediately see, the temporal part of this equation gives the divergence of the electric field and the spatial part the rotational magnetic field.

Indeed:

$$\begin{aligned}\partial_{\mu}F^{1\mu}&=\partial_1F^{11}+\partial_2F^{12}+\partial_3F^{13}+\partial_4F^{14}=\partial_tF^{11}+\partial_xF^{12}+\partial_yF^{13}+\partial_zF^{14}\\ &=\partial_t0+\partial_xE_x+\partial_yE_y+\partial_zE_z=\partial_xE_x+\partial_yE_y+\partial_zE_z\end{aligned} \tag{10.3.203}$$

This is latter equality is the equivalent of:

$$\partial_\mu F^{1\mu}=\vec{\nabla}\circ\vec{E} \tag{10.3.204}$$

And we also have:

$$\begin{aligned}\partial_\mu F^{2\mu}&=\partial_1 F^{21}+\partial_2 F^{22}+\partial_3 F^{23}+\partial_4 F^{24}=\partial_t F^{21}+\partial_x F^{22}+\partial_y F^{23}+\partial_z F^{24}\\&=\partial_t(-E_y)+\partial_x B_z+\partial_y 0+\partial_z(-B_x)=\partial_x B_z-\partial_z B_x-\partial_t E_y\\ \\ \partial_\mu F^{3\mu}&=\partial_1 F^{31}+\partial_2 F^{32}+\partial_3 F^{33}+\partial_4 F^{34}=\partial_t F^{31}+\partial_x F^{32}+\partial_y F^{33}+\partial_z F^{34}\\&=\partial_t(-E_y)+\partial_x B_z+\partial_y 0+\partial_z(-B_x)=\partial_x B_z-\partial_z B_x-\partial_t E_y\\ \\ \partial_\mu F^{4\mu}&=\partial_1 F^{41}+\partial_2 F^{42}+\partial_3 F^{43}+\partial_4 F^{44}=\partial_t F^{41}+\partial_x F^{42}+\partial_y F^{43}+\partial_z F^{44}\\&=\partial_t(-E_z)+\partial_x(-B_y)+\partial_y(B_x)+\partial_z 0=\partial_y B_x-\partial_x B_y-\partial_t E_z\end{aligned} \tag{10.3.205}$$

These three sets of equalities are the equivalent of:

$$\begin{pmatrix}\partial_\mu F^{2\mu}\\\partial_\mu F^{3\mu}\\\partial_\mu F^{4\mu}\end{pmatrix}=\vec{\nabla}\times\vec{B}-\partial_t\vec{E} \tag{10.3.206}$$

Also the both Maxwell equations:

$$\vec{\nabla}\circ\vec{B}=0 \qquad \vec{\nabla}\times\vec{E}+\frac{\partial\vec{B}}{\partial t}=\vec{0} \tag{10.3.207}$$

can be written in tensor form:

$$\boxed{\partial_\mu F^{\nu\lambda}+\partial_\nu F^{\lambda\mu}+\partial_\gamma F^{\mu\nu}=0} \tag{10.3.208}$$

Indeed we have first:

$$\begin{aligned}\partial_2 F^{43}+\partial_4 F^{32}+\partial_3 F^{24}&=\partial_x F^{43}+\partial_z F^{32}+\partial_y F^{24}=\partial_x B_x+\partial_z B_z+\partial_y B_y\\&=\partial_x B_x+\partial_y B_y+\partial_z B_z\end{aligned} \tag{10.3.209}$$

that corresponds obviously to:

$$\vec{B}\circ\vec{B} \tag{10.3.210}$$

and:

$$\begin{aligned}\partial_1 F^{43}+\partial_4 F^{31}+\partial_3 F^{14}&=\partial_t B_x+\partial_z(-E_y)+\partial_y(E_z)=\partial_y E_z-\partial_z E_y+\partial_t B_x\\\partial_1 F^{24}+\partial_2 F^{41}+\partial_4 F^{12}&=\partial_t B_y+\partial_x(-E_z)+\partial_z(E_x)=\partial_z E_x-\partial_x E_z+\partial_t B_y\\\partial_1 F^{32}+\partial_3 F^{21}+\partial_2 F^{13}&=\partial_t B_z+\partial_y(-E_x)+\partial_x(E_y)=\partial_x E_y-\partial_y E_x+\partial_t B_z\end{aligned} \tag{10.3.211}$$

These three sets of equalities are the equivalent of:

$$\begin{pmatrix}\partial_1 F^{43}+\partial_4 F^{31}+\partial_3 F^{14}\\\partial_1 F^{24}+\partial_2 F^{41}+\partial_4 F^{12}\\\partial_1 F^{32}+\partial_3 F^{21}+\partial_2 F^{13}\end{pmatrix}=\vec{\nabla}\times\vec{E}+\partial_t\vec{B} \tag{10.3.212}$$

Finally, all the Maxwell equations, adopting the natural units, are implicitly contained into the both relations:

$$\boxed{\begin{aligned}\partial_\mu F^{\nu\mu}=j^\nu\\ \partial_\mu F^{\nu\lambda}+\partial_v F^{\lambda\mu}+\partial_\lambda F^{\mu\nu}=0\end{aligned}} \tag{10.3.213}$$

We can also use the pseudo antisymmetric tensor of rank 4 that can be seen as a generalization of the Levi-Civita symbol (see section Tensor Calculus page 2045) such that we can write:

$$\boxed{\begin{aligned}\partial_\mu F^{\nu\mu}=j^\nu\\ \varepsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}=0\end{aligned}} \tag{10.3.214}$$

with:

$$\varepsilon^{\mu\nu\rho\sigma}=\begin{cases}1 & \text{if } \mu\nu\rho\sigma \text{ is an even permuation of } (1234)\\ -1 & \text{if } \mu\nu\rho\sigma \text{ is an odd permuation of } (1234)\\ 0 & \text{otherwise}\end{cases} \tag{10.3.215}$$

The Lagrangian we have determined earlier above, however, is not complete. Indeed, when we apply the variational principle, we have already seen many times in the various section of this textbook (Classical Mechanics, Wave Mechanics, Magnetostatic, Special Relativity, General Relativity, etc.) that we could get the equations of motion (trajectories) of the subjects (bodies) of interest. The equations obtained also contain the parameters that explained the source of this movement (material properties, speed, field, etc.) as it was the case before!

Previously, we applied the variational principle on the Lagrangian of the charge-field interaction (electrostatic + magnetic) and got the equation of motion corrected by the Lorentz force.

When we determined the equations of motion of the charged particle from the principle of least action, we fixed the electromagnetic field (the field is known) and we varied the trajectory. The variational principle, must also allow us to get the field equations from the opposite approach: we fix the path of the particle (known of course) and we vary the electromagnetic field (potential and tensor field).

We should then obtain the Maxwell equations that, in the same way that we get what makes the motion of the particle when fixing the field in the variational principle, should gives us the information on what is the source of electric and magnetic field when the trajectory is fixed in the variational principle (I hope you have followed that explanation........).

The desire is then great to just simply start again from the action obtained earlier:

$$S=-\int m_0 c\mathrm{d}s-qA^i\mathrm{d}x_i \tag{10.3.216}$$

and apply to it a variation on the field.

As we have:

$$\rho_Q=\frac{\mathrm{dq}}{\mathrm{d}V} \tag{10.3.217}$$

we can write:

$$S=-\int m_0c\mathrm{d}s-A^i(\rho_Q\mathrm{d}V)\mathrm{d}x_i \qquad (10.3.218)$$

Let us consider electrical charges moving at the speed v and let us write the following quantity (do not forget that we continue to work in natural units such as $\mathrm{d}x_0=c\mathrm{d}t=\mathrm{d}t$!):

$$\mathrm{d}q\mathrm{d}x_i=(\rho_Q\mathrm{d}V)\mathrm{d}x_i=\rho_Q\mathrm{d}V\mathrm{d}x_0\frac{\mathrm{d}x_i}{\mathrm{d}x_0}=\rho_Q\mathrm{d}\Omega\frac{\mathrm{d}x_i}{\mathrm{d}t}=\left(\rho_Q\frac{\mathrm{d}x_i}{\mathrm{d}t}\right)\mathrm{d}\Omega=j_i\mathrm{d}\Omega \qquad (10.3.219)$$

with in natural units:

$$\mathrm{d}\Omega=\mathrm{d}x_0\mathrm{d}x_1\mathrm{d}x_2\mathrm{d}x_3=\mathrm{d}t\mathrm{d}x\mathrm{d}y\mathrm{d}z \qquad (10.3.220)$$

Therefore we have:

$$S=\int -m_0\mathrm{d}s-A^ij_i\mathrm{d}\Omega \qquad (10.3.221)$$

If we apply the variational principle only on the field (constant in amplitude so that the source of the field is constant and therefore $\delta j_i=0$) and that we therefore consider the movement of electric charges known, it is immediate that the first term above is zero. Then we have:

$$\delta S=\int\delta(A^ij_i)\mathrm{d}\Omega=\int A^ij_i\mathrm{d}\Omega+A^i\delta j_i\mathrm{d}\Omega=\int\delta A^ij_i\mathrm{d}\Omega=\int j_i\delta A^i\mathrm{d}\Omega=0 \qquad (10.3.222)$$

that this integral to be zero it would require that j_i is zero ... which is pretty annoying if we wish to determine the characteristics of a source which then would not exist ... Therefore, we notice that something is missing in our Lagrangian!

The idea is the following: we know a tensor equation which involves the current density which is $\partial_\mu F^{\nu\mu}=j^\mu$ and that implicitly contains the only two Maxwell equations that give information on the source of the respective electric and magnetic fields (the other two giving properties of the field, not sources!) that is (always in natural units) for recall:

$$\begin{aligned}\vec{\nabla}\circ\vec{E}&=\rho_Q\\ \vec{\nabla}\times\vec{B}&=\frac{\mathrm{d}\vec{E}}{\mathrm{d}t}+\vec{j}\end{aligned} \qquad (10.3.223)$$

It is therefore sufficient to get these two equations (thus the corresponding tensor equation) following the variational principle to get the properties of the source of the field.

This simply means that ideally, we should (and expect) to have:

$$\delta S=\int\left(j^\nu-\partial_\mu F^{\nu\mu}\right)\delta A^\nu\mathrm{d}\Omega=0 \qquad (10.3.224)$$

where the integral equation vanishes exactly when $\partial_m uF^{\nu\mu}=j^\nu$!

It is then tempting to write something of the form (notice that we lowered the index of the potential A and raised that of the current density j in the second integral which does not change anything mathematically speaking to the result):

$$S=-\int m_0\mathrm{d}s-\int A_\nu j^\nu\mathrm{d}\Omega+\int ???\mathrm{d}\Omega \qquad (10.3.225)$$

We can use the following property of the Lagrangian quantities for to determine the missing expression "???": they all are invariant. In other words and for recall their pseudo-norm (scalar) is equal by Galilean basis change (see section Mechanics page 3239 and section Special Relativity page 5630) such that:

$$\begin{gathered}\mathrm{d}s=\mathrm{d}s'\\ A_\nu j^\nu = A'_\nu j'^\nu\end{gathered} \tag{10.3.226}$$

The first relation is quite obvious, we have already proved it many times. The second is perhaps less obvious therefore let us give a small indication (not general) to check whether it's correct: $A_\nu j^\nu$ is the dot product of j and A. If we apply the same (four) rotation to the two vectors, since Lorentz transformations are rotations (see section Special Relativity page 5642), the angle between j and A remains unchanged and thus the dot product.

But we must not forget that need to find the quantity "???" as a scalar invariant involving the Faraday tensor in one way or another.

We can then try directly with the following quantity (knowing in advance thanks to our precursors that this is the right hypothesis):

$$F_{\mu\nu}F^{\mu\nu}=(g_{\mu\sigma}g_{\nu\rho}F^{\sigma\rho})\,F^{\mu\nu}=(F^{\mu\nu})^2 \tag{10.3.227}$$

involving the covariant Faraday's tensor $F_{\mu\nu}$ and contravariant $F^{\mu\nu}$ because we know that:

1. It is a scalar invariant! Indeed, let us write $F_{\mu\nu}F^{\mu\nu}$ in terms of electric and magnetic fields to understand the physical meaning of that latter (still in natural units):

$$\begin{aligned}(g_{\mu\sigma}g_{\nu\rho}F^{\sigma\rho})F^{\mu\nu}=F_{\mu\nu}F^{\mu\nu}&=\begin{bmatrix}0 & E_x & E_y & E_z\\ -E_x & 0 & -B_z & B_y\\ -E_y & B_z & 0 & -B_x\\ -E_z & -B_y & B_x & 0\end{bmatrix}\begin{bmatrix}0 & -E_x & -E_y & -E_z\\ E_x & 0 & -B_z & B_y\\ E_y & B_z & 0 & -B_x\\ E_z & -B_y & B_x & 0\end{bmatrix}\\ &=F_{1\nu}F^{1\nu}+F_{2\nu}F^{2\nu}+F_{3\nu}F^{3\nu}+F_{4\nu}^{4\nu}\\ &=-E_x^2-E_y^2-E_z^2-E_x^2+B_z^2+B_y^2-E_y^2+B_z^2+B_x^2-E_z^2+B_y^2+B_x^2\\ &=2(\vec{B}\circ\vec{B}-\vec{E}\circ\vec{E})=2\left(\|\vec{B}\|^2-\|\vec{E}\|^2\right)\end{aligned} \tag{10.3.228}$$

Remark

If we were not in natural units, the calculation result would be of the form:

$$F_{\mu\nu}F^{\mu\nu}=\frac{2}{c^2}\left(c^2\|\vec{B}\|^2-\|\vec{E}\|^2\right) \tag{10.3.229}$$

The quantity:

$$c^2\|\vec{B}\|^2-\|\vec{E}\|^2 \tag{10.3.230}$$

(or $\|\vec{B}\|^2-\|\vec{E}\|^2$ in natural units) is therefore an invariant of the field.

✍**Example:**

In a repository O, let us consider a plane electromagnetic wave. The modules of the electric field and magnetic field are linked by the relation $E=cB$ (see below for proof). The invariant of the considered field is therefore zero. In another reference frame, with the same structure of the field, then we will also have $E'=cB'$.

2. Because a variational on this term gives:

$$\delta(F^{\mu\nu})^2=\delta(F_{\mu\nu}F^{\mu\nu})=F_{\mu\nu}\delta F^{\mu\nu}+\delta F_{\mu\nu}F^{\mu\nu}=2\delta F_{\mu\nu}F^{\mu\nu} \tag{10.3.231}$$

where we guess ... by digging a little bit, that $\delta F_{\mu\nu}$ implicitly contains the term δA^{ν}. We also see that a factor 2 appears such that we will have to introduce a normalization constant α, that anyway has to be introduced for a matter of homogeneity of the units of the expression of the action.

So eventually let try with something like:

$$S=-\int m_0\mathrm{d}s-\int A_{\mu}j^{\mu}\mathrm{d}\Omega+\alpha\int(F^{\mu\nu})^2\mathrm{d}\Omega \tag{10.3.232}$$

Now to find the equations of the electromagnetic field, we consider that the movement of electric charges are known and we use the principle of least action by varying only the components of the vector potential and those of the tensor of the electromagnetic field.

It follows that the variation of the first integral is zero and that it remains:

$$\begin{aligned}\delta S&=-\int\delta A_{\mu}j^{\mu}\mathrm{d}\Omega+\alpha\int\delta(F^{\mu\nu})^2\mathrm{d}\Omega\\&=-\int\delta A_{\mu}j^{\mu}\mathrm{d}\Omega+\alpha\int\delta(F_{\mu\nu}F^{\mu\nu})\mathrm{d}\Omega=-\int\delta A_{\mu}j^{\mu}\mathrm{d}\Omega+2\alpha\int F^{\mu\nu}\delta F_{\mu\nu}\mathrm{d}\Omega\end{aligned} \tag{10.3.233}$$

But we know that $F_{\mu\nu}$ is equal to $-F_{\nu\mu}$ since the Faraday tensor is antisymmetric:

$$F^{\mu\nu}\delta F_{\mu\nu}=-F^{\mu\nu}\partial_{\mu}\delta A_{\nu}-F^{\mu\nu}\partial_{\nu}\delta A_{\mu} \tag{10.3.234}$$

Nothing prevents us to swap the indices μ,ν in the first term at the right of the equality:

$$F^{\mu\nu}\delta F_{\mu\nu}=-F^{\mu\nu}\partial_{\mu}\delta A_{\nu}-F^{\mu\nu}\partial_{\nu}\delta A_{\mu}=-2F^{\mu\nu}\partial_{\nu}\delta A_{\mu} \tag{10.3.235}$$

But we know that $F_{\mu\nu}$ is equal to $-F_{\nu\mu}$ since the Faraday tensor is antisymmetric:

$$F^{\mu\nu}\delta F_{\mu\nu}=-F^{\mu\nu}\partial_{\mu}\delta A_{\nu}-F^{\mu\nu}\partial_{\nu}\delta A_{\mu} \tag{10.3.236}$$

Nothing prevents us to swap the indices μ,ν in the first term at the right of the equality:

$$F^{\mu\nu}\delta F_{\mu\nu}=-F^{\mu\nu}\partial_{\mu}\delta A_{\nu}-F^{\mu\nu}\partial_{\nu}\delta A_{\mu}=-2F^{\mu\nu}\partial_{\nu}\delta A_{\mu} \tag{10.3.237}$$

So finally:

$$\delta S=-\int\delta A_{\mu}j^{\mu}\mathrm{d}\Omega-4\alpha\int F^{\mu\nu}\partial_{\nu}\delta A_{\mu}\mathrm{d}\Omega=0 \tag{10.3.238}$$

Let us look at the second integral:

$$\int F^{\mu\nu}\partial_\nu \delta A_\mu \mathrm{d}\Omega = \int F^{\mu\nu}\frac{\partial}{\partial x^\nu}(\delta A_\mu)\mathrm{d}x_0\mathrm{d}x_1\mathrm{d}x_2\mathrm{d}x_3 \qquad (10.3.239)$$

Applying the Fubini theorem (see section Differential and Integral Calculus page 1521) that says that we can integrate in any order the integration variables (under certain conditions) then we can apply the integration by parts (see section Differential and Integral Calculus page 1532) to write:

$$\int F^{\mu\nu}\partial_\nu \delta A_\mu \mathrm{d}\Omega = \int F^{\mu\nu}\delta A_\mu \mathrm{d}S - \int \partial_\nu F^{\mu\nu}\delta A_\mu \mathrm{d}\Omega \qquad (10.3.240)$$

where $\mathrm{d}S$ represents the boundary surface of the hyper-volume $\mathrm{d}\Omega$ which we were initially integrating and that omits the variable considered by the choice of the superscript ν.

Now according to the superscript ν concerned, the boundaries of the first term of the equality:

$$\int F^{\mu\nu}\delta A_\mu \mathrm{d}S \qquad (10.3.241)$$

will be on the components of time or components of space. If we focus on the temporal boundaries of integration, these are the initial and final moments of the action at which we apply this variational.

But at the time ends, the variational of the vector potential δA_μ is zero (by definition), therefore the integral over the time component will be zero.

Now on the spatial components, the (spatial) boundaries are those that permits to integrate the border surface of the hyper-volume at the final time. If this one is taken as being the infinity, the radius of the border area will be infinite and at every point of this surface, the energy carried by the field and the amplitude of the field components will be zero (see proof further below).

Therefore the variational of action is finally written:

$$\delta S = -\int \delta A_\mu j^\mu \mathrm{d}\Omega + 4\alpha\int \partial_v F^{\mu\nu}\delta A_\mu \mathrm{d}\Omega = \int (4\alpha\partial_\nu F^{\mu\nu} - j^\mu)\delta A_\mu \mathrm{d}\Omega = 0 \qquad (10.3.242)$$

The variations of the vector potential being arbitrary, the preceding integral will be zero if the integrand is also zero, hence the relations:

$$4\alpha\partial_v F^{\mu\nu} - j^\mu = 0 \qquad (10.3.243)$$

which brings us to:

$$4\alpha\partial_v F^{\mu\nu} = j^\mu \qquad (10.3.244)$$

Remark

We return on this Lagrangian with another (very interesting) approach in the section of Quantum Field Theory.

10.3.4 Electromagnetic wave equation

Maxwell supposed that the electromagnetic wave was a combination of phenomena that explain the third and fourth equations. If an electromagnetic wave is far from its source, then we can then neglect the surface density of current from the source as having no influence on the wave (we say then that it is the Maxwell equations without sources which we have already mentioned earlier above). So the third and fourth Maxwell equations are written:

$$\vec{\nabla}\times\vec{E}=-\frac{\partial\vec{B}}{\partial t}\qquad\text{and}\qquad\vec{\nabla}\times\vec{H}=\varepsilon\frac{\mathrm{d}\vec{E}}{\mathrm{d}t}\tag{10.3.245}$$

Let us first prove that the magnetic field and electric field are perpendicular!

Proof 10.2.3. A plane wave can be written:

$$\vec{E}=\hat{E}\cos(\omega t-\vec{k}\circ\vec{r}+\varphi_e)\tag{10.3.246}$$

$$\vec{B}=\hat{B}\cos(\omega t-\vec{k}\circ\vec{r}+\varphi_m)\tag{10.3.247}$$

with constant amplitude vectors $\hat{E}$, $\hat{B}$ and where the plane that is perpendicular to a given vector $\vec{k}$.

Now let's put the plane wave in the third Maxwell equation:

$$\begin{aligned}\vec{\nabla}\times\vec{E}&=\left(\frac{\partial E_z}{\partial y}-\frac{\partial E_y}{\partial z}\right)\vec{x}+\left(\frac{\partial E_x}{\partial z}-\frac{\partial E_z}{\partial x}\right)\vec{y}+\left(\frac{\partial E_y}{\partial x}-\frac{\partial E_x}{\partial y}\right)\vec{z}\\&=\left[\left(\hat{E}_zk_y-\hat{E}_yk_z\right)\vec{x}+\left(\hat{E}_xk_z-\hat{E}_zk_x\right)\vec{y}+\left(\hat{E}_yk_x-\hat{E}_xk_y\right)\vec{z}\right]\sin(\omega t-\vec{k}\circ\vec{r}+\varphi_e)\\&=-\frac{\partial\vec{B}}{\partial t}=\omega\hat{B}\sin(\omega t-\vec{k}\circ\vec{r}+\varphi_m)\end{aligned}\tag{10.3.248}$$

with the Cartesian coordinate vectors $\vec{x}$, $\vec{y}$, $\vec{z}$.

Here we see that the electric and magnetic components have to be in phase ($\varphi_e=\varphi_m$) and hence we can focus on the amplitudes $\hat{E}$, $\hat{B}$. To check for orthogonality, we evaluate the scalar product of the amplitudes and use the representation of $\hat{B}$ in terms of $\hat{E}$ we just found:

$$\begin{aligned}\hat{\vec{E}}\circ\hat{\vec{B}}/\omega&=[E_x\vec{x}+E_y\vec{y}+E_z\vec{z}]\circ\left[\left(\hat{E}_zk_y-\hat{E}_yk_z\right)\vec{x}+\left(\hat{E}_xk_z-\hat{E}_zk_x\right)\vec{y}+\left(\hat{E}_yk_x-\hat{E}_xk_y\right)\vec{z}\right]\\&=\hat{E}_x\hat{E}_zk_y-\hat{E}_x\hat{E}_yk_z+\hat{E}_y\hat{E}_xk_z-\hat{E}_y\hat{E}_zk_x+\hat{E}_z\hat{E}_yk_x-\hat{E}_z\hat{E}_xk_y=0\end{aligned}\tag{10.3.249}$$

■ Q.E.D.

The excitation magnetic field $\vec{H}$ and electric field $\vec{E}$ being perpendicular (in the special case of electromagnetic waves in vacuum!), let us place ourselves conveniently in a system of orthonormal and Euclidean axes $(\vec{i},\vec{j},\vec{k})$ belonging to $\mathbb{R}^3$ by choosing:

$$\vec{H}=(0,0,H)=\frac{B}{\mu}\vec{k}\qquad\text{and}\qquad\vec{E}=(0,E,0)\tag{10.3.250}$$

Remark

Warning! The reader must remember that in what follows, H is the z component of $\vec{H}$ and E the y component of $\vec{E}$.

The (simple) calculations of $\vec{\nabla}\times\vec{E}$ and $\vec{\nabla}\times\vec{H}$ gives, after simplification:

$$\vec{\nabla}\times\vec{E}=\frac{\partial\vec{E}}{\partial x}=-\frac{\partial\vec{B}}{\partial t}\qquad\text{and}\qquad\vec{\nabla}\times\vec{H}=-\frac{\partial H}{\partial x}=\varepsilon\frac{\partial\vec{E}}{\partial t}\tag{10.3.251}$$

Before going further, a reader asked us to develop the details that lead to the left equality. So we start from:

$$\vec{\nabla}\times\vec{E}=\begin{pmatrix}\partial_x\\\partial_y\\\partial_z\end{pmatrix}\times\begin{pmatrix}E_x\\E_y\\E_z\end{pmatrix}=\begin{pmatrix}\partial_y E_z-\partial_z E_y\\\partial_z E_x-\partial_x E_z\\\partial_x E_y-\partial_y E_x\end{pmatrix}=\begin{pmatrix}-\partial_z E_y\\0\\\partial_x E_y\end{pmatrix}=-\frac{\vec{B}}{\partial t}\tag{10.3.252}$$

But:

$$\partial_z E_y=0\tag{10.3.253}$$

because the wave is a plane wave and the component of the electric field being in y, it does not vary following z. Then we have:

$$\vec{\nabla}\times\vec{E}=\begin{pmatrix}-\partial_z E_y\\0\\\partial_x E_y\end{pmatrix}=\begin{pmatrix}0\\0\\\partial_x E_y\end{pmatrix}=\partial_x\vec{E}=-\frac{\partial\vec{B}}{\partial t}\tag{10.3.254}$$

This being done, if we continue, we have:

$$\frac{\partial E}{\partial x}=-\frac{\partial B}{\partial t}\Rightarrow\frac{\partial^2 E}{\partial x^2}=-\mu\frac{\partial^2 H}{\partial x\partial t}\qquad\text{and}\qquad-\frac{\partial H}{\partial x}=\varepsilon\frac{\partial E}{\partial t}\Rightarrow-\frac{\partial^2 H}{\partial x\partial t}=\varepsilon\frac{\partial^2 E}{\partial t^2}\tag{10.3.255}$$

Identifying similar terms, we get the "equation of propagation of the electric field":

$$\boxed{\frac{\partial^2 E}{\partial t^2}=\frac{1}{\mu\varepsilon}\frac{\partial^2 E}{\partial x^2}}\tag{10.3.256}$$

and proceeding exactly in a similar way:

$$\boxed{\frac{\partial^2 B}{\partial t^2}=\frac{1}{\mu\varepsilon}\frac{\partial^2 B}{\partial x^2}}\tag{10.3.257}$$

relations that are both in the form of a wave equation (see section Wave Mechanics page 3476) of the type (for recall) of a "Poisson equation" (specifically it is a "d'Alembert's equation"):

$$\frac{\partial^2 y}{\partial t^2}=v^2\frac{\partial^2 y}{\partial x^2}\tag{10.3.258}$$

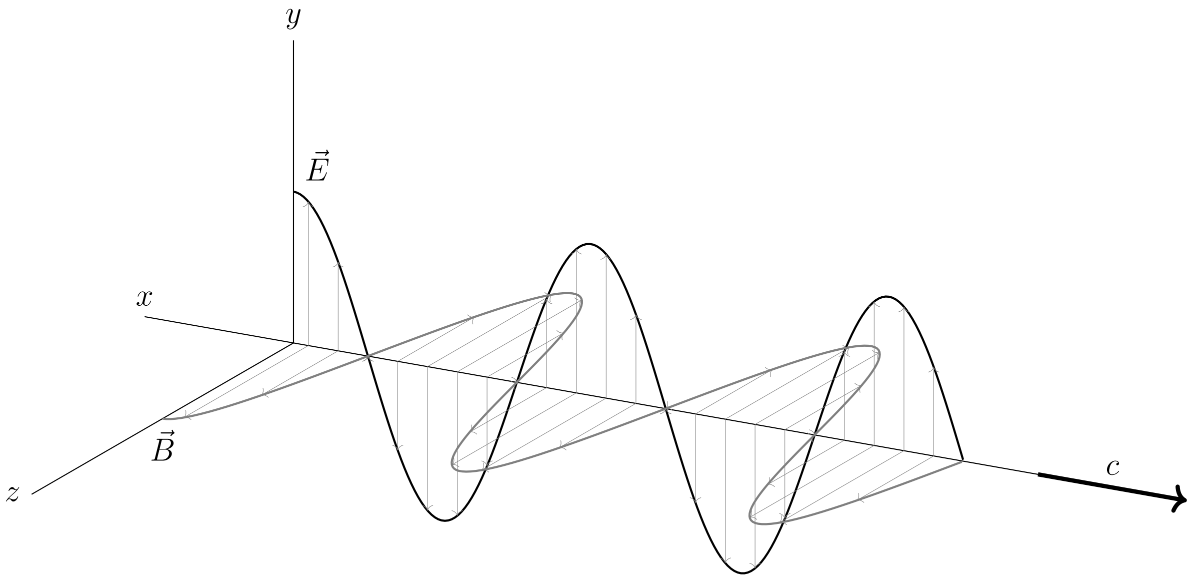
where we have:

$$\varepsilon=\varepsilon_0\varepsilon_r\,[\mathrm{A}\cdot\mathrm{s}\cdot\mathrm{V}^{-1}\cdot\mathrm{m}^{-1}]\qquad\text{and}\qquad\mu=\mu_0\mu_r\,[\mathrm{V}\cdot\mathrm{s}\cdot\mathrm{A}^{-1}\cdot\mathrm{m}^{-1}]\tag{10.3.259}$$

The propagation speed of an electromagnetic wave in vacuum is:

$$c=\frac{1}{\sqrt{\mu_0\varepsilon_0}}=\frac{1}{\sqrt{4\pi 10^{-7}\cdot 8.8542\cdot 10^{-12}}}=2.997292\cdot 10^8\,[\mathrm{m}\cdot\mathrm{s}^{-1}]\tag{10.3.260}$$

the units and numerical values agree...



$$c=\frac{E}{B}$$

$\vec{E}=$ electric field amplitude (instantaneous values)
$\vec{B}=$ magnetic field amplitude (instantaneous values)
$c=$ speed of light ($\sim 3\cdot 10^8\,[\text{m}\cdot\text{s}^{-1}]$)

$$c=\frac{1}{\sqrt{\mu_0\varepsilon_0}}$$

$\mu_0=$ magnetic permeability in vacuum, $\mu_0=\sim 1.3\cdot 10^{-6}\,[\text{N}\cdot\text{A}^{-2}]$
$\varepsilon_0=$ electric permeability in vacuum, $\varepsilon_0=\sim 8.9\cdot 10^{-12}\,[\text{C}^2\cdot\text{N}\cdot\text{m}^{-2}]$

Remark

The amplitudes of the two components of the electromagnetic waves are generally not comparable, and they are only drawn as equal for visual convenience! The reason for this is that the units of electric field and magnetic field don't generally match, so trying to compare an electric field amplitude with a magnetic field amplitude is completely meaningless. In certain unit systems this comparison can indeed be made, with the most prominent example being CGS (Centimeter, Gram, Second) units, where electric and magnetic fields have the same physical dimension and are therefore comparable; in this system the electric and magnetic field amplitudes for a plane wave are exactly equal! In other systems, such as SI units, no such comparison can be made.

The propagation velocity of the electromagnetic wave in the a material is then given by:

$$\boxed{v=\frac{1}{\sqrt{\mu_0\mu_r\varepsilon_0\varepsilon_r}}} \tag{10.3.261}$$

We have $v<c$ because experience has show so far that we can not exceed the speed of light, which is one of the postulates of Special and General Relativity.

In vacuum we have in S.I. units:

$$c=299,792.4562\pm 0.0011\,[\text{km}\cdot\text{s}^{-1}]$$

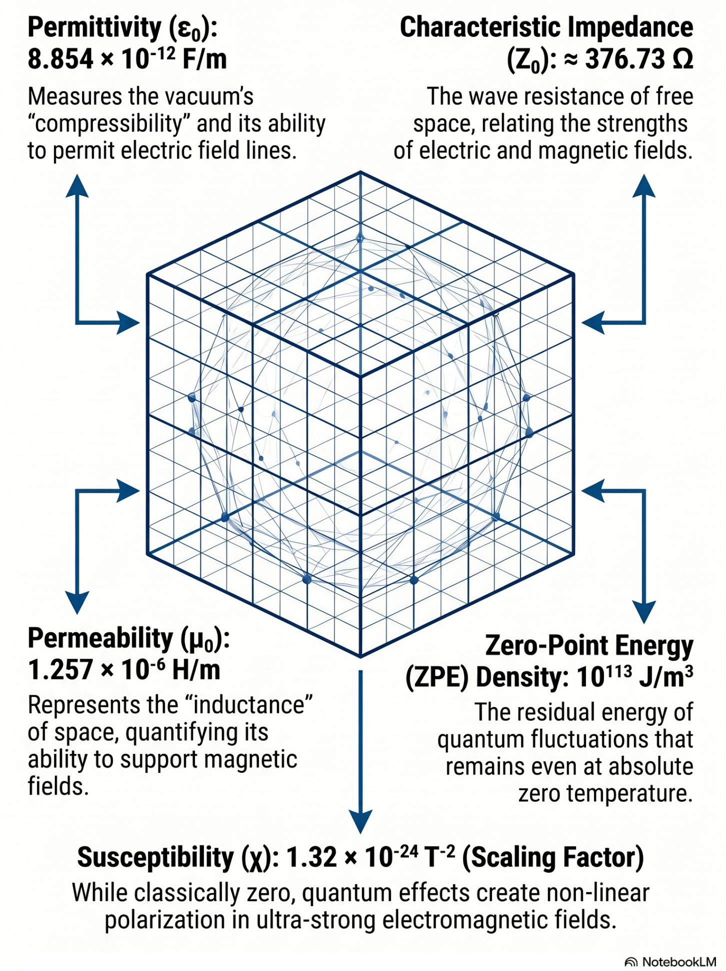
Or in imperial units (...):

$$c=186,282\,[\text{miles}],\ 698\,[\text{yards}],\ 2\,[\text{feet}],\ 5\frac{21}{127}\,[\text{inches}\cdot\text{s}^{-1}]$$

Or in natural units:

$$c = 1\,[\text{einstein}]$$

So as light propagates by self-sustaining electromagnetic wave in vacuum, we then have the obvious fact that space (or at least the electromagnetic quantum field) can be considered as a medium with at the following physical properties:



Permittivity (ε_0): 8.854 × 10^{-12} F/m

Measures the vacuum's "compressibility" and its ability to permit electric field lines.

Characteristic Impedance (Z_0): ≈ 376.73 Ω

The wave resistance of free space, relating the strengths of electric and magnetic fields.

Permeability (μ_0): 1.257 × 10^{-6} H/m

Represents the "inductance" of space, quantifying its ability to support magnetic fields.

Zero-Point Energy (ZPE) Density: 10^{113} J/m^3

The residual energy of quantum fluctuations that remains even at absolute zero temperature.

Susceptibility (χ): 1.32 × 10^{-24} T^{-2} (Scaling Factor)

While classically zero, quantum effects create non-linear polarization in ultra-strong electromagnetic fields.

Figure 10.67: Some properties of the medium "space" (vacuum) that we will see through this textbooks

Remarks

R1. In the 11970s (holocene calendar), interferometry was used to get the most accurate value for the speed of light that had been measured yet: $299,792.4562 \pm 0.0011\,[\text{km}\cdot\text{s}^{-1}]$. Then, in 11983, the meter was redefined in the International System of Units (SI) as the distance travelled by light in vacuum in $1/299,792,458$ of a second. As a result, the numerical value of the speed of light c in meters per second is now fixed exactly by the definition of the meter.

R2. The ancient Egyptian royal cubit (meh niswt) is the earliest attested standard measure of a length, and in that measurement system the speed of light is equal $571,033,253\,[\text{cubits}\cdot\text{s}^{-1}]$.

So we can finally write:

$$\begin{aligned}\frac{\partial^2 E}{\partial t^2}=c^2\frac{\partial^2 E}{\partial x^2}\Leftrightarrow\left(\frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)E=0\\ \frac{\partial^2 B}{\partial t^2}=c^2\frac{\partial^2 B}{\partial x^2}\Leftrightarrow\left(\frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)B=0\end{aligned}\tag{10.3.262}$$

Therefore using the d'Alembertian in one dimension:

$$\boxed{\begin{aligned}\Box E=0\\ \Box B=0\end{aligned}}\tag{10.3.263}$$

As we failed to get a direct expression of $E(x,t)$ and $B(x,t)$, we have just obtained differential equations containing only one of these fields. We name these equations respectively "wave equation for the electric field" and "wave equation for the magnetic field of induction".

The both equations have the same form and admit a solution of the same type. An obvious and particular solution (we leave it to the reader to make this check) of these differential equations is the sine trigonometric function:

$$\boxed{\begin{aligned}E(x,t)=\hat{E}\sin(kx-\omega t)\\ B(x,t)=\hat{B}\sin(kx-\omega t)\end{aligned}}\tag{10.3.264}$$

by not forgetting the relation between the pulsation ω, the propagation velocity c and the wave number k that we had proved in the section of Wave Mechanics!

A more general solution is the sum of the trivial solutions (see section Differential and Integral Calculus page 1607):

$$\begin{aligned}E(x,t)=\hat{E}\sin(kx-\omega t)+\hat{E}\cos(kx-\omega t)\\ B(x,t)=\hat{B}\sin(kx-\omega t)+\hat{B}\cos(kx-\omega t)\end{aligned}\tag{10.3.265}$$

But we have seen in our study of phasors (see section Wave Mechanics page 3510) that this real solution is only a particular case of a more general solution that is in the imaginary number field. So finally we can write:

$$E(x,t)=\hat{E}e^{\mathrm{i}(kx-\omega t)}\qquad B(x,t)=\hat{B}e^{\mathrm{i}(kx-\omega t)}\tag{10.3.266}$$

Which constitutes the "monochromatic plane wave" which is the simplest type of wave to manipulate in physics.

In three dimensions, the solution is by extension:

$$\vec{E}(\vec{r},t)=\vec{E}_0e^{\mathrm{i}(\vec{k}\circ\vec{r}-\omega(\vec{k})t)}\qquad \vec{B}(\vec{r},t)=\vec{B}_0e^{\mathrm{i}(\vec{k}\circ\vec{r}-\omega(\vec{k})t)}\tag{10.3.267}$$

where $\vec{k}$ is named the "propagation vector".

Remark

The monochromatic wave can has no real signification as physical reality. Indeed, if we calculate the electrical energy associated with in all space, we obtain for it an infinite energy (as it has neither beginning nor end!) Which is not realistic. We will see in the section of Wave Quantum Physics that in fact the light is enclosed in a quantum of energy.

But the wave equation is linear (solution is always the sum of other solutions). This implies that a superposition of waves of different frequencies (wave number and pulsation also!) is also a solution. Thus, by varying the wave vector $\vec{k}$ (and implicitly via its norm $\|\vec{k}\|$, pulsation ω, frequency f and period T) we also scan all the possible directions of propagation.

Written mathematically this gives, for the electric field:

$$\vec{E}(\vec{r},t)=\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\vec{E}_0(\vec{k})e^{\mathrm{i}(\vec{k}\circ\vec{r}-\omega(\vec{k})t)}\mathrm{d}^3k=\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\vec{E}_0(\vec{k})e^{\mathrm{i}(\vec{k}\circ\vec{r}-\omega(\vec{k})t)}\mathrm{d}k_x\mathrm{d}k_y\mathrm{d}k_z \tag{10.3.268}$$

And nothing prevents us from extracting a coefficient of the initial amplitude of the field such that:

$$\vec{E}(\vec{r},t)=\frac{1}{(2\pi)^{3/2}}\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\vec{E}_0(\vec{k})e^{\mathrm{i}(\vec{k}\circ\vec{r}-\omega(\vec{k})t)}\mathrm{d}^3k \tag{10.3.269}$$

and we find here a relation very similar to that of an inverse Fourier transform (see section Sequences and Series page 1758) which is a remarkable fact! So the trick is now to put $t=0$ because the previous relation is not just a simple analogy with the Fourier transform, it is a Fourier transform!!!!

We can therefore relate the real field $\vec{E}(\vec{r},0)$ to the field $\vec{E}_0(\vec{k})$:

$$\begin{aligned}\vec{E}(\vec{r},0)&=\frac{1}{(2\pi)^{3/2}}\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\vec{E}_0(\vec{k})e^{\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^3k\\ \vec{E}_0(\vec{r})&=\frac{1}{(2\pi)^{3/2}}\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty}\vec{E}(\vec{r},0)e^{\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^3k\end{aligned} \tag{10.3.270}$$

These two relations are often condensed as following:

$$\begin{aligned}\vec{E}(\vec{r},0)&=\frac{1}{(2\pi)^{3/2}}\int\limits_{-\infty}^{+\infty}\vec{E}_0(\vec{k})e^{\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^3k\\ \vec{E}_0(\vec{r})&=\frac{1}{(2\pi)^{3/2}}\int\limits_{-\infty}^{+\infty}\vec{E}(\vec{r},0)e^{\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^3k\end{aligned} \tag{10.3.271}$$

The real field is thus at the initial instant the inverse Fourier transform of the field $\vec{E}_0(\vec{k})$. The term $\vec{E}_0(\vec{k})$ therefore represents the spectral component related to the particular wave vector $\vec{k}$ of the real field. This general solution of the wave equation is named "wave packet".

Remarks

R1. Identically to our study of Wave Mechanics the coefficients ω (pulsation) and $\vec{k}$ (wave number) coefficients are required to express the variation of the sine by radians and to give it a direction and a pulsation (see section Wave Mechanics page 3479).

R2. The periodicity of the sine function requires (see section Trigonometry page 2511):

$$\sin(kx-\omega(t+T))=\sin(kx-\omega t-2\pi) \qquad (10.3.272)$$

hence the definition of the period of a wave:

$$T=\frac{2\pi}{\omega} \qquad (10.3.273)$$

R3. The periodicity in space makes it possible to define identically the wavelength of the function as:

$$\lambda=\frac{2\pi}{k} \qquad (10.3.274)$$

We thus observe that the plane wave moves along x by travelling a distance λ in a time T. The velocity of the electromagnetic wave is then:

$$v=\frac{\lambda}{T}=c \qquad (10.3.275)$$

By introducing:

$$\begin{aligned}E(x,t)&=\hat{E}\sin(kx-\omega t)=\hat{E}\sin(k(x-ct))\\B(x,t)&=\hat{B}\sin(kx-\omega t)=\hat{B}\sin(k(x-ct))\end{aligned} \qquad (10.3.276)$$

Into the one dimensional version of:

$$\frac{\partial\vec{E}}{\partial t}=-\frac{\partial\vec{B}}{\partial t} \qquad (10.3.277)$$

we get:

$$\hat{E}k\cos(k(x-ct))=-\hat{B}(-kc)\cos(k(x-ct)) \qquad (10.3.278)$$

to finally obtain the famous result for the plane electromagnetic wave:

$$\boxed{\frac{\hat{E}}{\hat{B}}=c} \qquad (10.3.279)$$

Now let us generalize the above two relations as:

$$\begin{aligned}\vec{E}(x,t)&=\vec{E}_0e^{\mathrm{i}(\vec{k}\circ\vec{r}-\omega t)}\\\vec{B}(x,t)&=\vec{B}_0e^{\mathrm{i}(\vec{k}\circ\vec{r}-\omega t)}\end{aligned} \qquad (10.3.280)$$

We can see that the Maxwell relation impose other constraints in that case like:

$$\begin{aligned}\vec{\nabla}\circ\vec{E}=0 &\Longrightarrow \frac{\partial E_x}{\partial x}+\frac{\partial E_y}{\partial y}+\frac{\partial E_z}{\partial z}=0\\ &\Longrightarrow \mathrm{i}k_xE_x+\mathrm{i}k_yE_y+\mathrm{i}k_zE_z=0\\ &\Longrightarrow \vec{k}\circ\vec{E}=0\end{aligned} \tag{10.3.281}$$

This says that $\vec{E}$ is always perpendicular to $\vec{k}$.

Using $\vec{\nabla}\circ\vec{B}=0$ we get the analogous result for $\vec{B}$, namely:

$$\vec{k}\circ\vec{B}=0 \tag{10.3.282}$$

We also have then:

$$\begin{aligned}\nabla\times\vec{E}=-\frac{\partial\vec{B}}{\partial t} &\Longrightarrow \left(\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\right)\times\vec{E}=-\frac{\partial\vec{B}}{\partial t}\\ &\Longrightarrow (\mathrm{i}k_x,\mathrm{i}k_y,\mathrm{i}k_z)\times\vec{E}=-(-\mathrm{i}\omega)\vec{B}\\ &\Longrightarrow \vec{k}\times\vec{E}=\omega\vec{B}\end{aligned} \tag{10.3.283}$$

Therefore we get a quite famous relation used in optics and plasma physics:

$$\vec{B}=\frac{\vec{k}\times\vec{E}}{\omega}=\frac{\vec{k}\times\vec{E}}{ck} \tag{10.3.284}$$

10.3.4.1 Foucault light speed experiment

In 11850 (holocene calendar), Léon Foucault used a rotating mirror to perform a differential measurement of the speed of light in water versus its speed in air. In 11862 (holocene calendar), he used a similar apparatus to measure the speed of light in the air[4]. His published values in 11862 (holocene calendar) was $c=298,000\,[\mathrm{m}\cdot\mathrm{s}^{-1}]$ and was thought to be accurate to about $500\,[\mathrm{m}\cdot\mathrm{s}^{-1}]$

The Foucault experiment, conducted by Léon Foucault in 11850 (holocene calendar), is another clever method to measure the speed of light. Here's an intuitive explanation:

- Imagine a light source, a rotating mirror, and a fixed mirror placed some distance away. The light source sends a beam of light towards the rotating mirror.
- The rotating mirror reflects the light beam towards the fixed mirror. The fixed mirror then reflects the light back to the rotating mirror, which has rotated slightly in the meantime.
- Because the rotating mirror has moved during the time it takes for the light to travel to the fixed mirror and back, the returning light beam is reflected at a slightly different angle.

---

[4] In 11848-49 (holocene calendar), Hippolyte Fizeau used a toothed wheel apparatus to perform an absolute measurement of the speed of light in air.

- By measuring the angle of displacement of the returning light beam and knowing the speed at which the mirror is rotating, Foucault could calculate the time it took for the light to make the round trip.
- Using the distance between the mirrors and the time calculated from the angular displacement, Foucault was able to determine the speed of light.

This experiment was significant because it provided a more accurate measurement of the speed of light and demonstrated that light travels slower in water than in air, supporting the wave theory of light.

The value, published by his collaborators after his death in 11935 (holocene calendar) was $c=299,774\,[\text{m}\cdot\text{s}^{-1}]$ and had a stated "average deviation" of $11\,[\text{m}\cdot\text{s}^{-1}]$. It was incorporated in a collection of physical constants and, for over a decade, the velocity of light was quoted as $c=299,774\pm 4\,[\text{m}\cdot\text{s}^{-1}]$. The striking feature of this measurement and the one most relevant to the aims of this experiment is that the stated result differs from the modern value by $19\,[\text{m}\cdot\text{s}^{-1}]$, over four times the stated uncertainty.

The Swiss company PASCO® scientific sells for schools a complete speed of light apparatus already made for the price of almost $8,000$ USD to measure the speed of light still using multiple mirrors (among them on rotated at a rate between 0 and $1,500$ revolutions pers second), lenses and a LASER:

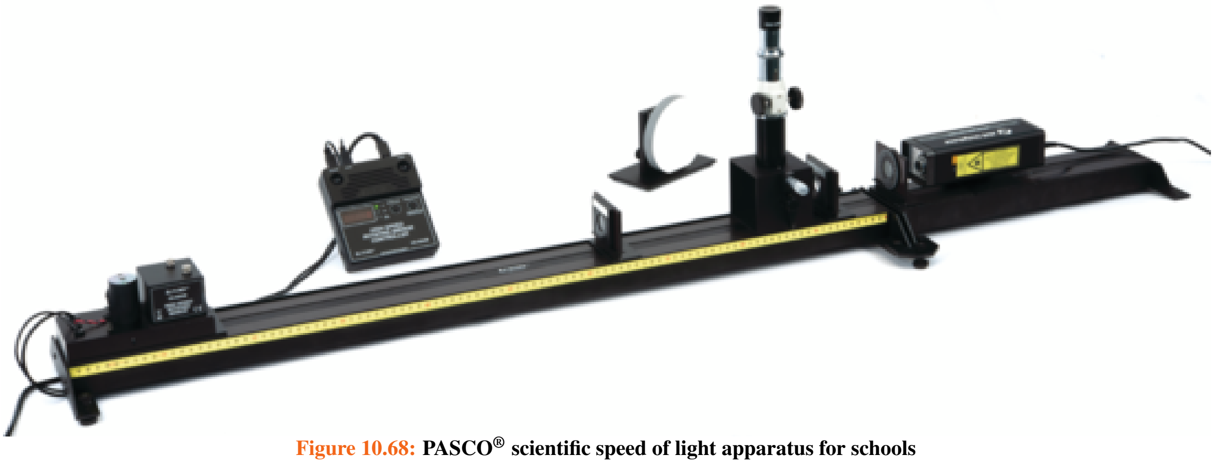


Figure 10.68: PASCO® scientific speed of light apparatus for schools

Notice that various methods were used accrossed recent history to measure the speed of light and using different experimental ideas:

- Ole Rømer was a Danish astronomer who was observing the orbital motion of Io (one of the four satellites of Jupiter), when he determined the speed of light in 11675 (holocene calendar) being $c\cong 200,000\,[\text{km}\cdot\text{s}^{-1}]$.
- James Bradley was a british astronomer who used stellar aberration to calculate the relative speed of light, when he determined the speed of light in 11728 (holocene calendar) being $c\cong 301,000\,[\text{km}\cdot\text{s}^{-1}]$.

- Hippolyte Louis Fizeau was an french physicist who used optics and carefully manipulated toothed wheel to investigate the speed of light, when he determined the speed of light in 11849 (holocene calendar) being $c \cong 313,000\,[\text{km}\cdot\text{s}^{-1}]$.
- Leon Foucault was an french physicist who used optics and carefully manipulated rotating mirror to investigate the speed of light, when he determined the speed of light in 11849 (holocene calendar) being $c \cong 298,000\,[\text{km}\cdot\text{s}^{-1}]$.
- Edward Bennett Rosa and Noah Ernest Dorsey both american physicists used the electric permittivity (ε) and magnetic permeability (μ) constants to calculate the speed of light thanks to the work of James Clerk Maxwell, when he determined the speed of light in 11907 (holocene calendar) being $c \cong 299,788\,[\text{km}\cdot\text{s}^{-1}]$.
- Keith Davy Froom was a british physicist that studied the interference pattern of radiowaves to obtain the speed of light thanks again to the work of James Clerk Maxwell, when he determined the speed of light in 11958 (holocene calendar) being $c \cong 299,972.500\,[\text{km}\cdot\text{s}^{-1}]$.
- Evenson et al used LASERs with high spectral stability to measure the speed of light. Like Froome, this experiment also involved interferometry to measure the wavelength of light, , when they determined the speed of light in 11973 (holocene calendar) being $c \cong 299,972.457\,[\text{km}\cdot\text{s}^{-1}]$.

Before going into the details of the Swiss PASCO® scientific speed of light apparatus experiment, it must be emphasized that the primary objective of this experiment is to understand the operation of the apparatus well enough to derive a value for the precision with which c can be measured by the apparatus, not to obtain a value of c equal to the defined value.

A diagram of the clever experimental setup is shown in the figure below when the system is static (at the beginning of the experiment we have to calibrate the setup):

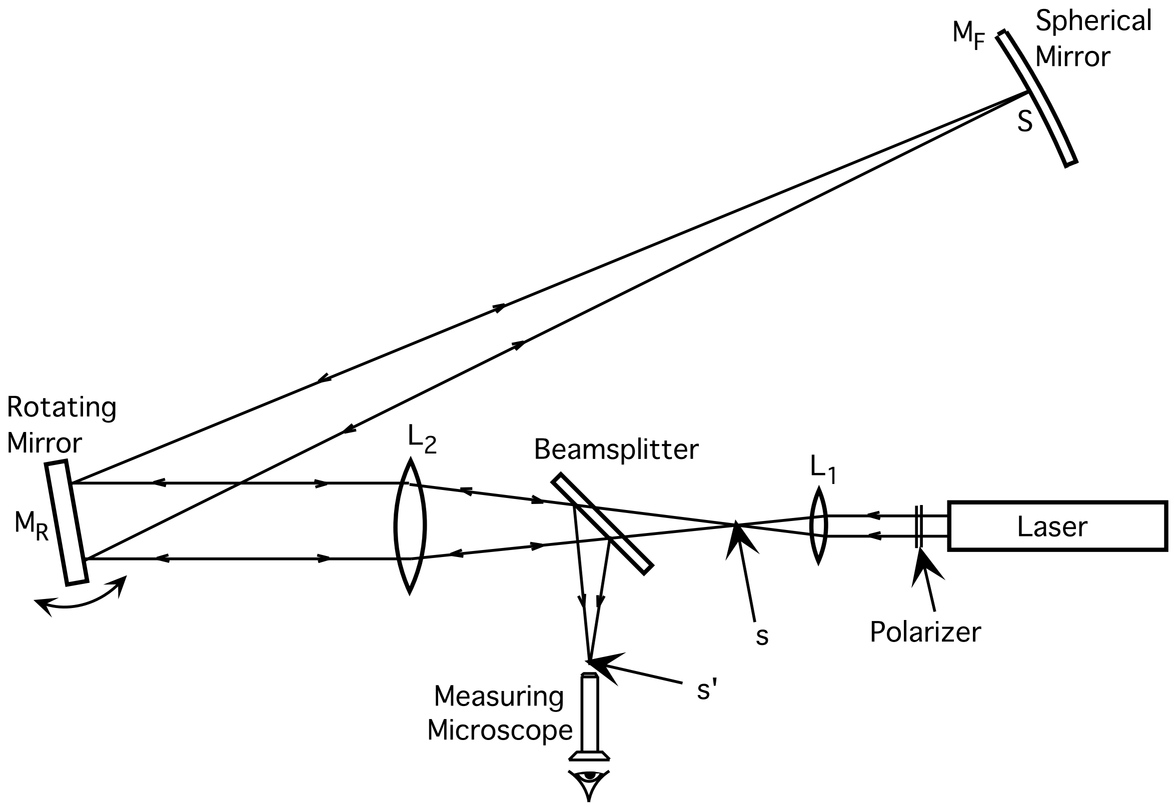

Figure 10.69: Schematic of the PASCO® scientific speed-of-light apparatus

With all the equipment properly aligned and with the rotating mirror stationary, the optical path is as follows:

The parallel beam of light from the LASER is focused to a point s by lens L_1. Lens L_2 is positioned so that light from the image at s is reflected from the rotating mirror M_R, and is refocused onto the fixed, spherical mirror M_F with a radius of curvature of 13.5 meters (remember that a spherical mirror return all the light coming from its center back at its center assimilated to the focal). M_F reflects the light back along the same path and L_2 focuses it at point s. In order that the reflected point image can be viewed through the microscope, a beamsplitter is placed in the optical path, so a reflected image of the returning light is also formed at point s'.

The lens and mirror optics are designed so that light coming from s and reflected from M_F is again focused at s. This must continue to be true even if M_R is rotated slightly and the beam strikes M_F at a different point on its surface. Because s is focused on M_F, the spot on M_F is the image of s. Since light rays through any optical system are reversible, light coming from the image on M_F will pass through the object at s just as light from the source at s passes through the image spot on M_F. The spherical shape of the mirror is important for two reasons. The first is that the light rays from s are directed nearly as though they came from the center of curvature of M_F. Light originating from the center of curvature will be reflected back on itself, so the return beam will again pass through L_2. The second is that the optical path length is nearly independent of the position of the spot on M_F. It helps if the length of the optical path from s to M_F is close to 13.5 [m] (approximately the radius of curvature of the Mirror M_F) , the radius of curvature of M_F, although the shorter path available in the lab does not present a significant problem. In all rotating mirror experiments, image quality is an important issue, especially if, as was the case for Michelson, the optical path includes a mile or so of wavy air. In summary, the spherical shape of M_F, ensures that the beam will be reflected directly back toward M_R and the return image of the source point will be formed at points s and s'.

Now imagine that M_R is rotating continuously. In this case, the return image of the source point will obviously no longer be formed at the same points s and s' that is was when the mirror was stationary. A light pulse that travels from M_R to M_F and back now finds M_R at a different angle when it returns than when it was first reflected. As shown in the following derivation, the velocity of light can be determined by measuring the displacement of the image point caused by the rotation of M_R.

To begin the derivation, we will first look at a simplified and exaggerated form of the optical system consisting of only the rotating mirror M_R and the fixed mirror M_F, as shown in the figure below:

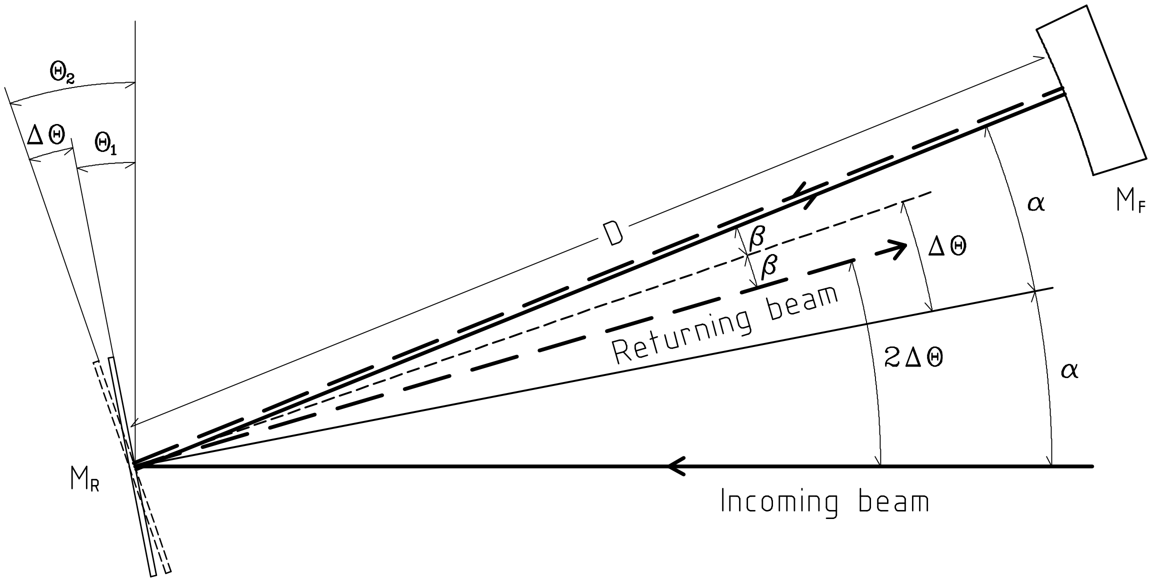

Figure 10.70: **Simplified diagram of the speed-of-light optics showing the important angles**

A LASER is aligned to create a pencil of light to hit the rotating mirror: the "incoming beam" in the figure above. Now think of a small piece of the beam, or "packet" of light which strikes M_R when the mirror is at angle Θ_1. The packet is reflected and follows the path denoted by the thick solid lines, making incident and reflected angles α relative to the normal of the mirror M_R. The packet of light hits the fixed spherical mirror M_F and is reflected directly back towards M_R. When it reaches M_R, the mirror has rotated to a new angle Θ_2, and so the angles of incidence and reflection off of M_R on this return trip are different; the new path is denoted by the thick dashed lines, and the new incident and reflected angles are β. Thus, because the light takes time to make the round trip between M_R and M_F, the "returning beam" of light is tilted away from the path of the "incoming beam".

The difference between the mirror's angle governing the outgoing path Θ_1 and that governing the return path Θ_2 will be denoted $\Delta\Theta$. There are a couple of ways to convince yourself that the angle between the returning beam and the incoming beam, what we will name the "deflection angle", should be twice this angle, i.e. $2\Delta\Theta$.

First, whenever the mirror angle changes, both the incident angle and the reflected angle change by the same amount, so if the mirror angle changes by $\Delta\Theta$, then the path of the light must change by $2\Delta\Theta$.

Another way to see this is by a direct calculation from the figure above. It is clear by inspection of the figure that the deflection angle is $2\alpha-2\beta$. It is also clear that $\beta=\alpha-\Delta\Theta$ (looking at the upper angle α in the figure). Thus the deflection angle is:

$$2\alpha-2\beta=2\alpha-2(\alpha-\Delta\Theta)=2\Delta\Theta \qquad (10.3.285)$$

Now, what is the relationship between the deflection angle and the speed of light??

During the time interval Δt, the mirror moves by an angle $\Delta\Theta$, and the light packet travels a round trip distance of $2D$ where D is the distance between M_R and M_F. Let us choose now a time Δt such that the light travels the distance:

$$2D=c\Delta t \qquad (10.3.286)$$

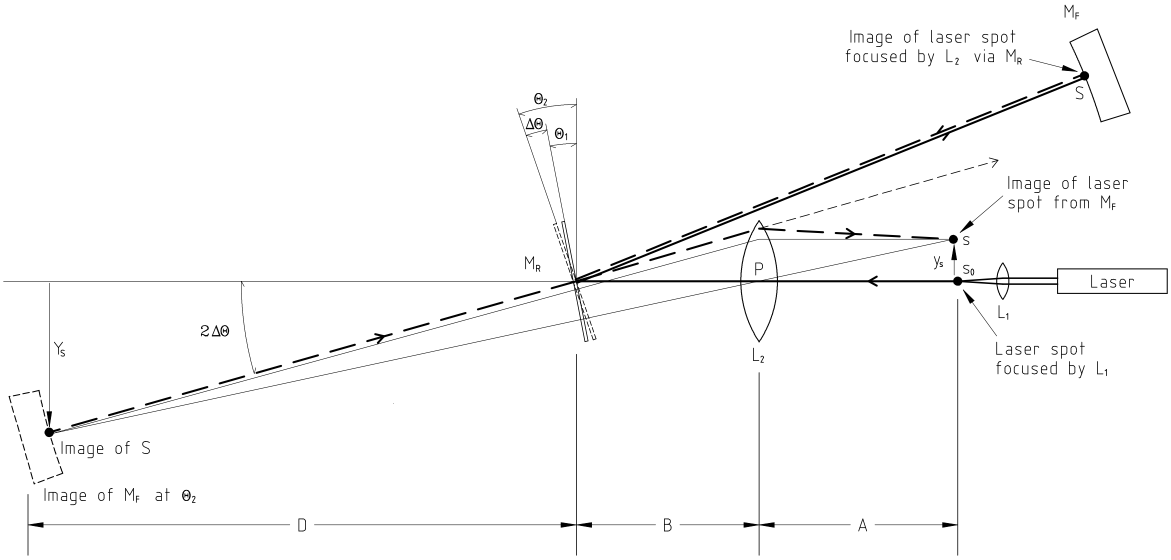
During that same time, as the mirror rotation speed being ω, we also have:

$$\Delta\Theta=\omega\Delta t \qquad (10.3.287)$$

When we combine these equations, we get for the deflection angle:

$$2\Delta\Theta=\frac{4D\omega}{c} \qquad (10.3.288)$$

This relations gives that if we measure the deflection angle $2\Delta\Theta$ for a known rotation speed ω and a known separation distance D, we can then calculate c.



In our apparatus, the distance D is conveniently measured with a tape measure, and the rotation speed is measured with an electronic tachometer that is part of the rotating-mirror device. We measure the deflection angle by means of the additional optics shown in the first figure above.

To reiterate the action of these components: Lens L_1 focuses the light from the LASER to a spot located at point s. The (real) image of this spot is created by lens L_2 at the surface of M_F at point S. This image, in turn, acts as the object that is focused by L_2 back towards s. But before the light from the round trip can return to the point s, it is reflected by the beamsplitter to be focused to a spot s' in front of the measuring microscope.

From the point of view of the observer looking through the microscope, the lens L_2 acts on light coming from the image of the fixed mirror M_F which is created by the moving mirror M_R. A diagram showing this image is given in the figure above. As shown in the figure, the light from the LASER is focused to a point s_0, and the image of this point is created by the lens L_2 at the fixed mirror surface at S when the mirror is at Θ_1. The observer sees the returning light when the mirror is at angle Θ_2; the light appears to follow the path denoted by the thick dashed lines. The image of the spot at S appears to be coming from a point displaced from the horizontal by a distance Y_S. The light from this (apparent) point is refracted by the lens L_2 and creates a real image of S at the point s that is displaced from the original spot s_0 by a distance y_s. By using the beamsplitter and microscope, one can measure the displacement of the image at s from the (original) "object" at s_0.

The dimensions and angles shown in the figure above are not to scale. In fact, the angle $2\Delta\Theta$ is typically very small about 0.1° or less. We can use this fact to allow us to calculate the angle $2\Delta\Theta$ in terms of the vertical distance y_s. By geometry, in the small-angle limit, the vertical distance Y_S, is given by:

$$Y_S \cong D \cdot 2\Delta\Theta \qquad (10.3.289)$$

By means of the construction rays used to locate the image of S at the point s, which are the thin lines going through the lens L_2 centered at the point P, we can see by similar triangles located about P that:

$$\frac{Y_S}{D+B} = \frac{y_s}{A} \qquad (10.3.290)$$

By the two previous relations, we get:

$$2\Delta\Theta \cong y_s \frac{D+B}{AD} \qquad (10.3.291)$$

If we eliminate $\Delta\Theta$ by combining the previous relation with $2\Delta\Theta = 4D\omega/s$ obtained earlier above, we get a relatinship for the speed of light in terms of measurable quantities:

$$c \cong \frac{4AD^2}{D+B}\left(\frac{\omega}{y_s}\right) \qquad (10.3.292)$$

Or as we will measure y_s as function of ω it makes more sense to write the latter as:

$$y_s \cong \frac{1}{c}\frac{4AD^2}{D+B}\omega \qquad (10.3.293)$$

Any change in y_s will be reflected into a change in s', the position of the spot as seen through the microscope, in an exactly proportional manner. In this experiment, we can get better results by plotting s' versus ω.

With the data obtained experimentally we get by statistical interpolation a straight line $y_s=f(\omega)$ whose slope is:

$$\frac{1}{c}\frac{4AD^2}{D+B} \tag{10.3.294}$$

where:

- c is the speed of light
- A is the distance between lens L_2 and lens L_1 minus the focal length of L_1
- B is the distance between lens L_2 and the rotating mirror (M_R)
- D is the distance between the rotating mirror (M_R) and the fixed mirror (M_F)
- s' is the position of the image point as viewed through the microscope.
- ω the rotational velocity of the rotating mirror (M_R)

To get therefore the statistical estimate of c we just have to inverse this slope and multiply it by the geometric factor of our experiment $(4AD^2/(D+B))$.

The relation above was derived on the assumption that the image point is the result of a single, short pulse of light from the LASER. But the displacement of the image point depends only on the difference in the angular position of M_R in the time it takes for the light to travel between the mirrors. The displacement does not depend on the specific mirror angles for any given pulse. If we think of the continuous LASER beam as a series of infinitely short pulses, the image due to each pulse will be displaced by the same amount. All these images displaced by the same amount will, of course, result in a single image. By measuring the displacement of this image, the rate of rotation of M_R, and the relevant distances between components, the speed of light can be measured.

10.3.4.2 Helmholtz equation

Now let us examine in detail another solution of the form:

$$E_y(x,t)=E_0\cos(\omega t+\varphi) \tag{10.3.295}$$

where this time we make explicit mention of the coordinates in order to avoid any confusion.

> **Remark**
>
> The particular solution with the cosine is more appreciated by many teachers than the one with the sine, as it allows, as we will see, a condensed writing using the phasors (see section Wave Mechanics page 3510).

If we use the concept of phasor, we can rewrite this solution in the form:

$$E_y(x,t)=E_0\cos(\omega t+\varphi)=\Re(E_0e^{\mathrm{i}(\omega t+\varphi)})=\Re(E_0e^{\mathrm{i}\varphi}e^{\mathrm{i}\omega t})=\Re(\tilde{E}_ye^{\mathrm{i}\omega t}) \tag{10.3.296}$$

Therefore:

$$\frac{\partial^2 E_y(x,t)}{\partial t^2}=\frac{\partial^2 \Re(\tilde{E}_y e^{\mathrm{i}\omega t})}{\partial t^2}=-\omega^2 \Re(\tilde{E}_y e^{\mathrm{i}\omega t}) \tag{10.3.297}$$

into the wave equation:

$$\frac{\partial^2 E_y(x,t)}{\partial t^2}=\frac{1}{\mu\varepsilon}\frac{\partial^2 E_y(x,t)}{\partial x^2} \tag{10.3.298}$$

we get:

$$\frac{\partial^2 E_y(x,t)}{\partial t^2}=-\omega^2\mu\varepsilon \Re(\tilde{E}_y e^{\mathrm{i}\omega t}) \tag{10.3.299}$$

which is nothing else that one the "one-dimensional Helmholtz equation for electrodynamics". It is just a special way to write the conventional Helmholtz that is traditional in this field of physics.

More generally in undergraduate courses it is defined using the prior previous wave equation and rearranging it as following:

$$\frac{\partial^2 E_y(x,t)}{\partial x^2}-\mu\varepsilon\frac{\partial^2 E_y(x,t)}{\partial t^2}=0 \tag{10.3.300}$$

and using the property established earlier above:

$$\frac{\partial^2 E_y(x,t)}{\partial x^2}-c^2\frac{\partial^2 E_y(x,t)}{\partial t^2}=0 \tag{10.3.301}$$

But we can write it for the three dimension case also:

$$\sum_{i=1}^{3}\frac{E_i(\vec{r},t)}{\partial x_i^2}-k^2\frac{\partial^2 E(\vec{r},t)}{\partial t^2}=0 \tag{10.3.302}$$

And using the laplacian operator (see section Vector Calculus page 1903):

$$\nabla^2 E(\vec{r},t)-k^2\frac{\partial^2 E(\vec{r},t)}{\partial t^2}=0 \tag{10.3.303}$$

Factorized:

$$\left(\nabla^2-k^2\frac{\partial}{\partial t^2}\right)E(\vec{r},t)=0 \tag{10.3.304}$$

And as it is also valid for the magnetic field we can generalize the notation a last time:

$$\left(\nabla^2-k^2\frac{\partial}{\partial t^2}\right)f(\vec{r},t)=0 \tag{10.3.305}$$

to get the "homogeneous wave equation" (as the second term is zero).

This done, separation of variables (see section Differential and Integral Calculus page 1617) begins by assuming that the wave function $f(\vec{r},t)$ is in fact separable:

$$f(\vec{r},t)=A(\vec{r})T(t) \tag{10.3.306}$$

Substituting this form into the homogeneous wave equation, and then simplifying, we get immediately the following equation:

$$\frac{\nabla^2 A}{A}=\frac{k^2}{T}\frac{\mathrm{d}^2 T}{\mathrm{d}t^2} \tag{10.3.307}$$

Notice the expression on the left-hand side depends only on $\vec{r}$, whereas the right-hand expression depends only on t. As a result, this equation is valid in the general case if and only if both sides of the equation are equal to a constant value that we will denote by C. From this observation, we obtain two equations, one for $A(\vec{r})$, the other for $T(t)$:

$$\frac{\nabla^2 A}{A}=c^{te} \qquad \text{and} \qquad \frac{k^2}{T}\frac{\mathrm{d}^2 T}{\mathrm{d}t^2}=C \tag{10.3.308}$$

Rearranging the first equation, we get the famous "general homogeneous Helmholtz equation:

$$\boxed{(\nabla^2-C)A(\vec{r})=0} \tag{10.3.309}$$

and this is the common general "Helmholtz equation" partial differential equation.

Remark

If in the Helmholtz equation we put $C=0$ we get:

$$\nabla^2 A(\vec{r})=0 \tag{10.3.310}$$

More commonly denoted:

$$\boxed{\nabla^2\varphi=0} \tag{10.3.311}$$

and named the "Laplace's equation". It is therefore a special case of the Poisson's equation but where the second member is equal to zero.

Let us found a famous solution of the Helmholtz equation used in the framework of the Michelson interferometer!

Let us choose for example $C=k^2$ with as traditionally $k=\omega/c$ and lets see if we can found a solution to:

$$\left(\nabla^2+k^2\right)E(x,y,z)=0 \tag{10.3.312}$$

Let us consider waves that are propagating principally along the z-axis:

$$E(x,y,z)=E_0\psi(x,y,z)e^{-\mathrm{i}kz} \tag{10.3.313}$$

where ψ describes complex transverse profile, and its variation with propagation.

Plug into Helmholtz equation:

$$\nabla E=\left[(\nabla\psi)e^{-\mathrm{i}kz}-(\mathrm{i}k\psi_{\hat{z}})\,e^{-\mathrm{i}kz}\right]E_0 \tag{10.3.314}$$

Hence:

$$\nabla^2 E=\left[\left(\nabla^2\psi\right)e^{-\mathrm{i}kz}-2\mathrm{i}k\hat{z}(\nabla\psi)e^{-\mathrm{i}kz}-k^2\psi e^{-\mathrm{i}kz}\right]E_0 \tag{10.3.315}$$

$$\left(\nabla^2+k^2\right)E=E_0\left\{\nabla^2\psi-2\mathrm{i}k\frac{\partial\psi}{\partial z}\right\}e^{-\mathrm{i}kz}=0 \tag{10.3.316}$$

Let's consider a "paraxial wave" (waves are perpendicular to the wavefront, i.e. the propagation essentially along the z axis that is sometimes denoted therefore R):

$$E(\vec{r})=A\frac{e^{-\mathrm{i}kr}}{r} \tag{10.3.317}$$

with $r=\sqrt{x^2+y^2+R^2}$. But we have obviously:

$$r=\sqrt{x^2+y^2+z^2}=z\left(1+\frac{x^2+y^2}{z^2}\right)^{1/2} \tag{10.3.318}$$

Hence:

$$E(\vec{r})=A\frac{e^{-\mathrm{i}kr}}{r}=\frac{A}{z\sqrt{1+\frac{x^2+y^2}{z^2}}}e^{-\mathrm{i}k\left(1+\frac{x^2+y^2}{z^2}\right)^{1/2}} \tag{10.3.319}$$

We apply now the paraxial approximation again, i.e. we consider the region near the z axis, such that:

$$x^2+y^2\ll z^2 \tag{10.3.320}$$

Hence (we used a Macalaurin approximation in the exponential):

$$E(\vec{r})\cong\frac{A}{z}e^{-\mathrm{i}kz\left(1+\frac{x^2+y^2}{2z^2}\right)} \tag{10.3.321}$$

Where we have neglected $\left(x^2+y^2\right)/z^2$ in the denominator, since it's just a tiny change in the amplitude, but we kept the first-order correction term in the phase in the exponential, since even a small charge in the exponent can change the phase noticeably.

This approximation is often named the "Fresnel approximation". At $z=R$, we have:

$$E(\vec{r})\cong A\frac{e^{-\mathrm{i}kR}}{R}e^{-\mathrm{i}k\left(x^2+y^2\right)/2R} \tag{10.3.322}$$

This is sometimes named a "paraboloidal wave". It's almost a spherical wave, but has a phase that varies quadratically in the transverse direction.

And now the nice thing is that if the reader remembers that the Helmholtz equation is obtained by a simple separation of variables (one function of position and another of time) of the function of the homogeneous wave equation. Therefore:

$$\boxed{E(\vec{r})\cong A\frac{e^{-\mathrm{i}kR}}{R}e^{-\mathrm{i}k\left(x^2+y^2\right)/2R}e^{\mathrm{i}\omega t}} \tag{10.3.323}$$

is a solution the homogeneous wave equation. Also sometimes denoted:

$$E_i(\rho,t)\cong\frac{A}{R}e^{\mathrm{i}\left(\omega t-k\left(R_i+\rho^2/2R_i\right)\right)} \tag{10.3.324}$$

where A is the amplitude, R is an average distance, ω is the angular frequency, $\boldsymbol{k}$ is the wave vector $k=2\pi/\lambda$, and $\rho=\left(x^2+y^2\right)^{1/2}$. The subscript i is specific to each source if there are multiple one.

10.3.4.3 Energy flow transportation (Poynting vector)

It is relatively intuitive that any electromagnetic wave must carry energy. Let us express the value of this energy in a classical (non-probabilistic and non-quantum) point of view.

Since the propagation direction of an electromagnetic wave is that of the vector $\vec{E}\times\vec{B}$ as proven earlier above, we can define the "Poynting vector" as:

$$\boxed{\vec{S}=\frac{1}{\mu_0}\vec{E}\times\vec{B}} \tag{10.3.325}$$

named sometimes the "Abraham form" and whose value is expressed indeed in joules per second and per unit area (radiated power by surface unit) as $[\mathrm{J}\cdot\mathrm{s}^{-1}\cdot\mathrm{m}^{-2}]$.

The norm of the Poynting vector represents therefore the instantaneous power which is transported by the electromagnetic wave through a unitary perpendicular surface (we insist on the "perpendicular") to its direction of propagation. Therefore, we can also write the Poynting vector in the following form (be careful not to confuse the energy and the electric field which are represented by the same letter):

$$P=\frac{\mathrm{d}E}{\mathrm{d}t}=\frac{1}{\mu}\oint_S(\vec{E}\times\vec{B})\circ\mathrm{d}\vec{S}=c^2\varepsilon_0\oint_S(\vec{E}\times\vec{B})\circ\vec{n}\mathrm{d}S \tag{10.3.326}$$

where $\vec{n}$ is as usual the unit vector perpendicular to $\mathrm{d}S$ (this last relation will be useful to study a small property of the synchrotron radiation further below).

For a plane electromagnetic wave, the norm of the Poynting vector is:

$$S(x,t)=\frac{E(x,t)B(x,t)\sin\left(\dfrac{\pi}{2}\right)}{\mu_0}=\frac{\hat{E}\hat{B}}{\mu_0}\sin^2(kx-\omega t)=\frac{\hat{E}^2}{\mu_0 c}\sin^2(kx-\omega t) \tag{10.3.327}$$

This quantities varies according to time and place. At a given location, its average value is the mean value of the $\sin^2(\ldots)$ for a period T:

Let us recall that (see section Differential and Integral Calculus page 1534):

$$\frac{1}{T}\int_0^T\sin^2(\omega T)\mathrm{d}t=\frac{1}{T}\left[\frac{1}{2}\int_0^T\mathrm{d}t-\frac{1}{2}\int_0^T\cos(2\omega t)\mathrm{d}t\right]=\frac{1}{T}\left[\frac{T}{2}-\frac{1}{2}\left[\frac{1}{2\omega}\sin(2\omega t)\right]_0^T\right]=\frac{1}{2} \tag{10.3.328}$$

Therefore $\forall x$ we have:

$$\boxed{\bar{S}=\frac{\hat{E}\hat{B}}{2\mu_0}=\frac{\hat{E}^2}{2\mu_0 c}=\frac{c\hat{B}^2}{2\mu_0}} \tag{10.3.329}$$

The average value of the Poynting vector of a plane electromagnetic wave is a constant ... which does not depend on position and time.

There is another way to express the energy density that will be useful to us during our study of plasma (especially of ionospheric propagation)! Indeed, using the relations proved earlier we have:

$$\vec{S}=\frac{1}{\mu_0}\vec{E}\times\vec{B}=\frac{1}{\mu_0}\vec{E}\times\left(\frac{\vec{k}\times\vec{E}}{\omega}\right)=\frac{1}{\mu_0\omega}\vec{E}\times\vec{k}\times\vec{E} \tag{10.3.330}$$

Using the triple cross product identity (see section Vector Calculus page 1835), we get:

$$\vec{S}=\frac{1}{\mu_0\omega}\vec{E}\times\vec{k}\times\vec{E}=\frac{1}{\mu_0\omega}\left[\left(\vec{E}\circ\vec{E}\right)\vec{k}-\left(\vec{E}\circ\vec{k}\right)\vec{E}\right] \tag{10.3.331}$$

However we have proven just above that $\vec{k}$ is perpendicular to $\vec{E}$, therefore $\vec{E}\circ\vec{k}=0$, hence:

$$\vec{S}=\frac{1}{\mu_0\omega}\left[\left(\vec{E}\circ\vec{E}\right)\vec{k}-\left(\vec{E}\circ\vec{k}\right)\vec{E}\right]=\frac{1}{\mu_0\omega}\left(\vec{E}\circ\vec{E}\right)\vec{k}=\frac{E^2}{\mu_0\omega}\vec{k} \tag{10.3.332}$$

Remark

We can make a daring and fun analogy with electrokinetics by doing a dimensional analysis of the above product $\mu_0 c$. We have:

$$\mu_0 c=\sqrt{\frac{\mu_0}{\varepsilon_0}}\cong 377\,[\Omega] \tag{10.3.333}$$

... to demonstrate the energy contained in a unit of volume pragmatic physicists would do a dimensional analysis. Let us avoid this and focus ourselves with the special case of the plane wave!

For this purpose we base ourselves on the electrical energy of an ideal plane capacitor (see section Electrostatics page 3997) producing plane electromagnetic waves with a yield of 100%:

$$E_C=\frac{1}{2}CU=\frac{1}{2}\left(\frac{S\varepsilon}{L}\right)(\hat{E}^2L^2)=\frac{1}{2}SL\varepsilon\hat{E}^2=\frac{1}{2}V\varepsilon\hat{E}^2 \tag{10.3.334}$$

Therefore:

$$\frac{E_C}{V}=\frac{1}{2}\varepsilon\hat{E}^2=\frac{1}{2}\varepsilon_0\varepsilon_r\hat{E}^2 \tag{10.3.335}$$

and that is denoted in most textbooks by:

$$\boxed{u_E=\frac{1}{2}\varepsilon\hat{E}^2} \tag{10.3.336}$$

from which we get:

$$\boxed{u_B=\frac{1}{2\mu}\hat{B}^2} \tag{10.3.337}$$

And the total energy transported by the electromagnetic wave in this particular case is thus:

$$\boxed{u_{\text{tot}}=\frac{1}{2}\varepsilon\hat{E}^2+\frac{1}{2\mu}\hat{B}^2=\frac{1}{2}\varepsilon\hat{E}^2+\frac{1}{2\mu c^2}\hat{E}^2=\varepsilon\hat{E}^2=\frac{1}{\mu}\hat{B}^2} \tag{10.3.338}$$

Therefore, the electrical energy density of an electromagnetic wave is equal to its magnetic energy density. For the power we just multiply by c to get:

$$P_{\text{tot}}=c\varepsilon\hat{E}^2=\frac{c}{\mu}\hat{B}^2 \tag{10.3.339}$$

Remarks

R1. Notice that the intensity of an electromagnetic wave is then only related to its amplitude and not its frequency!!!! So if a light source is kept at the same amplitude and the wave length is reduced, its intensity remain the same even though its photons now carry more energy!

R2. Keep in mind that the Planck's relation $E=h\nu$ is for a single photon and the amplitude of Electric field and Magnetic field of the electromagnetic weave is a classical term in classical electromagnetism and is available only for multiple photons. In quantum electrodynamics the so named "amplitude" (simplistically) flutuates. In essence the photons collectively generate the electric and the magnetic fields, and so it depends on the number of photons, their phases, etc.

From this result, we are led to define the "mean intensity I of an electromagnetic wave" by the average value of its Pointing vector:

$$\boxed{I=\bar{S}} \tag{10.3.340}$$

It is therefore the average power that carries the wave per unit area. We have already demonstrated the mean expression of the Poynting vector, which leads us to write:

$$I=\bar{S}=\frac{\hat{E}\hat{B}}{2\mu_0} \tag{10.3.341}$$

Now, using the relation between energy and linear momentum (see section Special Relativity page 5684):

$$p=\frac{E_{\text{tot}}}{c} \tag{10.3.342}$$

we get the "linear momentum density" of the electromagnetic wave:

$$p=\frac{u_{\text{tot}}}{c}=\frac{\varepsilon\hat{E}^2}{c}=\frac{\hat{B}^2c}{\mu} \tag{10.3.343}$$

But if the direction of $\vec{E}\times\vec{B}$ is perpendicular to the wavefront and is therefore confounded with the propagation direction of the wave its module is:

$$\|\vec{E}\times\vec{B}\|=\hat{E}\hat{B}=\frac{1}{c}\hat{E}^2=c\hat{B}^2 \tag{10.3.344}$$

We therefore have for the linear momentum density:

$$\boxed{p=\varepsilon\|\vec{E}\times\vec{B}\|=\frac{1}{\mu c^2}\|\vec{E}\times\vec{B}\|} \tag{10.3.345}$$

As the linear momentum density must have the direction of propagation, we can write it in vector form:

$$\vec{p}=\varepsilon\vec{E}\times\vec{B}=\frac{1}{\mu c^2}\vec{E}\times\vec{B} \tag{10.3.346}$$

If an electromagnetic wave has a linear momentum density, it also has a kinetic angular momentum. The angular momentum per unit volume is then:

$$\boxed{\vec{b}=\vec{r}\times\vec{p}=\varepsilon\vec{r}\times(\vec{E}\times\vec{B})=\frac{1}{\mu c^2}\vec{r}\times(\vec{E}\times\vec{B})} \tag{10.3.347}$$

Thus, an electromagnetic wave carries both linear momentum density and angular momentum density as well as energy density !!!

This result is not surprising. Electromagnetic interaction between two electrical charges involves an exchange of energy and momentum between loads. This is done through the electromagnetic field which carries a density of energy and momentum density that are exchanged.

10.3.4.4 Emissions

To predict the shape and properties of the radiation emitted by antennas or other sources, computers and numerical models corresponding to the problem to be studied should be rigorously used. Formally, solving Maxwell's equations in macroscopic systems is quite difficult and takes time. Moreover, this is rather the work of the engineer who seeks practical exploitation from fundamental theories. The theoretical physicist is interested in the foundations of the Universe and with isolated and perfect systems.

However, we would like to expose the theory of diffraction and for this we must make a theoretical trip on an approximation of the properties of the radiation of a spherical point source in the vacuum.

The wave in the case of a spherical point source propagates spherically in space (we speak then of "spherical wave") and the Poynting vector of is therefore obviously radial to the source.

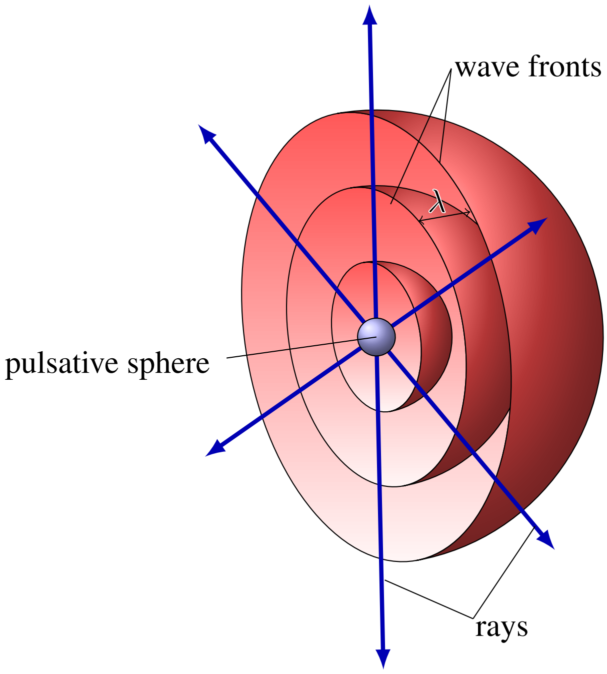


Figure 10.71: Spherical wavefront (author: Juan Castaño)

The vector $\vec{E}(r,t)$ and $\vec{B}(r,t)$ and vectors are locally contained in the plane tangent to the sphere of radius r (logical!) as shown in the figure below:

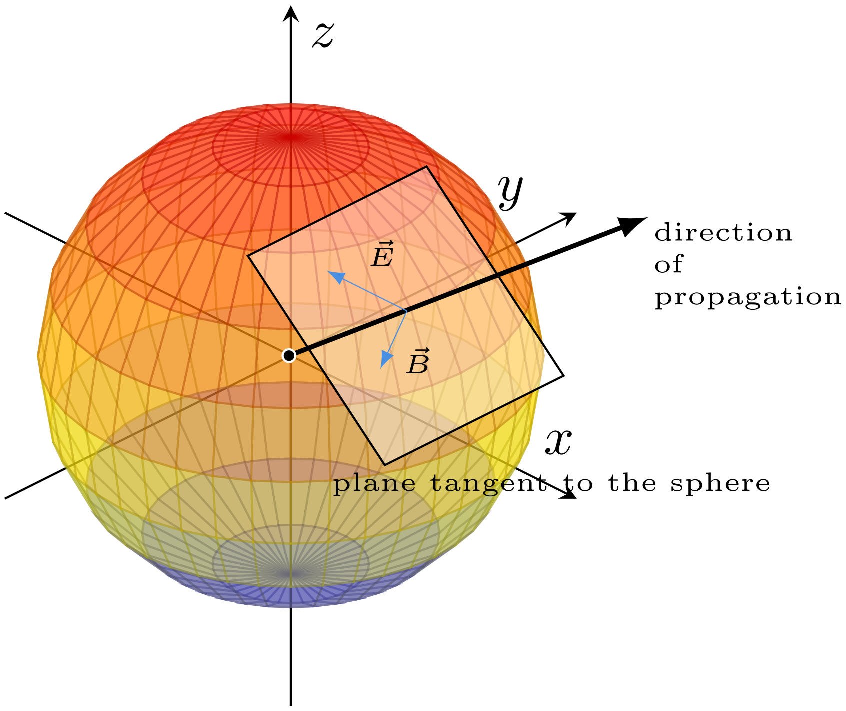

Figure 10.72: Representation of the propagation with respect to the plane tangent to the sphere

For the flow energy to be constant, the intensity of the wave must decrease with distance. Indeed, the conservation of the energy imposes that through a sphere of radius r_1 the energy radiated per unit of time (written with a right "E" so as not to be confused with the notation of the electric field) is equal to that which traverses the sphere of radius r_2:

$$\frac{\mathrm{dE}_1}{\mathrm{d}t}=I_1 4\pi r_1^2=\frac{\mathrm{dE}_2}{\mathrm{d}t}=I_2 4\pi r_2^2 \tag{10.3.348}$$

This naturally implies:

$$\frac{I_2}{I_1}=\left(\frac{r_1}{r_2}\right)^2 \tag{10.3.349}$$

But using the relation proved earlier above:

$$I=\bar{S}=\frac{\hat{E}\hat{B}}{2\mu_0} \tag{10.3.350}$$

and using the property of perpendicularity of the electric and magnetic field for a plane wave:

$$I=\overline{\|\vec{S}\|}=\frac{1}{2\mu_0}\overline{\|\vec{E}\times\vec{B}\|}=\frac{1}{2}\frac{c\hat{B}^2}{\mu_0}=\frac{1}{2c}\mu_0\hat{E}^2 \tag{10.3.351}$$

Therefore:

$$\frac{I_2}{I_1}=\left(\frac{\hat{B}_2}{\hat{B}_1}\right)^2=\left(\frac{\hat{E}_2}{\hat{E}_1}\right)^2=\left(\frac{r_1}{r_2}\right)^2 \tag{10.3.352}$$

which implies:

$$\hat{E}(r_2)r_2=\hat{E}(r_1)r_1=c^{te} \tag{10.3.353}$$

that is to say:

$$\hat{E}(r)r=c^{te} \tag{10.3.354}$$

and therefore the magnitude of the electric or magnetic of a electromagnetic plane wave field decrease inversely proportional to the distance r:

$$\boxed{\hat{E}(r)=\frac{c^{te}}{r}} \tag{10.3.355}$$

Thus the intensity density I of a spherical electromagnetic wave propagating in the vacuum decreases in r^2 since:

$$\begin{aligned}I_B&=\frac{1}{2}\frac{c}{\mu_0}\hat{B}(r)^2=\frac{1}{2}\frac{c}{\mu_0}\frac{c^{te}}{r^2}=\frac{1}{2}\frac{c}{\mu_0}\frac{\hat{B}(r=0)^2}{r^2}=\frac{1}{2}\frac{c}{\mu_0}\frac{B_0^2}{r^2}\\ I_E&=\frac{1}{2}c\mu_0\hat{E}(r)^2=\frac{1}{2}c\mu_0\frac{c^{te}}{r^2}=\frac{1}{2}c\mu_0\frac{\hat{E}(r=0)^2}{r^2}=\frac{1}{2}c\mu_0\frac{\hat{E}_0^2}{r^2}\end{aligned} \tag{10.3.356}$$

Therefore:

$$\boxed{I_B=\frac{1}{2}\frac{c}{\mu_0}\frac{B_0^2}{r^2}\qquad I_E=\frac{1}{2}c\mu_0\frac{\hat{E}_0^2}{r^2}} \tag{10.3.357}$$

By extension (important information for mobile phones and radio communications), in view of the results demonstrated above, the energy transported thus decreases in also in $1/r^2$.

It is now easy to understand now why physicists systematically use the frequency to characterize a electromagnetic wave because its amplitude is not constant in the vacuum whereas the frequency is a kind of signature of the transmitter that is not lost through a static empty space (assumed as because we will see during study of quantum field theory that there are not such things as "empty space") !!!

10.3.5 Synchrotron radiation (bremsstrahlung)

Broadly speaking, "Bremsstrahlung" or "braking radiation" is any radiation produced due to the deceleration (negative acceleration) of a charged particle, which includes synchrotron radiation, cyclotron radiation, and the emission of electrons and positrons during beta decay. However, the term is frequently used in the more narrow sense of radiation from electrons (from whatever source) slowing in matter.

Remark

"Thermal bremsstrahlung" is a X-ray emission mechanism that typically takes place in a high temperature, low-density plasma. As a free electron passes close to an ion in the gas it is deflected without being captured. As a result of this acceleration the electron emits a photon while at the same time losing a corresponding amount of kinetic energy and slowing down a little.

A synchrotron light source is a source of electromagnetic radiation (EM) usually produced by a storage ring or more generally any electric charge particle in acceleration. First observed in synchrotrons, synchrotron light is now produced by storage rings and other specialized particle accelerators, typically accelerating electrons. Once the high-energy electron beam has been generated, it is directed into auxiliary components such as bending magnets and insertion devices (ondulators or wigglers) in storage rings and free electron LASERs. These supply the strong magnetic fields perpendicular to the beam which are needed to convert high energy electrons into photons.

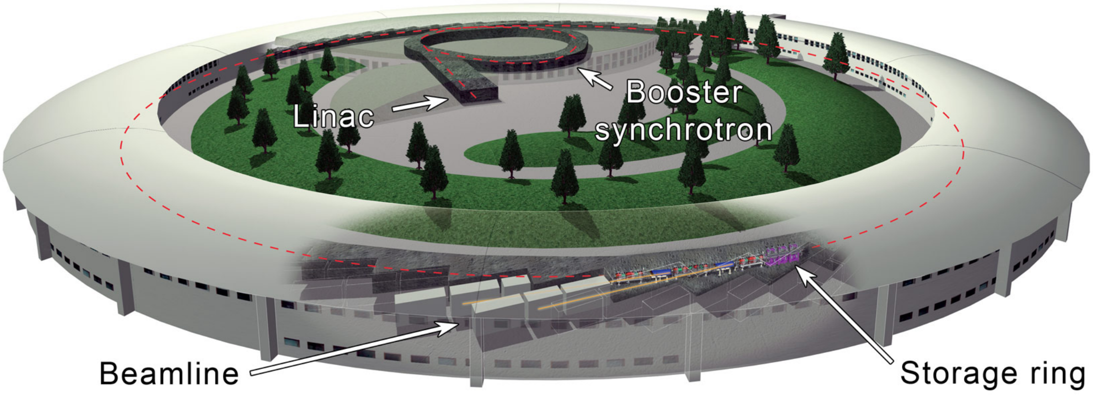

Figure 10.73: European synchrotron (source: ESRF)

The major applications of synchrotron light are in condensed matter physics, materials science, biology and medicine. A large fraction of experiments using synchrotron light involve probing the structure of matter from the sub-nanometer level of electronic structure to the micrometer and millimetre level important in medical imaging. An example of a practical industrial application is the manufacturing of micro-structures by the LIGA process.

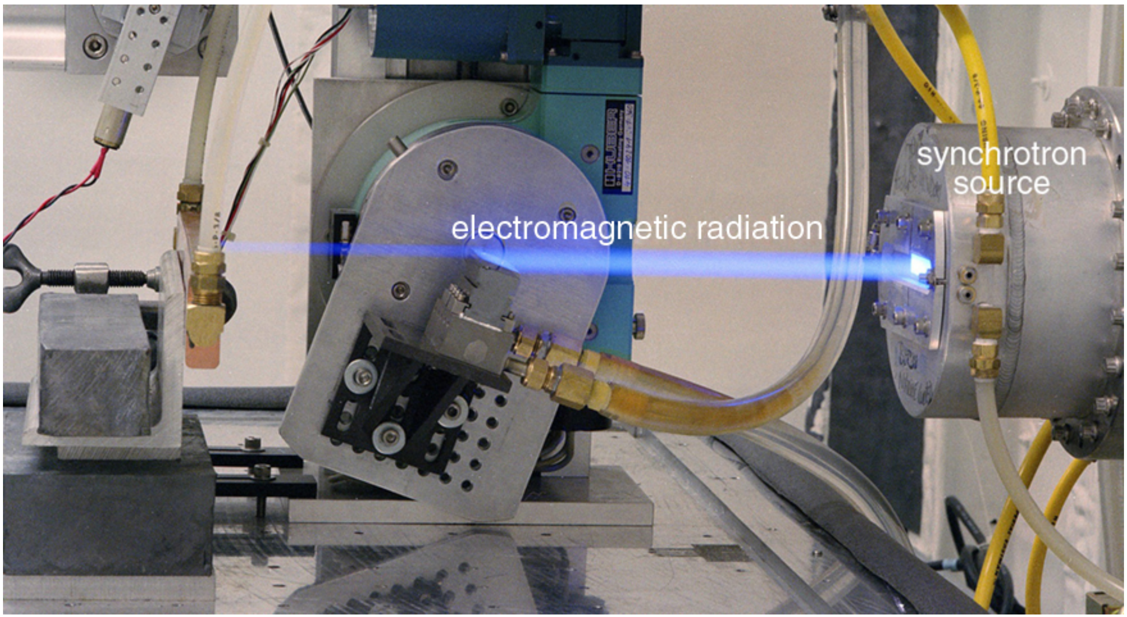

Figure 10.74: Synchrotron source producing electromagnetic radiation, as evident from the visible glow (source: United States Department of Energy)

It is also an important subject of study because the Rutherford Model (see section Corpuscular Quantum Physics page 4623) was not able to explain the fact that there was not Bremsstrahlung of the electron orbiting around the nucleus as at it's time the Bremsstrahlung was a well known effect!

To begin, let us consider an electric charge in uniform rectilinear motion. The electrical and magnetic fields of such an electric charge have been studied in the previous sections. We have also shown above that the magnetic field is in this configuration, always perpendicular to the electric field. The first consequence is that the electric field is radial and the magnetic field transverse.

So if we surround the moving particle of an imaginary closed spherical surface, we then have trivially (see the definition of the Poynting vector):

$$\frac{\mathrm{d}E}{\mathrm{d}t}=c^2\varepsilon_0\oint_S(\vec{E}\times\vec{B})\circ\vec{n}\mathrm{d}S=0 \tag{10.3.358}$$

since at any point on the surface, $\vec{E}$ is perpendicular to it and $\vec{B}$ tangent to it, hence $\vec{E}\times\vec{B}$ is also tangent to the surface and therefore the angle between $\vec{E}\times\vec{B}$ and $\vec{n}$ is equal to a right angle therefore the scalar product is zero.

Thus, in conclusion, the total flux of radiated energy is zero for an electric charge in uniform rectilinear motion. In other words, a uniformly rectilinear moving electric charge does not radiate electromagnetic energy but carries with it the energy of the electromagnetic field (here we are reassured!). This is confirmed by the experimental observations.

However, the situation is very different for an accelerated moving electric charge. The electric field of an accelerated charge is no longer radial and no longer possesses the symmetry with respect to the charge which it possesses when the motion is uniform (as will we prove it). Consequence: ... an accelerated electric charge radiates electromagnetic energy and therefore sees its kinetic energy that decrease!

An important conclusion is that in order to maintain an electric charge in accelerated motion, it is necessary to provide energy to compensate for that lost by radiation. If the particle instead of being accelerated is decelerated (it is typically what we seek to do in radio-protection) again the particle will emit the same radiation in the same way (we will also prove it). This happens, for example, when an electric charge, such as an electron or a proton, strikes a target at high speed. A substantial fraction of its total energy goes in the form of a radiation.

The equations that we are going to determine remain valid for any type of relativistic accelerated motion or not (but not from a quantum point of view!). For example, a charged particle moving in a circular orbit is subjected to centripetal acceleration and therefore emits radiation. Consequently, when an ion is accelerated in a cyclic accelerator such as a cyclotron, betatron or synchrotron, a fraction of the energy supplied to it is lost as electromagnetic radiation. Cyclic accelerators than in linear accelerators.

When the electric charges reach very high energies, as it happens in synchrotrons where the acceleration is great (fortunately for us because it will allow us to make a very useful approximation ...), the losses due to radiation, named "synchrotron radiation" as we already know, become important and constitute a serious limitation in the construction of cyclic accelerators of very high energy but nevertheless remain infinitely useful to the advanced industry and scientific medicine and archaeology.

Another important consideration relates to the atomic structure. According to the atomic model of Rutherford (see section Corpuscular Quantum Physics page 4623), we imagine the atom as formed of a positively charged central nucleus, the negatively charged electrons describing closed orbits around it. But this implies that the electrons move with accelerated motion and, if we apply the ideas developed so far, all atoms should continuously radiate energy (even in the absence of an external source of energy like the Sun). As a result of this loss of energy, electronic orbits should contract, resulting in a corresponding reduction in the size of all bodies. Fortunately for us, this is not observable (matter does not collapse on itself), but this leads us to suppose, within the framework of the Rutherford model, that the movements of electrons in atoms are governed by certain principles which were not considered at its time. This is what will lead us to generate the Bohr model of the atom (see section Corpuscular Quantum Physics page 4626) but which, as we shall see, will also have other defects.

To determine the energy emitted by an electric charge in accelerated motion we will have to make use of mathematical tools that are no longer at the same level as those used previously. It is therefore recommended that the reader have a good mathematical background. Moreover, exceptionally we will make use of CAD softwares for certain points of the development.

Let us consider first the following figure:

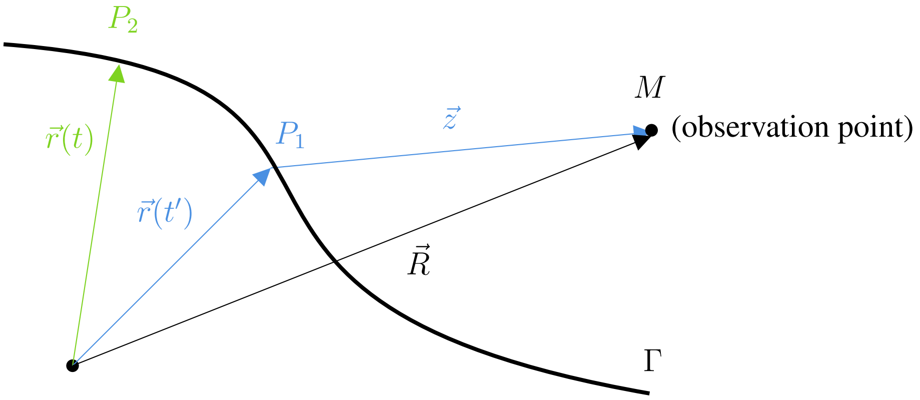

Figure 10.75: Scenario to consider for the study of synchrotron radiation

When the charge distribution $\rho(\vec{r},t')$ and the current distribution $\vec{J}(\vec{r},t')$ are at the point P_2, the point M receives the electromagnetic wave emitted by the electric charges and the current when they were at the point P_1, i.e. at the instant t' (because of the speed limit c of the propagation of the field in space). The time delay is the propagation time from the point P_1 to the point M, i.e.:

$$\Delta t = \frac{\|\vec{R}-\vec{r}(t')\|}{c} \tag{10.3.359}$$

Therefore:

$$t = t' + \Delta t \rightarrow t' = t - \Delta t = t - \frac{\|\vec{R}-\vec{r}(t')\|}{c} \tag{10.3.360}$$

Therefore:

$$t' = t - \frac{\|\vec{R}-\vec{r}(t')\|}{c} \tag{10.3.361}$$

The scalar and vectorial potentials associated respectively with the electric field and the magnetic field at the point of vectorial coordinate $\vec{R}$ at time t have, on the basis of the results obtained in the two preceding sections, the following expressions:

$$\boxed{\begin{aligned} U(\vec{R},t) &= \frac{1}{4\pi\varepsilon_0}\oint_V \frac{\rho(\vec{r},t')\mathrm{d}V}{\|\vec{R}-\vec{r}\|} \\ \vec{A}(\vec{R},t) &= \frac{\mu_0}{4\pi}\oint_V \frac{\vec{J}(\vec{r},t')\mathrm{d}V}{\|\vec{R}-\vec{r}\|} \end{aligned}} \tag{10.3.362}$$

where on the other hand we have to prove immediately in detail that the vector potential associated with the magnetic field is expressed as indicated above!

Remark

We will use these two relations of potential in our study of the radiated field because their similar mathematical form will allow us, at least we hope it..., to simplify the developments.

These two relations are already partially familiar to us, the first one expressing the (delayed) electrical potential has been proved in the section of Electrostatics in the non-relativistic framework (so our calculations may not be correct if we come across a result that depends on the speed! We will see...).

Concerning the second relation which expresses the delayed potential-vector, we have seen above that:

$$\vec{B}=\vec{\nabla}\times\vec{A} \tag{10.3.363}$$

was always correct to given gradient of an additive function for $\vec{A}$ (due to the properties of the differential vector operators) such that:

$$\vec{B}=\vec{\nabla}\times\vec{A}=\vec{\nabla}\times(\vec{A}'+\vec{\nabla}\psi)=\vec{\nabla}\times\vec{A}'+\underbrace{\vec{\nabla}\times\vec{\nabla}\psi}_{=\vec{0}} \tag{10.3.364}$$

and that $\vec{B}$ is in relativistic form or not, we have:

$$\vec{\nabla}\times\vec{B}=\mu_0\vec{j}+\mu_0\varepsilon_0\frac{\mathrm{d}\vec{E}}{\mathrm{d}t} \tag{10.3.365}$$

Let us also recall that we have the Biot-Savart law (see section Magnetostatics page 4023) that:

$$\mathrm{d}\vec{B}=\frac{\mu_0}{4\pi}\frac{\vec{J}\times\vec{r}}{r^3}\mathrm{d}V=\frac{\mu_0}{4\pi}\frac{\vec{J}\times\vec{r}}{\|\vec{r}\|^3}\mathrm{d}V \tag{10.3.366}$$

It follows that if we put:

$$\mathrm{d}\vec{A}=\frac{\mu_0}{4\pi}\frac{\vec{J}\mathrm{d}V}{\|\vec{r}\|}=f(\|\vec{r}\|)\cdot\vec{J} \tag{10.3.367}$$

we fall back on the Biot-Savart law since if and only if $\vec{J}$ does not depend on r then (trivial):

$$\vec{\nabla}\times(\vec{J}\cdot f(\|\vec{r}\|))=(\vec{\nabla}\cdot f(\|\vec{r}\|))\times\vec{J} \tag{10.3.368}$$

We thus get indeed:

$$\begin{aligned}\mathrm{d}\vec{B}&=\vec{\nabla}\times\mathrm{d}\vec{A}=\vec{\nabla}\times\left(\frac{\mu_0}{4\pi}\frac{\vec{J}\mathrm{d}V}{\|\vec{r}\|}\right)=\vec{\nabla}\times(\vec{J}\cdot f(\|\vec{r}\|))=(\vec{\nabla}\cdot f(\|\vec{r}\|))\times\vec{J}\\&=\frac{\mu_0}{4\pi}\begin{pmatrix}-\dfrac{\mathrm{d}Vx}{\|\vec{r}\|^3}\\-\dfrac{\mathrm{d}Vy}{\|\vec{r}\|^3}\\-\dfrac{\mathrm{d}Vz}{\|\vec{r}\|^3}\end{pmatrix}\times\vec{J}=\frac{\mu_0}{4\pi}(-)\vec{J}\times\begin{pmatrix}-\dfrac{\mathrm{d}Vx}{\|\vec{r}\|^3}\\-\dfrac{\mathrm{d}Vy}{\|\vec{r}\|^3}\\-\dfrac{\mathrm{d}Vz}{\|\vec{r}\|^3}\end{pmatrix}=\frac{\mu_0}{4\pi}\frac{\vec{J}\times\vec{r}}{\|\vec{r}\|^3}\mathrm{d}V\end{aligned} \tag{10.3.369}$$

Although this form of vector potential gives only the Biot-Savart's law in non-relativistic form, as still always satisfies:

$$\vec{\nabla}\times\vec{B}=\mu_0\vec{j}+\mu_0\varepsilon_0\frac{\mathrm{d}\vec{E}}{\mathrm{d}t} \tag{10.3.370}$$

this is still valid in the relativistic framework because this Maxwell equation does not depend on the velocity. Moreover, if our results in the study of synchrotron radiation gives us at the end an expression independent of velocity, we shall have once again confirmed this fact.

10.3.5.1 Liénard-Wiechert potentials

Liénard–Wiechert potentials describe the classical electromagnetic effect of a moving electric point charge in terms of a vector potential and a scalar potential in the Lorenz gauge. Built directly from Maxwell's equations, these potentials describe the complete, relativistically correct, time-varying electromagnetic field for a point charge in arbitrary motion, but are not corrected for quantum-mechanical effects. Electromagnetic radiation in the form of waves can be obtained from these potentials. These expressions were developed in part by Alfred-Marie Liénard in 11898 (holocene calendar) and independently by Emil Wiechert in 11900 (holocene calendar).

Caution! The only purpose of the twenty pages of hard and abstract mathematics that follow have for only purpose in this textbook to derive the Larmor's relativistic equation which for small speeds ($v \ll c$) leads to the Larmor's (classical) equation. And it is that later "classical version" that we need for many other sections of this textbook. However there is also a much simpler derivation that leads directly to the classical version of Larmor's equation. If the reader wants he can directly jump to that one by going at page 4198.

To start this study, let us consider the case where a particle of mass m and of electric charge q travel a path Γ. Compared to an origin point O, its vector coordinate is $\overrightarrow{\mathrm{O}P}=\vec{h}(t)$, its velocity vector will be denoted:

$$\vec{v}=\mathrm{d}_t\vec{h}(t) \tag{10.3.371}$$

and its acceleration:

$$\vec{a}=\mathrm{d}_t^2\vec{h}(t) \tag{10.3.372}$$

If the point charge q is at the origin O, we saw in the section of Differential and Integral Calculus that the Dirac function gives us:

$$\int\limits_{-\infty}^{+\infty} q\delta(x)\mathrm{d}x=q \tag{10.3.373}$$

and if the punctual electric charge q is at an abscissa x_0, we have:

$$\int\limits_{-\infty}^{+\infty} q\delta(x-x_0)\mathrm{d}x=\begin{cases} q & x=x_0 \\ 0 & x\neq x_0 \end{cases} \tag{10.3.374}$$

What has just been said for a one-dimensional space can also be applied to a three-dimensional space as we saw it and then we write:

$$q(\vec{r},t)=q\delta(\vec{r}-\vec{h}(t)) \tag{10.3.375}$$

If we choose inverse cubic meters ($[\mathrm{m}^{-3}]$) for units for the Dirac function, then we can write:

$$\rho(\vec{r},t)=q\delta(\vec{r}-\vec{h}(t)) \tag{10.3.376}$$

where q is then the total charge at the point $\vec{r}$.

For the distribution of the current density, we also have by choosing the same units as for the Dirac function:

$$\vec{J}(\vec{r},t)=q\delta(\vec{r}-\vec{h}(t))\mathrm{d}_t\vec{h}(t)=q\delta(\vec{r}-\vec{h}(t))\vec{v} \tag{10.3.377}$$

Therefore, at point M, the potentials at time t have for expression:

$$\begin{aligned}U(\vec{R},t)&=\frac{1}{4\pi\varepsilon_0}\oint_V\frac{q\delta(\vec{R}-\vec{h}(t'))\mathrm{d}V}{\|\vec{R}-\vec{r}\|}\\ \vec{A}(\vec{R},t)&=\frac{\mu_0}{4\pi}\oint_V\frac{q\delta(\vec{R}-\vec{h}(t'))\vec{v}\,'\mathrm{d}V}{\|\vec{R}-\vec{r}\|}\end{aligned} \tag{10.3.378}$$

This is a very useful formulation (a workaround) that will enable us to solve our problem.

For this purpose, when the electric charge is at the point P_1 at the time t', we put:

$$\vec{h}\,'=\vec{h}(t')\qquad\vec{v}\,'=\vec{v}(t')\qquad\vec{a}\,'=\vec{a}(t') \tag{10.3.379}$$

We will use a looooong artifice to solve the integral of the electrical potential (which is therefore a multiple integral in Cartesian coordinates)!

This begins by multiplying the factor under the integrand $U(\vec{R},t)$ by:

$$\delta(t'-t+\|\vec{R}-\vec{r}\|c^{-1}) \tag{10.3.380}$$

this does not modify the integral since:

$$t'=t-\|\vec{R}-\vec{r}\|c^{-1}\rightarrow t'-t+\|\vec{R}-\vec{r}\|c^{-1}=0 \tag{10.3.381}$$

and that (see section Functional Analysis page 1569):

$$\delta(0)=1 \tag{10.3.382}$$

We then have the following expression in which the time t' appears:

$$\begin{aligned}U(\vec{R},t)&=\frac{1}{4\pi\varepsilon_0}\int\delta\left(t'-t+\frac{\|\vec{R}-\vec{r}(t')\|}{c}\right)\mathrm{d}t'\int\frac{q\delta(\vec{R}-\vec{h}(t'))}{\|\vec{R}-\vec{r}(t')\|}\\ &=\frac{1}{4\pi\varepsilon_0}\int\frac{q\delta(\vec{R}-\vec{h}(t'))}{\|\vec{R}-\vec{r}(t')\|}\delta\left(t'-t+\frac{\|\vec{R}-\vec{r}(t')\|}{c}\right)\mathrm{d}x\mathrm{d}y\mathrm{d}\mathrm{d}t'\\ &=\frac{1}{4\pi\varepsilon_0}\int\frac{q}{\|\vec{R}-\vec{r}(t')\|}\delta(\vec{R}-\vec{h}(t'))\delta\left(t'-t+\frac{\|\vec{R}-\vec{r}(t')\|}{c}\right)\mathrm{d}x\mathrm{d}y\mathrm{d}z\mathrm{d}t'\end{aligned} \tag{10.3.383}$$

what we have the right to write because the second integral does not depend explicitly on t'.

Good now if we try to solve this integral, we will spend our lives on it... for nothing. We'll have to be more clever!

Before looking for a solution of this integral, we must first deal with the more general case of the following integral:

$$I=\int g[f_1,f_2,f_3,f_4]\delta[f_1(x,y,z,t')]\delta[f_2(x,y,z,t')]\delta[f_3(x,y,z,t')]\delta[f_4(x,y,z,t')]\mathrm{d}x\mathrm{d}y\mathrm{d}z\mathrm{d}t' \tag{10.3.384}$$

Or written in a more condensed form:

$$I=\int g[f_1,f_2,f_3,f_4]\delta[f_1]\delta[f_2]\delta[f_3]\delta[f_4]\mathrm{d}x\mathrm{d}y\mathrm{d}z\mathrm{d}t' \tag{10.3.385}$$

which it is easy to approximate with the prior-previous integral:

$$\begin{aligned}f_1&=\|\vec{R}-\vec{r}(t')\|\\ g[f_1,f_2,f_3,f_4]&=\frac{1}{4\pi\varepsilon_0}\frac{q}{\|\vec{R}-\vec{r}(t')\|}=\frac{1}{4\pi\varepsilon_0}\frac{q}{f_1}\\ \delta[f_1]&=\delta(R_x-h_x(t'))\\ \delta[f_2]&=\delta(R_y-h_y(t'))\\ \delta[f_3]&=\delta(R_z-h_z(t'))\\ \delta[f_4]&=\delta\left(t'-t+\frac{\|\vec{R}-\vec{r}(t')\|}{c}\right)\end{aligned} \tag{10.3.386}$$

where we have deal such that f_1,f_2,f_3,f_4 depend respectively only (explicitly) on x, y, z and t'.

We now want now to make the following change of variables:

$$x\rightarrow f_1\qquad y\rightarrow f_2\qquad z\rightarrow f_3\qquad t'\rightarrow f_4 \tag{10.3.387}$$

Let us recall that in changes of variables in multiple integrals (see the Jacobian in the section of Differential and Integral Calculus), we have, passing from Cartesian coordinates to curvilinear coordinates, the following relations:

$$I=\int_D F(x,y,z)\mathrm{d}x\mathrm{d}y\mathrm{d}z=\int_{D'}G(r_1,r_2,r_3)\left|\frac{\partial(x,y,z)}{\partial(r_1,r_2,r_3)}\right|\mathrm{d}r_1\mathrm{d}r_2\mathrm{d}r_3 \tag{10.3.388}$$

where for recall:

$$r_1=r_1(x,y,z)\qquad r_2=r_2(x,y,z)\qquad r_3=r_3(x,y,z) \tag{10.3.389}$$

and where:

$$\left|\frac{\partial(x,y,z)}{\partial(r_1,r_2,r_3)}\right| \tag{10.3.390}$$

is not an absolute value but the determinant of a matrix!

Now, in our case, let us recall that we have all the f_i which are null and therefore:

$$\delta[f_i]_{f_i=0}=1 \tag{10.3.391}$$

and in the case where during the developments one of the f_i would no longer be zero for reasons not yet determined, we would have:

$$\delta[f_i]_{f_i\neq 0}=0 \tag{10.3.392}$$

The multiple integral then becomes:

$$I=\int g[f_1,f_2,f_3,f_4]\left\{\delta[f_1]\delta[f_2]\delta[f_3]\delta[f_4]\left|\frac{\partial(x,y,z,t')}{\partial(f_1,f_2,f_3,f_4)}\right|\right\}_{f_i=0}\mathrm{d}f_1\mathrm{d}f_2\mathrm{d}f_3\mathrm{d}f_4 \tag{10.3.393}$$

Where the term between braces is taken at $f_i=0$ by necessity of the construction of previous developments preparing the mathematical artifice!

And let us recall once more (!!) the property of Dirac functions:

$$\int f(x)\delta(x)\mathrm{d}x=[f(x)]_{x=0} \tag{10.3.394}$$

We then have immediately the simplification:

$$I=g[f_1,f_2,f_3,f_4]\left|\frac{\partial(x,y,z,t')}{\partial(f_1,f_2,f_3,f_4)}\right|_{f_i=0} \tag{10.3.395}$$

where:

$$\left|\frac{\partial(x,y,z,t')}{\partial(f_1,f_2,f_3,f_4)}\right| \tag{10.3.396}$$

is therefore the Jacobian of the transformation of the artifice ...

It is evident that by construction of the Jacobian we have:

$$\left|\frac{\partial(x,y,z)}{\partial(r_1,r_2,r_3)}\right|\left|\frac{\partial(r_1,r_2,r_3)}{\partial(x,y,z)}\right|=|\det(J)||\det(J)|^{-1}=1 \tag{10.3.397}$$

Therefore it comes:

$$\left|\frac{\partial(x,y,z)}{\partial(r_1,r_2,r_3)}\right|=\left|\frac{\partial(r_1,r_2,r_3)}{\partial(x,y,z)}\right|^{-1} \tag{10.3.398}$$

For the integral I we then have:

$$I=g[f_1,f_2,f_3,f_4]\left|\frac{\partial(f_1,f_2,f_3,f_4)}{\partial(x,y,z,t')}\right|^{-1}_{f_i=0} \tag{10.3.399}$$

Let us now calculate our Jacobian ...:

$$|\det(J)|^{-1}=\left|\det\begin{bmatrix}\partial_x f_1 & \partial_x f_2 & \partial_x f_3 & \partial_x f_4\\ \partial_y f_1 & \partial_y f_2 & \partial_y f_3 & \partial_y f_4\\ \partial_z f_1 & \partial_z f_2 & \partial_z f_3 & \partial_z f_4\\ \partial_{t'} f_1 & \partial_{t'} f_2 & \partial_{t'} f_3 & \partial_{t'} f_4\end{bmatrix}\right|^{-1} \tag{10.3.400}$$

Returning to the our treated case, $\vec{R}-\vec{h}(t')$ therefore has for components:

$$\begin{aligned}
&f_1=R_x-h_x(t')=x-h'_x\\
&f_2=R_y-h_y(t')=y-h'_y\\
&f_3=R_z-h_z(t')=z-h'_z\\
&f_4=t'-t+\frac{\|\vec{R}-\vec{r}(t')\|}{c}=t'-t+\frac{\sqrt{(X-x)^2+(Y-y)^2+(Z-z)^2}}{c}
\end{aligned} \tag{10.3.401}$$

Therefore, we have the calculation of the elements of the inverse of the Jacobian:

$$|\det(J)|^{-1}=\left|\det\begin{bmatrix}\partial_x f_1=1 & \partial_x f_2=0 & \partial_x f_3=0 & \partial_x f_4=-\dfrac{X-x}{c\|\vec{R}-\vec{r}(t')\|}\\ \partial_y f_1=0 & \partial_y f_2=1 & \partial_y f_3=0 & \partial_y f_4=-\dfrac{Y-y}{c\|\vec{R}-\vec{r}(t')\|}\\ \partial_z f_1=0 & \partial_z f_2=0 & \partial_z f_3=1 & \partial_z f_4=-\dfrac{Z-z}{c\|\vec{R}-\vec{r}(t')\|}\\ \partial_{t'} f_1=-\dot{h}'_x & \partial_{t'} f_2=-\dot{h}'_y & \partial_{t'} f_3=-\dot{h}'_z & \partial_{t'} f_4=1\end{bmatrix}\right|^{-1} \tag{10.3.402}$$

Well... now that we have the components of the Jacobian matrix, we have only to calculate its determinant. So either we use the general relation of the calculus of determinant proved in the section of Linear Algebra, or we use Maple™ ... So to win a little bit time let's do it with Maple™ 4.00b:

```
>with(linalg):
>A:=matrix(4,4,[1,0,0,a,0,1,0,b,0,0,1,c,d,e,f,1]);
```

where (for people having difficulty to read Maple™ notations):

$$A=\begin{bmatrix}1&0&0&a\\0&1&0&b\\0&0&1&c\\d&e&f&1\end{bmatrix} \tag{10.3.403}$$

with:

$$\begin{gathered}
a=-\frac{X-x}{c\|\vec{R}-\vec{r}(t')\|}\qquad b=-\frac{Y-y}{c\|\vec{R}-\vec{r}(t')\|}\qquad c=-\frac{Z-z}{c\|\vec{R}-\vec{r}(t')\|}\\
d=\dot{h}'_x\qquad e=\dot{h}'_y\qquad f=\dot{h}'_z
\end{gathered} \tag{10.3.404}$$

Let us continue with Maple™ 4.00b:

```
>Det(A);
```

Which gives as output:

```
1-cf-eb-da=1-(fc+eb+da)
```

The inverse of the Jacobian has then for expression:

$$\begin{aligned}|\det(J)|^{-1}&=\left|1-\left\{(-\dot{h}'_x\left[-\frac{X-x}{c\|\vec{R}-\vec{r}(t')}\right]+(-\dot{h}'_z\left[-\frac{Z-z}{c\|\vec{R}-\vec{r}(t')||}\right])\right\}\right|^{-1}\\&=\left|1-\left\{\frac{\dot{h}'_x(X-x)+\dot{h}'_y(Y-y)+\dot{h}'_z(Z-z)}{c\|\vec{R}-\vec{r}(t')||}\right\}\right|^{-1}=\left|1-\left\{\frac{\dot{h}'\circ(\vec{R}-\vec{r}(t'))}{c\|\vec{R}-\vec{r}(t')||}\right\}\right|^{-1}\\&=\left|1-\left\{\frac{\vec{v}\,'\circ(\vec{R}-\vec{r}(t'))}{c\|\vec{R}-\vec{r}(t')||}\right\}\right|^{-1}\end{aligned} \tag{10.3.405}$$

Where we used the dot product in the prior-previous equality in order to condense the expression.

Therefore:

$$|\det(J)|^{-1}=\frac{1}{\left|1-\dfrac{\vec{v}\,'}{c}\dfrac{(\vec{R}-\vec{r}(t'))}{\|\vec{R}-\vec{r}(t')||}\right|} \tag{10.3.406}$$

The multiple integral:

$$I=g[f_1,f_2,f_3,f_4]\left|\frac{\partial(f_1,f_2,f_3,f_4)}{\partial(x,y,z,t')}\right|^{-1}_{f_i=0} \tag{10.3.407}$$

where for recall:

$$g[f_1,f_2,f_3,f_4]=\frac{1}{4\pi\varepsilon_0}\frac{q}{\|\vec{R}-\vec{r}(t')||} \tag{10.3.408}$$

or written differently:

$$g[f_1,f_2,f_3,f_4]=\frac{1}{4\pi\varepsilon_0}\frac{q}{\left\|\begin{bmatrix}X\\Y\\Z\end{bmatrix}-\begin{bmatrix}x\\y\\z\end{bmatrix}\right\|} \tag{10.3.409}$$

But as a result of our change of coordinate system we have for recall:

$$g[f_1,f_2,f_3,f_4]\rightarrow g\left[(f_1=x-h'_x),(f_2=y-h'_y),(f_3=z-h'_z),\left(f_4=t'-t+\frac{\|\vec{R}-\vec{r}(t')||}{c}\right)\right] \tag{10.3.410}$$

And let us recall once again that:

$$\int f(x)\delta(x)\mathrm{d}x=[f(x)]_{x=0} \tag{10.3.411}$$

Therefore we have to take g on $f_1=f_2=f_3=f_4=0$! It comes:

$$g\left[(x=h'_x),(y=h'_y),(h=h'_z),\left(t'=t-\frac{\|\vec{R}-\vec{r}(t')||}{c}\right)\right] \tag{10.3.412}$$

Which allows us to write:

$$g[f_1,f_2,f_3,f_4]=\frac{1}{4\pi\varepsilon_0}\frac{q}{\left\|\begin{bmatrix}X\\Y\\Z\end{bmatrix}-\begin{bmatrix}h'_x\\h'_y\\h'_z\end{bmatrix}\right\|}=\frac{1}{4\pi\varepsilon_0}\frac{q}{\|\vec{R}-\vec{h}\,'\|} \tag{10.3.413}$$

We have to apply the same process for:

$$|\det(J)|^{-1}=\frac{1}{\left|1-\dfrac{\vec{v}\,'}{c}\circ\dfrac{\left(\vec{R}-\vec{r}(t')\right)}{\|\vec{R}-\vec{r}(t')\|}\right|} \tag{10.3.414}$$

that can then be written as:

$$|\det(J)|^{-1}=\frac{1}{\left|1-\dfrac{\vec{v}\,'}{c}\circ\dfrac{\left(\vec{R}-\vec{h}\right)}{\|\vec{R}-\vec{h}\|}\right|} \tag{10.3.415}$$

Finally, the resolution of the integral I is written:

$$\begin{aligned}I&=g[f_1,f_2,f_3,f_4]\left|\frac{\partial(f_1,f_2,f_3,f_4)}{\partial(x,y,z,t')}\right|^{-1}_{f_i=0}=g[f_1,f_2,f_3,f_4]\frac{1}{\left|1-\dfrac{\vec{v}\,'}{c}\circ\dfrac{\left(\vec{R}-\vec{h}\right)}{\|\vec{R}-\vec{h}\|}\right|}\\&=\frac{1}{4\pi\varepsilon_0}\frac{q}{\|\vec{R}-\vec{h}\,'\|}\frac{1}{\left|1-\dfrac{\vec{v}\,'}{c}\circ\dfrac{\left(\vec{R}-\vec{h}\right)}{\|\vec{R}-\vec{h}'\|}\right|}=\frac{1}{4\pi\varepsilon_0}\frac{1}{\|\vec{R}-\vec{h}\|\left|1-\dfrac{\vec{v}\,'}{c}\circ\dfrac{\left(\vec{R}-\vec{h}\right)}{\|\vec{R}-\vec{h}\|}\right|}\end{aligned} \tag{10.3.416}$$

Finally, we get the expressions of the potentials.

- The scalar potential is then written:

$$\boxed{U(\vec{R},t)=\frac{1}{4\pi\varepsilon_0}\frac{q}{\|\vec{R}-\vec{h}\|\left|1-\dfrac{\vec{v}\,'}{c}\circ\dfrac{\left(\vec{R}-\vec{h}\right)}{\|\vec{R}-\vec{h}\|}\right|}} \tag{10.3.417}$$

- The vector potential is written:

$$A(\vec{R},t)=\frac{\mu_0}{4\pi}\oint_V\frac{q\delta(\vec{R}-\vec{h}(t'))\vec{v}\,'\mathrm{d}V}{\|\vec{R}-\vec{r}(t')\|}=\frac{\mu_0}{4\pi}\oint\frac{q\delta(\vec{R}-\vec{h})\vec{v}\,'}{\|\vec{R}-\vec{r}(t')\|}\mathrm{d}x\mathrm{d}y\mathrm{d}z \tag{10.3.418}$$

  Considering that the integral which is almost the same as for the scalar potential except the term $\vec{v}\,'$, we arrive by making the same developments as before with to the expression (please... don't ask us to put also the details for this one... plzzzzz!):

$$\boxed{\vec{A}(\vec{R},t)=\frac{\mu_0}{4\pi}\frac{q\vec{v}\,'}{\|\vec{R}-\vec{h}\|\left|1-\dfrac{\vec{v}\,'}{c}\circ\dfrac{(\vec{R}-\vec{h})}{\|\vec{R}-\vec{h}\|}\right|}} \tag{10.3.419}$$

In summary, the potentials taken at the moment (time delay of propagation):

$$t'=t-\frac{\|\vec{R}-\vec{r}(t')\|}{c} \tag{10.3.420}$$

have for expression in a very condensed form (K_e in the Coulomb constant for recall as introduced in the section of Electrostatics!):

$$\begin{aligned}U(\vec{R},t)&=K_e\frac{q}{s}\\ \vec{A}(\vec{R},t)&=\frac{\mu_0}{4\pi}\frac{q\vec{v}\,'}{s}\end{aligned} \tag{10.3.421}$$

These potentials are named "Liénard-Wiechert retarded potentials" with:

$$s=\left(\|\vec{R}-\vec{h}\|\left|1-\frac{\vec{v}\,'}{c}\circ\frac{\left(\vec{R}-\vec{h}\right)}{\|\vec{R}-\vec{h}\|}\right|\right)_{t'=t-\dfrac{\|\vec{R}-\vec{r}(t')\|}{c}} \tag{10.3.422}$$

10.3.5.2 Retarded Electric and Magnetic fields

Let us recall that we have proved earlier above (see page 4116) that:

$$\vec{E}(\vec{R},t)=-\vec{\nabla}U-\partial_t\vec{A} \tag{10.3.423}$$

and by definition and the construction of potential vector we also have:

$$\vec{B}(\vec{R},t)=\mu_0\vec{H}\rightarrow\vec{H}(\vec{R},t)=\frac{1}{\mu_0}\vec{\nabla}\times\vec{A} \tag{10.3.424}$$

Therefore a difficulty appears in the sense that the Liénard-Wiechert potentials are at the moment $t'=t-\frac{\|\vec{R}-\vec{r}\|}{c}$ and that the fields are given at the moment t. It is therefore advisable to review the expressions of the fields corresponding to the instant t'.

By taking back the two relations:

$$\begin{aligned}U(\vec{R},t)&=\frac{1}{4\pi\varepsilon_0}\frac{q}{\|\vec{R}-\vec{h}\|\left|1-\dfrac{\vec{v}\,'}{c}\circ\dfrac{\left(\vec{R}-\vec{h}\right)}{\|\vec{R}-\vec{h}\|}\right|}=\frac{q}{4\pi\varepsilon_0}\frac{1}{s}\\ \vec{A}(\vec{R},t)&=\frac{\mu_0}{4\pi}\frac{q\vec{v}\,'}{\|\vec{R}-\vec{h}\|\left|1-\dfrac{\vec{v}\,'}{c}\circ\dfrac{(\vec{R}-\vec{h})}{\|\vec{R}-\vec{h}\|}\right|}=\frac{\mu_0 q}{4\pi}\frac{\vec{v}}{s}\end{aligned} \tag{10.3.425}$$

with for recall:

$$\begin{aligned}&s=z\left(1-\frac{\vec{v}}{c}\frac{\vec{z}}{z}\right)=z-\frac{\vec{v}\circ\vec{z}}{c}\\ &t'=t-\frac{z}{c}\\ &\vec{h}=\vec{r}(t')\\ &\vec{z}=\vec{R}-\vec{r}(t')\quad\text{and}\quad z=\|\vec{R}-\vec{r}(t')\|\end{aligned} \tag{10.3.426}$$

The notation in the last line may be confusing, but it's just a change of notation.

Let us now determine the retarded electric field. For this, let us first rearrange t' given above:

$$t'=t-\frac{z}{c}\Leftrightarrow z=c(t-t') \quad (10.3.427)$$

As $z=z(t')$ and $t=t(t')$ (in other words, z is function of t' and t is function of t'), we have the following partial derivative:

$$\partial_t z=\partial_{t'}z\partial_t t' \quad (10.3.428)$$

We also have $z^2=\|\vec{z}\|^2$. Deriving relatively to t':

$$z\partial_{t'}z=\vec{z}\circ\partial_{t'}\vec{z} \quad (10.3.429)$$

By definition we put (!):

$$\partial_{t'}\vec{z}=-\vec{v} \quad (10.3.430)$$

By isolating the derivative with respect to t' in $z\partial_{t'}z=\vec{z}\circ\partial_{t'}\vec{z}$ and taking into account from $\partial_{t'}\vec{z}=-\vec{v}$, we get:

$$\partial_{t'}z=\frac{\vec{z}}{z}\circ\partial_{t'}\vec{z}=-\frac{\vec{z}\circ\vec{v}}{z} \quad (10.3.431)$$

If we derive $z=c(t-t')$ relatively to t:

$$\partial_t z=c(1-\partial_t t')\Leftrightarrow\partial_t t'=1-\frac{\partial_t z}{c} \quad (10.3.432)$$

and equating:

$$\partial_{t'}z\partial_t t'=-\frac{\vec{z}\circ\vec{v}}{z}\partial_t t' \quad \text{and} \quad \partial_t z=c(1-\partial_t t') \quad (10.3.433)$$

We get:

$$-\frac{\vec{z}\circ\vec{v}}{z}\partial_t t'=c(1-\partial_t t') \quad (10.3.434)$$

Isolating $\partial_t t'$:

$$\partial_t t'=\frac{1}{\left(1-\frac{\vec{z}\circ\vec{v}}{zc}\right)}=\frac{z}{\left(z-\frac{\vec{z}\circ\vec{v}}{c}\right)}=\frac{z}{s} \quad (10.3.435)$$

We multiply both side by $\partial_{t'}$:

$$\frac{\partial}{\partial t'}\frac{\partial t'}{\partial t}=\frac{\partial}{\partial t}=\frac{z}{s}\frac{\partial}{\partial t'} \quad (10.3.436)$$

At constant t we apply the nabla operator (i.e. gradient... and for reminder that gives then a vector!) to z:

$$\vec{\nabla}(z)=\vec{\nabla}\left(c(t-t')\right)=-c\vec{\nabla}(t') \quad (10.3.437)$$

But we also have (denoting by $\vec{\nabla}'$ the nabla operator only on the spatial components and remembering as seen above that $\partial_t z = \partial_{t'} z \partial_t t'$):

$$\vec{\nabla}(z) = \vec{\nabla}'(z) + \partial_t z = \vec{\nabla}'(z) + \partial_{t'} z \partial_t t' = \vec{\nabla}'(z) + \partial_{t'} z \vec{\nabla}(t') \tag{10.3.438}$$

where the last equality holds because anyway t' depends only on t.

Therefore we can write:

$$\vec{\nabla}(z) = c\vec{\nabla}(t') = \vec{\nabla}'(z) + \partial_{t'} z \vec{\nabla}(t') \tag{10.3.439}$$

But from:

$$\partial_{t'} z = -\frac{\vec{z} \circ \vec{v}}{z} \tag{10.3.440}$$

We can then write:

$$\vec{\nabla}(z) = c\vec{\nabla}(t') = \vec{\nabla}'(z) - \frac{\vec{z} \circ \vec{v}}{z} \vec{\nabla}(t') \tag{10.3.441}$$

Remark

Now let us denote $u = \|\vec{R} - \vec{r}(t')\|$ instead of z and imagine we explicit that relation in the following way:

$$u = \sqrt{f^2(x(t)) + g^2(y(t)) + h^2(z(t))} = \sqrt{k(x,y,z)} \tag{10.3.442}$$

Now let us recall that if f and g are both differentiable and $F(x)$ is the composite function defined by $F(x) = u(k(x))$ then F is differentiable and F' is given by the product chain rule:

$$F'(x) = u'(k(x))k'(x) \tag{10.3.443}$$

Then:

$$\begin{aligned}\vec{\nabla}(u) &= \begin{pmatrix} \dfrac{\partial u}{\partial x} \\ \dfrac{\partial u}{\partial y} \\ \dfrac{\partial u}{\partial z} \end{pmatrix} = \begin{pmatrix} \dfrac{\partial u}{\partial x}\dfrac{\partial k}{\partial x} \\ \dfrac{\partial u}{\partial y}\dfrac{\partial k}{\partial y} \\ \dfrac{\partial u}{\partial z}\dfrac{\partial k}{\partial z} \end{pmatrix} = \begin{pmatrix} \dfrac{1}{2}\dfrac{1}{\sqrt{f^2(x(t)) + g^2(y(t)) + h^2(z(t))}}2f(x) \\ \dfrac{1}{2}\dfrac{1}{\sqrt{f^2(x(t)) + g^2(y(t)) + h^2(z(t))}}2g(x) \\ \dfrac{1}{2}\dfrac{1}{\sqrt{f^2(x(t)) + g^2(y(t)) + h^2(z(t))}}2h(x) \end{pmatrix} \\ &= \frac{1}{\sqrt{f^2(x(t)) + g^2(y(t)) + h^2(z(t))}} \begin{pmatrix} f(x) \\ g(x) \\ h(x) \end{pmatrix} = \frac{\vec{u}}{u}\end{aligned} \tag{10.3.444}$$

So going back to the notation we have in this section:

$$\vec{\nabla}'(z) = \frac{\vec{z}}{z} \tag{10.3.445}$$

Taking into account what we just detailed in the remark above. We can then also write:

$$\vec{\nabla}(z)=c\vec{\nabla}(t')=\vec{\nabla}'(z)-\frac{\vec{z}\circ\vec{v}}{z}\vec{\nabla}(t')=\frac{\vec{z}}{z}-\frac{\vec{z}\circ\vec{v}}{z}\vec{\nabla}(t') \tag{10.3.446}$$

Rearranging the following par:

$$c\vec{\nabla}(t')=\vec{\nabla}'(z)-\frac{\vec{z}\circ\vec{v}}{z}\vec{\nabla}(t')=\frac{\vec{z}}{z}-\frac{\vec{z}\circ\vec{v}}{z}\vec{\nabla}(t') \tag{10.3.447}$$

we get:

$$\vec{\nabla}(t')=-\frac{\vec{z}}{c\left(z-\frac{\vec{z}\circ\vec{v}}{c}\right)}=-\frac{\vec{z}}{sc} \tag{10.3.448}$$

Therefore the relation we have derived earlier:

$$\vec{\nabla}(z)=\vec{\nabla}'(z)+\partial_{t'}z\vec{\nabla}(t') \tag{10.3.449}$$

can be written:

$$\vec{\nabla}(z)=\vec{\nabla}'(z)+\partial_{t'}z\left(-\frac{\vec{z}}{sc}\right)=\vec{\nabla}'(z)-\frac{\vec{z}}{sc}\partial_{t'}z \tag{10.3.450}$$

If we get rid of the z this gives the following useful relation for further calculations (nabla operator expressed form a retarded nabla operator):

$$\vec{\nabla}=\vec{\nabla}'-\frac{\vec{z}}{sc}\frac{\partial}{\partial t'} \tag{10.3.451}$$

Now remember that we have:

$$\vec{E}(\vec{R},t)=-\vec{\nabla}U-\partial_t\vec{A}\qquad\text{with}\qquad U(\vec{R},t)=\frac{q}{4\pi\varepsilon_0}\frac{1}{s}\qquad\text{and}\qquad\vec{A}(\vec{R},t)=\frac{\mu_0 q}{4\pi}\frac{\vec{v}}{s} \tag{10.3.452}$$

Therefore:

$$\vec{E}(\vec{R},t)=-\vec{\nabla}\left(\frac{q}{4\pi\varepsilon_0}\frac{1}{s}\right)-\partial_t\left(\frac{\mu_0 q}{4\pi}\frac{\vec{v}}{s}\right) \tag{10.3.453}$$

Rearranging (and remembering that $\varepsilon\mu_0c^2=1$) gives:

$$\frac{4\pi\varepsilon_0}{q}\vec{E}=-\vec{\nabla}\left(\frac{1}{s}\right)-\frac{1}{c^2}\partial_t\frac{\vec{v}}{s} \tag{10.3.454}$$

Now we can use the result we get before about the nabla operator because we will compute:

$$\vec{\nabla}\left(\frac{1}{s}\right)=\vec{\nabla}'\frac{1}{s}-\frac{z}{sc}\frac{\partial}{\partial t'}\frac{1}{s}=-\frac{\vec{\nabla}'(s)}{s^2}-\frac{\vec{z}}{sc}\left(-\frac{1}{s^2}\right)\frac{\partial s}{\partial t'}=-\frac{\vec{\nabla}'(s)}{s^2}+\frac{\vec{z}}{s^3c}\frac{\partial s}{\partial t'} \tag{10.3.455}$$

and we can also use the relation derived earlier above:

$$\frac{\partial}{\partial t}=\frac{z}{s}\frac{\partial}{\partial t'} \tag{10.3.456}$$

To calculate:

$$\frac{\partial}{\partial t}\frac{\vec{v}}{s}=\frac{z}{s}\frac{\partial}{\partial t'}\left(\frac{\vec{v}}{s}\right)=\frac{z}{s}\frac{s\frac{\partial\vec{v}}{\partial t'}-\vec{v}\frac{\partial s}{\partial t'}}{s^2}=\frac{z}{s^2}\dot{\vec{v}}-\frac{z\vec{v}}{s^3}\frac{\partial s}{\partial t'} \tag{10.3.457}$$

Therefore:

$$\frac{4\pi\varepsilon_0}{q}\vec{E}=\frac{\vec{\nabla}'s}{s^2}-\frac{\vec{z}}{s^3c}\frac{\partial s}{\partial t'}-\frac{z}{s^2c^2}\dot{\vec{v}}+\frac{z\vec{v}}{s^3c^2}\frac{\partial s}{\partial t'} \tag{10.3.458}$$

Now let us open a parenthesis! Remember that by definition we have put earlier above $\partial_{t'}\vec{z}=-\vec{v}$ and that we have just seen that:

$$\vec{\nabla}(z)=\frac{\vec{z}}{z} \tag{10.3.459}$$

So now let us consider the following rectilinear case:

$$\partial_{t'}\vec{z}=\partial_{t'}\begin{pmatrix}v_xt'\\v_zt'\\v_zt'\end{pmatrix}=\begin{pmatrix}v_x\\v_y\\v_z\end{pmatrix}=-\vec{v} \tag{10.3.460}$$

Then:

$$\begin{aligned}\vec{\nabla}(z)=\frac{\vec{z}}{z}&=\frac{1}{\sqrt{(v_xt')^2+(v_yt')^2+(v_zt')^2}}\begin{pmatrix}v_xt'\\v_zt'\\v_zt'\end{pmatrix}=\frac{1}{t'\sqrt{v_x^2+v_y^2+v_z^2}}\begin{pmatrix}v_xt'\\v_zt'\\v_zt'\end{pmatrix}\\&=\frac{1}{\sqrt{v_x^2+v_y^2+v_z^2}}\begin{pmatrix}v_x\\v_z\\v_z\end{pmatrix}\end{aligned} \tag{10.3.461}$$

Therefore:

$$\begin{aligned}\vec{\nabla}(z)v=\frac{\vec{z}}{z}\partial_{t'}\vec{z}&=\frac{1}{\sqrt{v_x^2+v_y^2+v_z^2}}\begin{pmatrix}v_x\\v_z\\v_z\end{pmatrix}v=\frac{1}{\cancel{\sqrt{v_x^2+v_y^2+v_z^2+}}}\begin{pmatrix}v_x\\v_z\\v_z\end{pmatrix}\cancel{\sqrt{v_x^2+v_y^2+v_z^2}}\\&=-\vec{v}\end{aligned} \tag{10.3.462}$$

But is:

$$\vec{\nabla}(z)v=-\vec{v} \tag{10.3.463}$$

valid for any type of movement? The answer is no! Indeed, consider the famous example of the circular motion in a plane (typical of many particles accelerators):

$$\vec{z}=\begin{pmatrix}R\cos(\omega t')\\R\sin(\omega t')\\0\end{pmatrix} \tag{10.3.464}$$

Then obviously:

$$\begin{aligned}\vec{\nabla}(z)=\frac{\vec{z}}{z}&=\frac{1}{\sqrt{(R\cos(\omega t'))^2+(R\sin(\omega t'))^2}}\begin{pmatrix}R\cos(\omega t')\\R\sin(\omega t')\\0\end{pmatrix}\\&=\frac{1}{R}\begin{pmatrix}R\cos(\omega t')\\R\sin(\omega t')\\0\end{pmatrix}=\begin{pmatrix}\cos(\omega t')\\\sin(\omega t')\\0\end{pmatrix}\end{aligned} \tag{10.3.465}$$

And therefore:

$$\begin{aligned}\vec{\nabla}(z)v=\frac{\vec{z}}{z}v=\frac{\vec{z}}{z}||\partial_{t'}\vec{z}||=\begin{pmatrix}\cos(\omega t')\\ \sin(\omega t')\\ 0\end{pmatrix}||\partial_{t'}\vec{z}||=\begin{pmatrix}\cos(\omega t')\\ \sin(\omega t')\\ 0\end{pmatrix}\left\|\begin{pmatrix}-R\omega\sin(\omega t')\\ R\omega\cos(\omega t')\\ 0\end{pmatrix}\right\|\\ =\begin{pmatrix}\cos(\omega t')\\ \sin(\omega t')\\ 0\end{pmatrix}\sqrt{(-R\omega\sin(\omega t'))^2+(R\omega\cos(\omega t'))^2}=\begin{pmatrix}\cos(\omega t')\\ \sin(\omega t')\\ 0\end{pmatrix}R\omega\\ =\begin{pmatrix}R\omega\cos(\omega t')\\ R\omega\sin(\omega t')\\ 0\end{pmatrix}\neq-\vec{v}\end{aligned}\tag{10.3.466}$$

So that means we can use:

$$\frac{\partial\vec{z}}{\partial t'}=\vec{\nabla}(z)v=\frac{\vec{z}}{z}v=-\vec{v}\tag{10.3.467}$$

only as a locally linear approximation of the particle path when the movement is collinear to the speed! Therefore all relations that will follow are approximations!

So according to what we have just say above, we can write locally in the particle path that:

$$\vec{\nabla}'(s)=\vec{\nabla}\left(z-\frac{\vec{z}\circ\vec{v}}{c}\right)=\vec{\nabla}(z)-\vec{\nabla}\left(\frac{\vec{z}\circ\vec{v}}{c}\right)=\frac{\vec{z}}{z}-\frac{\vec{z}}{z}\frac{v}{c}=\frac{\vec{z}}{z}-\frac{\vec{v}}{c}\tag{10.3.468}$$

Injecting that result in the earlier relation:

$$\frac{4\pi\varepsilon_0}{q}\vec{E}=\frac{\vec{\nabla}'s}{s^2}-\frac{\vec{z}}{s^3c}\frac{\partial s}{\partial t'}-\frac{z}{s^2c^2}\dot{\vec{v}}+\frac{z\vec{v}}{s^3c^2}\frac{\partial s}{\partial t'}\tag{10.3.469}$$

we get:

$$\frac{4\pi\varepsilon_0}{q}\vec{E}=\frac{1}{s^2}\left(\frac{\vec{z}}{z}-\frac{\vec{v}}{c}\right)+\frac{1}{s^3c}\left(\frac{z}{c}\vec{v}-\vec{z}\right)\frac{\partial s}{\partial t'}-\frac{z}{s^2c^2}\dot{\vec{v}}\tag{10.3.470}$$

But we also have:

$$\frac{\partial s}{\partial t'}=\frac{\partial}{\partial t'}\left(z-\frac{\vec{z}\circ\vec{v}}{c}\right)=\frac{\partial z}{\partial t'}-\frac{\vec{z}\circ\dot{\vec{v}}}{c}-\frac{\vec{v}}{c}\circ\frac{\partial\vec{z}}{\partial t'}=\frac{\partial z}{\partial t'}-\frac{\vec{z}\circ\dot{\vec{v}}}{c}+\frac{v^2}{c}\tag{10.3.471}$$

Injecting the result in the previous relation a remembering that we have proved earlier that:

$$\partial_{t'}z=\frac{\vec{z}}{z}\circ\partial_{t'}\vec{z}=-\frac{\vec{z}\circ\vec{v}}{z}\tag{10.3.472}$$

we get:

$$\frac{4\pi\varepsilon_0}{q}\vec{E}=\frac{1}{s^2z}\left(\vec{z}-\frac{z\vec{v}}{c}\right)+\frac{1}{s^3c}\left(\frac{z}{c}\vec{v}-\vec{z}\right)\left(-\frac{\vec{z}\circ\vec{v}}{z}-\frac{\vec{z}\circ\dot{\vec{v}}}{c}+\frac{v^2}{c}\right)-\frac{z}{s^2c^2}\dot{\vec{v}}\tag{10.3.473}$$

Rearranging a bit:

$$\frac{4\pi\varepsilon_0}{q}\vec{E}=\frac{1}{s^2z}\left(\vec{z}-\frac{z\vec{v}}{c}\right)+\frac{1}{s^3c}\left(\vec{z}-\frac{z}{c}\vec{v}\right)\left(\frac{\vec{z}\circ\vec{v}}{z}-\frac{v^2}{c}+\frac{\vec{z}\circ\dot{\vec{v}}}{c}\right)-\frac{z}{s^2c^2}\dot{\vec{v}}\tag{10.3.474}$$

Let us now focus on that term:

$$\frac{1}{s^2z}\left(\vec{z}-\frac{z\vec{v}}{c}\right)+\frac{1}{s^3c}\left(\vec{z}-\frac{z}{c}\vec{v}\right)\left(\frac{\vec{z}\circ\vec{v}}{z}-\frac{v^2}{c}+\frac{\vec{z}\circ\dot{\vec{v}}}{c}\right)-\frac{z}{s^2c^2}\dot{\vec{v}} \tag{10.3.475}$$

Rearranging we get:

$$\frac{1}{s^3}\left(\vec{z}-\frac{z\vec{v}}{c}\right)\left(\frac{s}{z}-\frac{v^2}{c^2}\right)+\frac{1}{s^3c}\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\frac{\vec{z}\circ\vec{v}}{r}+\left(\vec{z}-\frac{z}{c}\vec{v}\right)\frac{\vec{z}\circ\dot{\vec{v}}}{c}\right]-\frac{z}{s^2c^2}\dot{\vec{v}} \tag{10.3.476}$$

Working on the first term we have:

$$\begin{aligned}\frac{1}{s^3}\left(\vec{z}-\frac{z\vec{v}}{c}\right)\left(\frac{s}{z}-\frac{v^2}{c^2}\right)&=\frac{1}{s^3}\left(\vec{z}-\frac{z\cdot\vec{v}}{c}\right)\left(\frac{z-\frac{\vec{z}\circ\vec{v}}{c}}{z}-\frac{v^2}{c^2}\right)\\&=\frac{1}{s^3}\left(\vec{z}-\frac{z\vec{v}}{c}\right)\left(1-\frac{\vec{z}\circ\vec{v}}{zc}-\frac{v^2}{c^2}\right)\\&=\frac{1}{s^3}\left(\vec{z}-\frac{z\vec{v}}{c}\right)\left(1-\frac{v^2}{c^2}\right)-\frac{1}{s^3}\left(\vec{z}-\frac{z\cdot\vec{v}}{c}\right)\frac{\vec{z}\circ\vec{v}}{zc}\end{aligned} \tag{10.3.477}$$

Injected into the previous relation and simplifying we get:

$$\begin{aligned}&\frac{1}{s^3}\left(\vec{z}-\frac{z\vec{v}}{c}\right)\left(1-\frac{v^2}{c^2}\right)-\frac{1}{s^3c}\left[-\cancel{\left(\vec{z}-\frac{z}{c}\vec{v}\right)\frac{\vec{z}\circ\vec{v}}{r}}+\cancel{\left(\vec{z}-\frac{z}{c}\vec{v}\right)\frac{\vec{z}\circ\vec{v}}{r}}-\left(\vec{z}-\frac{z}{c}\vec{v}\right)\frac{\vec{z}\circ\dot{\vec{v}}}{c}\right]-\frac{z}{s^2c^2}\dot{\vec{v}}\\&=\frac{1}{s^3}\left(\vec{z}-\frac{z\vec{v}}{c}\right)\left(1-\frac{v^2}{c^2}\right)+\frac{1}{s^3c}\left(\vec{z}-\frac{z}{c}\dot{\vec{v}}\right)\frac{\vec{z}\circ\dot{\vec{v}}}{c}-\frac{z}{s^2c^2}\dot{\vec{v}}\\&=\frac{1}{s^3}\left(\vec{z}-\frac{z\vec{v}}{c}\right)\left(1-\frac{v^2}{c^2}\right)+\frac{1}{s^3c}\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\frac{\vec{z}\circ\dot{\vec{v}}}{c}-sz\dot{\vec{v}}\right]\\&=\frac{1}{s^3}\left(\vec{z}-\frac{z\vec{v}}{c}\right)\left(1-\frac{v^2}{c^2}\right)+\frac{1}{s^3c^2}\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\vec{z}\circ\dot{\vec{v}}-z\left(z-\frac{\vec{z}\circ\vec{v}}{c}\right)\dot{\vec{v}}\right]\end{aligned} \tag{10.3.478}$$

The term between square bracket is a triple cross product and we have already proved in the section of Vector Calculus that this can be written (see page 1835):

$$\begin{aligned}&\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\vec{z}\circ\dot{\vec{v}}-\dot{\vec{v}}\left(z-\frac{\vec{z}\circ\vec{v}}{c}\right)z\right]=\\&\vec{z}\times\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\times\dot{\vec{v}}\right]=\left(\vec{z}-\frac{z}{c}\vec{v}\right)\left(\vec{z}\circ\dot{\vec{v}}\right)-\dot{\vec{v}}\left[\vec{z}\circ\left(\vec{z}-\frac{z\vec{v}}{c}\right)\right]\\&=\left(\vec{z}-\frac{z}{c}\vec{v}\right)\left(\vec{z}\circ\dot{\vec{v}}\right)-\dot{\vec{v}}\left[z\left(z-\frac{\vec{z}\circ\vec{v}}{c}\right)\right]\end{aligned} \tag{10.3.479}$$

Finally, we find for the retarded electric field, the following expression (we put now the approximate equal sign because we know that some assumptions made earlier make is an approximation):

$$\vec{E}\cong\frac{q}{4\pi\varepsilon_0 s^3}\left\{\left(1-\frac{v^2}{c^2}\right)\left(\vec{z}-\frac{z}{c}\vec{v}\right)+\frac{\vec{z}}{c^2}\times\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\times\dot{\vec{v}}\right]\right\} \tag{10.3.480}$$

Now let us do the same work with the magnetic retarded field. We start from:

$$\vec{B}=\vec{\nabla}\times\vec{A} \quad \text{with} \quad \vec{A}=\frac{q\mu_0}{4\pi}\left(\frac{\vec{v}}{s}\right) \tag{10.3.481}$$

Therefore:

$$\vec{B}=\vec{\nabla}\times\left(\frac{q\mu_0}{4\pi}\frac{\vec{v}}{s}\right) \tag{10.3.482}$$

Rearranging and using $\mu_0\varepsilon_0c^2=1$ we get:

$$\frac{4\pi\varepsilon_0c^2}{q}\vec{B}=\vec{\nabla}\times\frac{\vec{v}}{s} \tag{10.3.483}$$

We have proved in the section of Vector Calculus that (see page 1916):

$$\vec{\nabla}\times\left(\frac{\vec{v}}{s}\right)=\frac{1}{s}(\vec{\nabla}\times\vec{v})+\vec{\nabla}\left(\frac{1}{s}\right)\times\vec{v} \tag{10.3.484}$$

Therefore:

$$\frac{4\pi\varepsilon_0c^2}{q}\vec{B}=\frac{1}{s}(\vec{\nabla}\times\vec{v})+\vec{\nabla}\left(\frac{1}{s}\right)\times\vec{v} \tag{10.3.485}$$

For the next step Larmor used a trick (still debated nowadays) to simplify the expression to be able to fall back later on a simplified expression of radiated electromagnetic field that was known before his theory. The trick (mathematically quite wrong but physically it works...) is to expression the nabla operator on the $\vec{\nabla}\times\vec{v}$ by it's retarded version derived earlier above for the position (...) and given for reminder by:

$$\vec{\nabla}=\vec{\nabla}'-\frac{\vec{z}}{sc}\frac{\partial}{\partial t'} \tag{10.3.486}$$

If we do that we get for the first parenthesis or the prior relation:

$$\vec{\nabla}\times\vec{v}_t=\vec{\nabla}'\times\vec{v}-\frac{\vec{z}}{sc}\times\frac{\partial\vec{v}}{\partial t'} \tag{10.3.487}$$

After without mathematical reasons or also without physical interpretation, but very likely to fall back on a known result as mentioned above, Larmor put:

$$\vec{\nabla}'\times\vec{v}=\vec{0} \tag{10.3.488}$$

claiming (we don't how this claim makes any sense...) that's because $\vec{v}=f(t')$....???

We may think that Larmor did that because if $\vec{v}$ is a vector field, then $\vec{\nabla}'\times\vec{v}=\vec{0}$ assume that the velocity field is irrotational and therefore the velocity field is conservative (such fields have for reminder the property that the line integral around any closed loop, often representing the work done in moving a particle, is zero). But if $\vec{v}$ is a conservative field, in our point of view, then we should also have $\vec{\nabla}\times\vec{v}=\vec{0}$... and then nothing makes sense anymore. That's why it is very likely to be a physicist trick just because we have to it to fall back later on a result that was already known at his time.

Then obviously we get for the first parenthesis:

$$\vec{\nabla}\times\vec{v}_t\cong-\frac{\vec{z}}{sc}\times\frac{\partial\vec{v}}{\partial t'}=-\frac{\vec{z}\times\dot{\vec{v}}}{sc} \qquad (10.3.489)$$

Now coming back to:

$$\frac{4\pi\varepsilon_0c^2}{q}\vec{B}=\vec{\nabla}\times\frac{\vec{v}}{s}=\frac{1}{s}(\vec{\nabla}\times\vec{v})+\vec{\nabla}\left(\frac{1}{s}\right)\times\vec{v}=-\frac{\vec{z}\times\dot{\vec{v}}}{s^2c}+\vec{\nabla}\left(\frac{1}{s}\right)\times\vec{v} \qquad (10.3.490)$$

Now let us focus on the second term that we can immediately write as (using again the relation between the nabla operator and retarded nabla operator):

$$\vec{\nabla}\left(\frac{1}{s}\right)\times\vec{v}=-\frac{1}{s^2}\vec{\nabla}(s)\times\vec{v}=-\frac{1}{s^2}\left[\vec{\nabla}'(s)-\frac{\vec{z}}{sc}\frac{\partial s}{\partial t'}\right]\times\vec{v} \qquad (10.3.491)$$

And using again the relation derived earlier above that was:

$$\vec{\nabla}'(s)=\vec{\nabla}\left(z-\frac{\vec{z}\circ\vec{v}}{c}\right)=\vec{\nabla}(z)-\vec{\nabla}\left(\frac{\vec{z}\circ\vec{v}}{c}\right)=\frac{\vec{z}}{z}-\frac{\vec{z}}{z}\frac{v}{c}=\frac{\vec{z}}{z}-\frac{\vec{v}}{c} \qquad (10.3.492)$$

We get:

$$\vec{\nabla}\left(\frac{1}{s}\right)\times\vec{v}=-\frac{1}{s^2}\vec{\nabla}(s)\times\vec{v}=-\frac{1}{s^2}\left[\frac{\vec{z}}{z}-\frac{\vec{v}}{c}-\frac{\vec{z}}{sc}\frac{\partial s}{\partial t'}\right]\times\vec{v} \qquad (10.3.493)$$

But we have proved earlier above that:

$$\frac{\partial s}{\partial t'}=\frac{\partial}{\partial t'}\left(z-\frac{\vec{z}\circ\vec{v}}{c}\right)=\frac{\partial z}{\partial t'}-\frac{\vec{z}\circ\dot{\vec{v}}}{c}-\frac{\vec{v}}{c}\circ\frac{\partial\vec{z}}{\partial t'}=-\frac{\vec{z}\circ\vec{v}}{z}-\frac{\vec{z}\circ\dot{\vec{v}}}{c}+\frac{v^2}{c} \qquad (10.3.494)$$

Therefore:

$$\vec{\nabla}\left(\frac{1}{s}\right)\times\vec{v}=-\frac{1}{s^2}\vec{\nabla}(s)\times\vec{v}=-\frac{1}{s^2}\left[\frac{\vec{z}}{z}-\frac{\vec{v}}{c}-\frac{\vec{z}}{sc}\left(-\frac{\vec{z}\circ\vec{v}}{z}-\frac{\vec{z}\circ\dot{\vec{v}}}{c}+\frac{v^2}{c}\right)\right]\times\vec{v} \qquad (10.3.495)$$

Hence:

$$\begin{aligned}\frac{4\pi\varepsilon_0c^2}{q}\vec{B}&=\vec{\nabla}\times\frac{\vec{v}}{s}=\frac{1}{s}(\vec{\nabla}\times\vec{v})+\vec{\nabla}\left(\frac{1}{s}\right)\times\vec{v}=-\frac{\vec{z}\times\dot{\vec{v}}}{s^2c}+\vec{\nabla}\left(\frac{1}{s}\right)\times\vec{v}\\&=-\frac{\vec{z}\times\dot{\vec{v}}}{s^2c}-\frac{1}{s^2}\left[\frac{\vec{z}}{z}-\frac{\vec{v}}{c}-\frac{\vec{z}}{sc}\left(-\frac{\vec{z}\circ\vec{v}}{z}-\frac{\vec{z}\circ\dot{\vec{v}}}{c}+\frac{v^2}{c}\right)\right]\times\vec{v}\end{aligned} \qquad (10.3.496)$$

Let us rearrange and simplify the right hand side:

$$
\begin{aligned}
\vec{\nabla}\times\frac{\vec{v}}{s} &= -\frac{\left(\vec{z}\times\dot{\vec{v}}\right)}{s^2c}+\frac{\vec{v}}{s^2}\times\left\{\frac{\vec{z}}{z}-\frac{\vec{v}}{c}-\frac{\vec{z}}{sc}\left[-\frac{\left(\vec{z}\circ\vec{v}\right)}{z}+\frac{v^2}{c}-\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c}\right]\right\}\\
&= -\frac{\left(\vec{z}\times\dot{\vec{v}}\right)}{s^2c}+\frac{\left(\vec{v}\times\vec{z}\right)}{s^2z}-\cancel{\frac{\left(\vec{v}\times\vec{v}\right)}{s^2c}}-\frac{\left(\vec{v}\times\vec{z}\right)}{s^3c}\left[-\frac{\left(\vec{z}\circ\vec{v}\right)}{z}+\frac{v^2}{c}-\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c}\right]\\
&= -\frac{\left(\vec{z}\times\dot{\vec{v}}\right)}{s^2c}+\frac{\left(\vec{v}\times\vec{z}\right)}{s^2z}+\frac{\left(\vec{v}\times\vec{z}\right)}{s^3c}\cdot\frac{\left(\vec{z}\circ\vec{v}\right)}{z}-\frac{\left(\vec{v}\times\vec{z}\right)}{s^3c}\cdot\frac{v^2}{c}+\frac{\left(\vec{v}\times\vec{z}\right)}{s^3c}\cdot\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c}\\
&= \frac{1}{s^3}\left[-\left(\vec{z}\times\dot{\vec{v}}\right)\left(\frac{s}{c}\right)+\left(\vec{v}\times\vec{z}\right)\left(\frac{s}{z}\right)+\left(\vec{v}\times\vec{z}\right)\frac{\vec{z}\circ\vec{v}}{zc}-\left(\vec{v}\times\vec{z}\right)\left(\frac{v^2}{c^2}\right)+\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c^2}\right]\\
&= \frac{1}{s^3}\left[-\left(\vec{z}\times\dot{\vec{v}}\right)\frac{z-\frac{\left(\vec{z}\circ\vec{v}\right)}{c}}{c}+\left(\vec{v}\times\vec{z}\right)\frac{z-\frac{\left(\vec{z}\circ\vec{v}\right)}{c}}{z}+\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\vec{v}\right)}{zc}-\left(\vec{v}\times\vec{z}\right)\left(\frac{v^2}{c^2}\right)+\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c^2}\right]\\
&= \frac{1}{s^3}\left[-\left(\vec{z}\times\dot{\vec{v}}\right)\frac{z}{c}+\left(\vec{z}\times\dot{\vec{v}}\right)\frac{\left(\vec{z}\circ\vec{v}\right)}{c^2}+\left(\vec{v}\times\vec{z}\right)-\cancel{\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\vec{v}\right)}{zc}}+\cancel{\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\vec{v}\right)}{zc}}-\left(\vec{v}\times\vec{z}\right)\left(\frac{v^2}{c^2}\right)+\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c^2}\right]\\
&= \frac{1}{s^3}\left[-\left(\vec{z}\times\dot{\vec{v}}\right)\frac{z}{c}+\left(\vec{z}\times\dot{\vec{v}}\right)\frac{\left(\vec{z}circ\vec{v}\right)}{c^2}+\left(\vec{v}\times\vec{z}\right)\left(1-\frac{v^2}{c^2}\right)+\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c^2}\right]\\
&= \frac{1}{s^3}\left[\left(1-\frac{v^2}{c^2}\right)\left(\vec{v}\times\vec{z}\right)+\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c^2}-\left(\vec{z}\times\dot{\vec{v}}\right)\frac{z-\frac{\left(\vec{z}\circ\vec{v}\right)}{c}}{c}\right]
\end{aligned}
\tag{10.3.497}
$$

Therefore:

$$
\frac{4\pi\varepsilon_0c^2}{q}\vec{B}=\vec{\nabla}\times\frac{\vec{v}}{s}=\frac{1}{s^3}\left[\left(1-\frac{v^2}{c^2}\right)\left(\vec{v}\times\vec{z}\right)+\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c^2}-\left(\vec{z}\times\dot{\vec{v}}\right)\frac{z-\frac{\left(\vec{z}\circ\vec{v}\right)}{c}}{c}\right]
\tag{10.3.498}
$$

We now propose to investigate the possibility of bringing together the last two terms inside the square brackets in the form of cross-products. That means:

$$
\left(\vec{v}\times\vec{z}\right)\frac{\left(\vec{z}\circ\dot{\vec{v}}\right)}{c^2}-\left(\vec{z}\times\dot{\vec{v}}\right)\frac{z-\frac{\left(\vec{z}\circ\vec{v}\right)}{c}}{c}
\tag{10.3.499}
$$

By inverting the factors of the first cross product and simplifying by reducing to the same denominator in the second term we get:

$$
-\frac{1}{c^2}\left(\vec{z}\times\vec{v}\right)\left(\vec{z}\cdot\dot{\vec{v}}\right)-\left(\vec{z}\times\dot{\vec{v}}\right)\left[\frac{z}{c}-\frac{\left(\vec{z}\circ\vec{v}\right)}{c^2}\right]
\tag{10.3.500}
$$

We multiply this expression by z/z and factorize $1/(zc)$:

$$
\frac{1}{zc}\left\{\left[-\frac{z}{c}\left(\vec{z}\times\vec{v}\right)\left(\vec{z}\circ\dot{\vec{v}}\right)\right]-\left(\vec{z}\times\dot{\vec{v}}\right)\left[z^2-\frac{z}{c}\left(\vec{z}\circ\vec{v}\right)\right]\right\}
\tag{10.3.501}
$$

We introduce the term $\vec{z}\times\vec{z}$ (that is obviously equal to $\vec{0}$):

$$
\begin{aligned}
&\frac{1}{zc}\left\{\left[\vec{z}\times\vec{z}-\frac{z}{c}\left(\vec{z}\times\vec{v}\right)\left(\vec{z}\circ\dot{\vec{v}}\right)\right]-\left(\vec{z}\times\dot{\vec{v}}\right)\left[z^2-\frac{z}{c}\left(\vec{z}\circ\vec{v}\right)\right]\right\}=\\
&\frac{1}{zc}\left\{\vec{z}\times\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\left(\vec{z}\circ\dot{\vec{v}}\right)\right]-\left(\vec{z}\times\dot{\vec{v}}\right)\left[\vec{z}\left(\vec{z}-\frac{z}{c}\vec{v}\right)\right]\right\}=\\
&\frac{\vec{z}}{zc}\times\left\{\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\left(\vec{z}\circ\dot{\vec{v}}\right)\right]-\dot{\vec{v}}\left[\vec{z}\circ\left(\vec{z}-\frac{z}{c}\vec{v}\right)\right]\right\}
\end{aligned}
\tag{10.3.502}
$$

But the term between curl braces:

$$\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)(\vec{z}\circ\dot{\vec{v}})\right]-\dot{\vec{v}}\left[\vec{z}\circ\left(\vec{z}-\frac{z}{c}\vec{v}\right)\right] \tag{10.3.503}$$

can be recognized as being a triple cross-product (see section Vector Calculus page 1835). Indeed, if we put:

$$\vec{A}=\vec{z} \qquad \vec{B}=\left(\vec{z}-\frac{z}{c}\vec{v}\right) \qquad \vec{C}=\dot{\vec{v}} \tag{10.3.504}$$

We know that then we have the following relation:

$$\vec{A}\times(\vec{B}\times\vec{C})=\vec{B}(\vec{A}\circ\vec{C})-\vec{C}(\vec{A}\circ\vec{B}) \tag{10.3.505}$$

and it's corresponding:

$$\left(\vec{z}-\frac{z}{c}\vec{v}\right)(\vec{z}\circ\dot{\vec{v}})-\vec{v}\left[\vec{z}\circ\left(\vec{z}-\frac{z}{c}\vec{v}\right)\right]=\vec{z}\times\left(\vec{z}-\frac{z}{c}\vec{v}\right)\times\dot{\vec{v}} \tag{10.3.506}$$

Therefore:

$$\frac{4\pi\varepsilon_0 c^2}{q}\vec{B}\cong\vec{\nabla}\times\frac{\vec{v}}{s}=\frac{1}{s^3}\left\{\left(1-\frac{v^2}{c^2}\right)(\vec{v}\times\vec{z})+\frac{\vec{z}}{zc}\times\left[\vec{z}\times\left(\vec{z}-\frac{z}{c}\vec{v}\right)\times\dot{\vec{v}}\right]\right\} \tag{10.3.507}$$

After rearranging:

$$\vec{B}\cong\frac{q}{4\pi\varepsilon_0 c^2 s^3}\left[\left(1-\frac{v^2}{c^2}\right)(\vec{z}\times\vec{v})+\frac{\vec{z}}{zc}\times\left[\vec{z}\times\left(\vec{z}-\frac{z}{c}\vec{v}\right)\times\dot{\vec{v}}\right]\right] \tag{10.3.508}$$

In summary we find for the delayed fields, the following expressions:

$$\begin{gathered}\vec{E}\cong\frac{q}{4\pi\varepsilon_0 s^3}\left\{\left(1-\frac{v^2}{c^2}\right)\left(\vec{z}-\frac{z}{c}\vec{v}\right)+\frac{\vec{z}}{c^2}\times\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\times\dot{\vec{v}}\right]\right\}\\ \vec{B}\cong\frac{q}{4\pi\varepsilon_0 c^2 s^3}\left[\left(1-\frac{v^2}{c^2}\right)(\vec{v}\times\vec{z})+\frac{\vec{z}}{zc}\times\left[\vec{z}\times\left(\vec{z}-\frac{z}{c}\vec{v}\right)\times\dot{\vec{v}}\right]\right]\end{gathered} \tag{10.3.509}$$

Hence explicitly:

$$\boxed{\begin{gathered}\vec{E}\cong\frac{q}{4\pi\varepsilon_0\left(z\left(1-\dfrac{\vec{v}}{c}\circ\dfrac{\vec{z}}{z}\right)\right)^3}\left\{\left(1-\frac{v^2}{c^2}\right)\left(\vec{z}-\frac{z}{c}\vec{v}\right)+\frac{\vec{z}}{c^2}\times\left[\left(\vec{z}-\frac{z}{c}\vec{v}\right)\times\dot{\vec{v}}\right]\right\}\\ \vec{B}\cong\frac{q}{4\pi\varepsilon_0 c^2\left(z\left(1-\dfrac{\vec{v}}{c}\circ\dfrac{\vec{z}}{z}\right)\right)^3}\left[\left(1-\frac{v^2}{c^2}\right)(\vec{v}\times\vec{z})+\frac{\vec{z}}{zc}\times\left[\vec{z}\times\left(\vec{z}-\frac{z}{c}\vec{v}\right)\times\dot{\vec{v}}\right]\right]\end{gathered}} \tag{10.3.510}$$

Let us analyse these expressions of retarded electric fields and magnetic induction. For this analysis, we will modify somewhat the two expressions above.

For this purpose we put:

$$\frac{\vec{v}}{c}=\beta \qquad s=z-\frac{\vec{v}}{c}\circ\vec{z}=z-\vec{\beta}\circ\vec{z} \tag{10.3.511}$$

and we will denote by $\vec{u}_z$ the unitary vector collinear to $\vec{z}$.

Therefore:

$$\begin{aligned}\vec{E} &\cong \frac{q}{4\pi\varepsilon_0}\left[\frac{z(1-\beta^2)\left(\vec{u}_z-\vec{\beta}\right)}{z^3\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}+\frac{z\cdot\vec{u}_z\times z\left(\vec{u}_z-\vec{\beta}\right)\times\dot{\vec{v}}}{c^2z^3\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}\right]\\ \vec{B} &\cong \frac{q}{4\pi\varepsilon_0c^2}\left[\frac{z(1-\beta^2)\left(\dot{\vec{v}}\times\vec{u}_z\right)}{z^3\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}+\frac{z\cdot\vec{u}_z\times[z\cdot\vec{u}_z\times z]\left(\vec{u}_z-\vec{\beta}\right)\times\dot{\vec{\beta}}}{z^4\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}\right]\end{aligned} \tag{10.3.512}$$

Simplifying a bit more:

$$\begin{aligned}\vec{E} &\cong \frac{q}{4\pi\varepsilon_0}\left[\frac{(1-\beta^2)\left(\vec{u}_z-\vec{\beta}\right)}{z^2\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}+\frac{\vec{u}_z\times\left(\vec{u}_z-\vec{\beta}\right)\times\dot{\vec{v}}}{c^2z\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}\right]\\ \vec{B} &\cong \frac{q}{4\pi\varepsilon_0c^2}\left[\frac{(1-\beta^2)\left(\vec{v}\times\vec{u}_z\right)}{z^2\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}+\frac{\vec{u}_z\times\left[\vec{u}_z\times\left(\vec{u}_z-\vec{\beta}\right)\right]\times\dot{\vec{\beta}}}{z\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}\right]\end{aligned} \tag{10.3.513}$$

So we observe that the two retarded fields $\vec{E}$ and $\vec{B}$ are composed of two terms $\vec{E}_1+\vec{E}_2$ and $\vec{B}_1+\vec{B}_2$.

- The first terms $\vec{E}_1$ and $\vec{B}_1$ are:

  $$\begin{aligned}\vec{E}_1 &\cong \frac{q}{4\pi\varepsilon_0}\frac{(1-\beta^2)\left(\vec{u}_z-\vec{\beta}\right)}{z^2\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}\\ \vec{B}_1 &\cong \frac{q}{4\pi\varepsilon_0c^2}\frac{(1-\beta^2)\left(\vec{v}\times\vec{u}_z\right)}{z^2\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}\end{aligned} \tag{10.3.514}$$

  They correspond to a charge animated by a speed $\vec{v}$ and whose fields are functions of the speed of displacement of the so said charge and of the inverse of the square of the distance z.

  $$\vec{E}_1\cong f(\vec{v},z^{-2}) \qquad \vec{B}_1\cong f(\vec{v},z^{-2}) \tag{10.3.515}$$

  These fields decrease rapidly with the distance z.

  We notice that in the non-relativistic case $\beta\ll 1$, we fall back on the classical expression of the electric field and of magnetic induction:

  $$\begin{aligned}\vec{E}_1 &\cong \frac{q}{4\pi\varepsilon_0}\frac{\vec{u}_z}{z^2}\\ \vec{B}_1 &\cong \frac{q}{4\pi\varepsilon_0c^2}\frac{\vec{v}\times\vec{z}}{z^2}\end{aligned} \tag{10.3.516}$$

  Likewise, in the particular case where the speed is zero, only the electrostatic field remains as expected!

- The second terms $\vec{E}_2$ and $\vec{B}_2$ are:

$$\begin{aligned}\vec{E}_2 &\cong \frac{q}{4\pi\varepsilon_0 c}\frac{\vec{u}_z\times\left(\vec{u}_z-\vec{\beta}\right)\times\dot{\vec{\beta}}}{z\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}\\ \vec{B}_2 &\cong \frac{q}{4\pi\varepsilon_0 c^2}\frac{\vec{u}_z\times\left[\vec{u}_z\times\left(\vec{u}_z-\vec{\beta}\right)\right]\times\dot{\vec{\beta}}}{z\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}=\frac{\vec{u}_z\times\vec{E}_2}{c}\end{aligned}\tag{10.3.517}$$

They correspond to charges animated by an accelerated movement $\dot{\vec{\beta}}=\dot{\vec{v}}/c$ but which have a decreasing amplitude with z:

$$\vec{E}_2\cong f(\vec{v},z^{-1})\qquad \vec{B}_2\cong f(\vec{v},z^{-1})\tag{10.3.518}$$

These are radiating fields known as the "electromagnetic wave" (E.M).

These waves propagate from the charge in the form of a spherical wave but which at a great distance can be locally considered as plane.

In the non-relativistic $\beta\ll 1$ case we get:

$$\begin{aligned}\vec{E}_2 &\cong \frac{q}{4\pi\varepsilon_0 c}\frac{\vec{u}_z\times\left(\vec{u}_z\times\dot{\vec{\beta}}\right)}{z}\\ \vec{B}_2 &\cong \frac{q}{4\pi\varepsilon_0 c^2}\frac{\vec{u}_z\times\left[\vec{u}_z\times\left(\vec{u}_z\times\dot{\vec{\beta}}\right)\right]}{z}\end{aligned}\tag{10.3.519}$$

We can also write the fields as following (for the last equality see the explanations just afterwards!):

$$\begin{aligned}\vec{E}_2 &\cong \frac{q}{4\pi\varepsilon_0 c}\frac{z\cdot\vec{u}_z\times\left(z\cdot\vec{u}_z\times\dot{\vec{\beta}}\right)}{z\cdot z\cdot z}=\frac{q}{4\pi\varepsilon_0 c z^3}\vec{z}\times\left(\vec{z}\times\dot{\vec{\beta}}\right)\\ \vec{B}_2 &\cong \frac{q}{4\pi\varepsilon_0 c^2 z^3}z\left(\dot{\vec{\beta}}\times\vec{z}\right)\end{aligned}\tag{10.3.520}$$

Indeed, let us analyse how we can rewrite:

$$\vec{u}_z\times\left[\vec{u}_z\times\left(\vec{u}_z\times\dot{\vec{\beta}}\right)\right]\tag{10.3.521}$$

With a small change of variable we recognize again the triple cross-product (see section Vector Calculus page 1835):

$$\left.\begin{aligned}\vec{A}&=\vec{u}_z\\ \vec{B}&=\vec{u}_z\\ \vec{C}&=\vec{u}_z\times\dot{\vec{\beta}}\end{aligned}\right\}:\vec{A}\times\left(\vec{B}\times\vec{C}\right)=\vec{B}\left(\vec{A}\cdot\vec{C}\right)-\vec{C}\left(\vec{A}\circ\vec{B}\right)\tag{10.3.522}$$

Therefore:

$$\vec{u}_z\times\left[\vec{u}_z\times\left(\vec{u}_z\times\dot{\vec{\beta}}\right)\right]=\vec{u}_z\left[\vec{u}_z\circ\left(\vec{u}_z\times\dot{\vec{\beta}}\right)\right]-\left(\vec{u}_z\times\dot{\vec{\beta}}\right)\left(\vec{u}_z\circ\vec{u}_z\right)\tag{10.3.523}$$

It is immediate that $\vec{u}_z\circ\left(\vec{u}_z\times\dot{\vec{\beta}}\right)=0$, then it remains:

$$\vec{u}_z\times\left[\vec{u}_z\times\left(\vec{u}_z\times\dot{\vec{\beta}}\right)\right]=-\left(\vec{u}_z\times\dot{\vec{\beta}}\right)\left(\vec{u}_z\circ\vec{u}_z\right)=-\left(\vec{u}_z\circ\vec{u}_z\right)\left(\vec{u}_z\times\dot{\vec{\beta}}\right)=\left(\vec{u}_z\circ\vec{u}_z\right)\left(\dot{\vec{\beta}}\times\vec{u}_z\right)\tag{10.3.524}$$

Therefore:

$$\begin{aligned}\vec{B}_2 &\cong \frac{q}{4\pi\varepsilon_0 c^2}\frac{\vec{u}_z\times[\vec{u}_z\times(\vec{u}_z\times\dot{\vec{\beta}})]}{z}=\frac{q}{4\pi\varepsilon_0 c^2}\frac{zz(\vec{u}_z\circ\vec{u}_z)(\dot{\vec{\beta}}\times z\vec{u}_z)}{z^4}\\ &=\frac{q}{4\pi\varepsilon_0 c^2}\frac{(\vec{z}\circ\vec{z})(\dot{\vec{\beta}}\times\vec{z})}{z^4}=\frac{q}{4\pi\varepsilon_0 c^2 z^3}z(\dot{\vec{\beta}}\times z\vec{u}_z)=\frac{q}{4\pi\varepsilon_0 c^2 z}(\dot{\vec{\beta}}\times\vec{u}_z)\end{aligned} \quad (10.3.525)$$

In summary, keeping only the radiated part of the fields (!), we have:

- For the relativistic case:

$$\left.\begin{aligned}\vec{E}&\cong\frac{q}{4\pi\varepsilon_0 c}\frac{\vec{u}_z\times(\vec{u}_z-\vec{\beta})\times\dot{\vec{\beta}}}{z\left(1-\vec{\beta}\circ\vec{u}_z\right)^3}\\ \vec{B}&\cong\frac{q}{4\pi\varepsilon_0 c^2}\frac{\vec{u}_z\times[\vec{u}_z\times(\vec{u}_z\times\dot{\vec{\beta}})]}{z}\end{aligned}\right\}\vec{B}\cong\frac{\vec{u}_z\times\vec{E}}{c} \quad (10.3.526)$$

- And for the non-relativistic case:

$$\left.\begin{aligned}\vec{E}&=\frac{q}{4\pi\varepsilon_0 c z^3}\vec{z}\times(\vec{z}\times\dot{\vec{\beta}})\\ \vec{B}&=\frac{q}{4\pi\varepsilon_0 c^2 z^3}(\dot{\vec{\beta}}\times\vec{z})\end{aligned}\right\}\vec{B}\cong-\frac{\vec{z}\times\vec{E}}{c} \quad (10.3.527)$$

From now on, as the reader will have very likely noticed it, we will only work with the radiated fields and we will remove the index 2 from $\vec{E}_2$ and $\vec{B}_2$.

10.3.5.3 Power radiated through an elementary surface

Let us seek a relation for the power radiated through an elementary surface as function of $\vec{B}$.

Let us recall that we have(see page 4156):

$$\mathrm{d}P=\frac{1}{\mu_0}(\vec{E}\times\vec{B})\circ\mathrm{d}\vec{S} \quad (10.3.528)$$

And the relation above for the relativistic case:

$$\vec{B}\cong\frac{\vec{u}_z\times\vec{E}}{c} \quad (10.3.529)$$

We want to extract $\vec{E}$ as function of $\vec{B}$ from that latter relation to put it in the expression of the power.

For that purpose we use the following trick by calculating:

$$\vec{u}_z\times\vec{B}\cong\frac{\vec{u}_z\times(\vec{u}_z\times\vec{E})}{c} \quad (10.3.530)$$

We recognize here again the triple cross-product (see section Vector Calculus page 1835). Therefore if we put:

$$\left.\begin{aligned}\vec{A}&=\vec{u}_z\\ \vec{B}&=\vec{u}_z\\ \vec{C}&=\vec{E}\end{aligned}\right\}:\vec{A}\times\left(\vec{B}\times\vec{C}\right)=\vec{B}\left(\vec{A}\circ\vec{C}\right)-\vec{C}\left(\vec{A}\circ\vec{B}\right)\tag{10.3.531}$$

Therefore:

$$\vec{u}_z\times\left(\vec{u}_z\times\vec{E}\right)=\vec{u}_z\circ(\vec{u}_z\circ\vec{E})-\vec{E}(\vec{u}_z\circ\vec{u}_z)\tag{10.3.532}$$

For an electromagnetic wave far enough from its emission source, we have a plane wave as a first approximation and therefore: $\vec{E}\perp\vec{B}$ and $\{\vec{E},\vec{B}\}\perp\vec{z}$ which leads obviously to $\vec{u}_z\circ\vec{E}=0$, hence:

$$\vec{u}_z\times\left(\vec{u}_z\times\vec{E}\right)=-\vec{E}(\vec{u}_z\circ\vec{u}_z)\cong-\vec{E}\tag{10.3.533}$$

Therefore under these conditions:

$$\vec{u}_z\times\vec{B}\cong\frac{\vec{u}_z\times(\vec{u}_z\times\vec{E})}{c}\cong\frac{-\vec{E}}{c}\tag{10.3.534}$$

So:

$$\vec{E}=-c(\vec{u}_z\times\vec{B})\tag{10.3.535}$$

Injecting this into:

$$\mathrm{d}P=\frac{1}{\mu_0}(\vec{E}\times\vec{B})\circ\mathrm{d}\vec{S}\tag{10.3.536}$$

we get:

$$\mathrm{d}P=-\frac{c}{\mu_0}[(\vec{u}_z\times\vec{B})\times\vec{B}]\circ\mathrm{d}\vec{S}\tag{10.3.537}$$

We recognize here again the triple cross-product (see section Vector Calculus page 1835). So let us put:

$$\left.\begin{aligned}\vec{A}&=\vec{u}_z\\ \vec{B}&=\vec{B}\\ \vec{C}&=\vec{B}\end{aligned}\right\}:\vec{A}\times\left(\vec{B}\times\vec{C}\right)=\vec{B}\left(\vec{A}\circ\vec{C}\right)-\vec{C}\left(\vec{A}\circ\vec{B}\right)\tag{10.3.538}$$

Therefore:

$$(\vec{u}_z\times\vec{B})\times\vec{B}=\vec{B}\underbrace{(\vec{u}_z\circ\vec{B})}_{=0\text{ because }\perp}-\vec{u}_z\underbrace{(\vec{B}\circ\vec{B})}_{\|\vec{B}\|^2}=-\vec{u}_z\|\vec{B}\|^2\tag{10.3.539}$$

Hence:

$$\mathrm{d}P=\varepsilon_0c^3\|\vec{B}\|^2\vec{u}_z\circ\mathrm{d}\vec{S}\tag{10.3.540}$$

But we know that for the non-relativistic case:

$$\vec{B} \cong \frac{q}{4\pi\varepsilon_0 c^2 z}(\dot{\vec{\beta}} \times \vec{u}_z) \tag{10.3.541}$$

Injecting it in the relation above we get:

$$\begin{aligned}\mathrm{d}P &\cong \varepsilon_0 c^3 \left\| \frac{q}{4\pi\varepsilon_0 c^2 z} \underbrace{(\dot{\vec{\beta}} \times \vec{u}_z)}_{\|\dot{\vec{\beta}}\|\|\vec{u}_z\|\sin^2(\theta)} \right\|^2 \vec{u}_z \circ \mathrm{d}\vec{S} = \frac{q^2\|\dot{\vec{\beta}}\|^2}{16\pi^2\varepsilon_0 c}\frac{\sin^2(\theta)}{z^2}\vec{u}_z \circ \mathrm{d}\vec{S} \\ &= \frac{q^2\dot{\beta}^2}{16\pi^2\varepsilon_0 c}\frac{\vec{u}_z \circ \mathrm{d}\vec{S}}{z^2}\sin^2(\theta)\end{aligned} \tag{10.3.542}$$

Assuming that the following fraction can be interpreted as the solid angle that is the cone of vision of the surface $\mathrm{d}\vec{S}$ whose vertex coincides with the center of the charge and its axis coincides with the direction of $\vec{u}_z$:

$$\mathrm{d}\Omega = \frac{\vec{u}_z \circ \mathrm{d}\vec{S}}{z^2} \tag{10.3.543}$$

So finally we get:

$$\frac{\mathrm{d}P}{\mathrm{d}\Omega} \cong \frac{q^2\dot{\vec{\beta}}^2}{16\pi^2\varepsilon_0 c} = \frac{q^2\vec{a}^2}{16\pi^2\varepsilon_0 c^3}\sin^2(\theta) \tag{10.3.544}$$

where for recall, $\vec{a}$ is the acceleration of the electric charge $t' = t - z/c$.

So what we can say so far is that:

- The radiated power per steradian emitted by the accelerated charge is proportional to the square of its acceleration and to the square of its electric charge
- It is zero in the direction of the acceleration and maximum in the direction perpendicular $\theta = \pm\pi/2$.
- Importantly, it does not depend on the measuring distance (this is an approximation obviously!). This allows to detect it at a great distance.

We will now calculate the total power radiated by the accelerated electric charge on a sphere having for center the point O (the electric charge itself!) and for radius z (the distance between the electric charge and the observation point). In this case, it is useful to work with spherical coordinates

In spherical coordinates, a surface element $\mathrm{d}\vec{S}$ traced on the surface of the sphere of origin O and of radius z has the expression (see section Geometric Shapes page 2968):

$$\mathrm{d}\vec{S} = z^2\sin(\theta)\mathrm{d}\theta\mathrm{d}\phi\vec{u}_z \tag{10.3.545}$$

Injecting it in:

$$\mathrm{d}P \cong \frac{q^2\dot{\beta}^2}{16\pi^2\varepsilon_0 c}\frac{\vec{u}_z \circ \mathrm{d}\vec{S}}{z^2}\sin^2(\theta) \tag{10.3.546}$$

we get (see the usual primitives in the section of Differential and Integral Calculus):

$$\begin{gathered}P_T\cong\frac{q^2a^2}{16\pi^2\varepsilon_0c^3}\int\limits_0^{\pi}\sin^3\theta\mathrm{d}\theta\int\limits_0^{2\pi}\mathrm{d}\phi=\frac{q^2a^2}{16\pi^2\varepsilon_0c^3}\left[-\cos(\theta)+\frac{\cos^3(\theta)}{3}\right]_0^{\pi}\cdot 2\pi\\=\frac{q^2a^2}{8\pi\varepsilon_0c^3}\left[\underbrace{\left(1-\frac{1}{3}\right)-\left(-1+\frac{1}{3}\right)}_{=2-\frac{2}{3}=\frac{4}{3}}\right]=\frac{q^2a^2}{6\pi\varepsilon_0c^3}\end{gathered}\tag{10.3.547}$$

Therefore the expression of the total power radiated by an accelerated charge in the non-relativistic case is given by:

$$P_T\cong\frac{q^2a^2}{6\pi\varepsilon_0c^3}\tag{10.3.548}$$

And as we can notice it, the distance z has vanished as we would expect it!

The total power emitted in the form of radiation from a charge moving in an accelerated motion is proportional to the square of the acceleration a and the square of its charge q. It is independent of the distance z.

Now we want to calculate the power emitted by the electric charge in the relativistic case!

In the application of special relativity, the following two elements will be taken into account:

- there are invariants in all inertial frames of reference (here: q, ε_0, c).
- in the relativistic expression of power, we must be able to fall back on the previous relation if we consider the case of low speeds compared to the speed of light!

If we multiply the norm of the four-vector acceleration derived in the section of Special Relativity (see page 5649):

$$a^va_v=-\gamma^6\left[\vec{a}^2-(\vec{a}\times\vec{\beta})^2\right]\tag{10.3.549}$$

by the mass of the electric charge, we have then what is conventionally named the "Abraham-Becker radiation damping force".

The reader must remember that this result is performed in an instantaneous rest frame where the charged particle velocity and acceleration are collinear, and is independent of the internal structure of the particle and shows that the radiation damping force is essentially a relativistic effect.

$$P_T\cong-\frac{q^2}{6\pi\varepsilon_0c^3}\gamma^6\left[\vec{a}^2-(\vec{a}\times\vec{\beta})^2\right]\tag{10.3.550}$$

That is the "Liénard's generalization" to the Larmor's equation[5] we will just see afterwards:

$$\boxed{P_T\cong-\frac{q^2}{6\pi\varepsilon_0c^3(1-\beta^2)^3}\left[\vec{a}^2-(\vec{a}\times\vec{\beta})^2\right]}\tag{10.3.551}$$

---

[5] It was obtained by A. Liénard in 11898 (holocene calendar), only one year after the publication of Larmor's result, and seven years prior to the invention of special relativity!

We see obviously that for small speed $v \ll c$, it leads to:

$$\boxed{P_T \cong -\frac{q^2\vec{a}^2}{6\pi\varepsilon_0 c^3}} \tag{10.3.552}$$

And this is the result named the "Larmor's equation". It implies that any charged particle radiates when accelerated and that the total radiated power is proportional to the square of the acceleration. The largest astrophysical accelerations are usually produced by electromagnetic forces, so the acceleration is proportional to the charge/mass ratio of the particle.

This result is also an interesting and very difficult paradox that a number of physicists have addressed over the last century, including Pauli. If the charge radiates under uniform acceleration, it will violate the principle of equivalence. The famous Richard Feynman was one of those rare physics celebrities who did insist, based on his line of argumentation, that this is false paradigm that an uniformly accelerated charge actually radiates, and that actually it does not, and only oscillating and other non-uniform accelerations can lead to radiation (people interested in a detailed analysis of this point of view can read [496] and [495]). But with this remarkable exception, the overwhelming consensus of the physicists is that a uniformly accelerated charge does radiate! There is a large amount of literature and experience (worldwide) since many decades on synchrotron radiation (leptons but also hadrons for very high energies) and no further fundamental discussion required. Also keep in mind that accelerated charged particles in LINACs radiate a lot.

Remark

We will also see during our study or Special Relativity that the covariance of Maxwell's equations under general coordinate transformations, that, despite inertial observers can indeed detect electromagnetic radiation emitted from an accelerated charge, comoving observers will see only a static electric field. Therefore when the charge radiates it doesn't lost momentum!

Also the ready should keep in mind that a charge moving along a geodesic doesn't accelerate by definition (!), then it doesn't emit any electromagnetic radiation. Furthermore let us remind that we will prove during our study of General Relativity that gravitation isn't a force!

Larmor's extremely useful equation will be the basis for our derivations of radiation from a short dipole antenna as well as for synchrotron emission from astrophysical sources. Beware that Larmor's equation is non-relativistic; it is valid only in frames moving at velocities $v \ll c$ with respect to the radiating particle. Also the reader should keep in mind that an electric charge in free fall in a uniform and homogeneous gravitational field does not radiate because it is following a geodesic, i.e. it is moving by inertia!

Also, Larmor's equation does not incorporate the constraints of quantum mechanics, so it should be applied only with great caution to microscopic systems such as atoms. For example, Larmor's equation incorrectly predicts that the electron orbiting in the lowest energy level of a hydrogen atom will quickly radiate away all of its kinetic energy and fall into the nucleus. On the other hand, it correctly predicts the radio power emitted by an electron orbiting in a very high energy level of a hydrogen atom.

$$P_T \cong \frac{q^2}{6\pi\varepsilon_0 c^3(1-\beta^2)^3}\left[\vec{a}^2-(\vec{a}\times\vec{\beta})^2\right] \tag{10.3.553}$$

Anyway, that's a lot of words and not much to look at, so how about some soothing animations?

Below is a Flash animation illustrating the effect, made with MATLAB®, that will play in a PDF Reader having Adobe Flash installed and activated (otherwise see here: https://vimeo.com/575746945):

Figure 10.76: **Synchrotron radiation of a circle moving particle with $\gamma = 1.2$ (author: Jason Cole)**

The top left represents the Poynting flux S, or the radiation which would be observed. The retarded time is plotted beneath, and the two components of the electric field are plotted on the right. You can see how the retarded time is trailing the particle, and spreads out in a circle at the speed of light.

Now remember that by definition the Lorentz factor is given by:

$$\gamma=\frac{1}{\sqrt{1-\frac{v^2}{c^2}}}=\frac{1}{\sqrt{1-\beta^2}} \tag{10.3.554}$$

We can turn up the energy a bit, now $\gamma=5$ (the animation will play in a PDF Reader having Adobe Flash installed and activated otherwise see here: https://vimeo.com/575747231):

Figure 10.77: Synchrotron radiation of a circle moving particle with $\gamma=5$ (author: Jason Cole)

Here the electron is much closer to the speed of light, and is consequently chasing it's own light-cone – notice how there is a much larger jump in retarded time (from yellow to green). This causes the Poynting flux to be squeezed into a smaller time window, it's much more compressed, intense, and energetic. The temporal shortening of the radiation pulse corresponds to a broad bandwidth, and it is precisely this pulse of radiation that corresponds to broadband synchrotron radiation.

What about something less extreme, an electron travelling at constant velocity in a straight line, again at $\gamma = 1.2$ (the animation will play in a PDF Reader having Adobe Flash installed and activated otherwise see here: `https://vimeo.com/575745050`):

Figure 10.78: **Synchrotron radiation of a uniform moving particle with $\gamma = 1.2$ (author: Jason Cole)**

We now see that the field is being dragged along with the particle, but otherwise not radiating. Because the electron is travelling significantly slower than the speed of light, the field looks relatively undistorted. If you squint you'll notice that the transverse field E_y is stronger than the longitudinal field, which is a manifestation of special relativity (Lorentz transforming a uniform field back into the lab frame where the charge is moving).

Back to something more interesting, a simple dipole motion at $\gamma = 1.2$ (the animation will play in a PDF Reader having Adobe Flash installed and activated otherwise see here: https://vimeo.com/575745668):

Figure 10.79: Synchrotron simple dipole motion with $\gamma = 1.2$ (author: Jason Cole)

We see what we hoped for, oscillating radiation perpendicular to the dipole, and zero far-field radiation parallel to the dipole. In the near-field (close to the dipole), there are electric field components everywhere, but it is clear that these must correspond to non-radiative terms and they die off rapidly.

Finally, let us turn to a use for this radiation: ondulators/wigglers. These are machines which purposefully oscillate an electron bunch to force synchrotron radiation emission, where the electron travels with high velocity in one direction and oscillates in the other (the animation will play in a PDF Reader having Adobe Flash installed and activated otherwise see here: https://vimeo.com/575747509):

Figure 10.80: Synchrotron uniform oscillating moving particle (author: Jason Cole)

Notice that:

$$P_T \cong \frac{q^2\gamma^6}{6\pi\varepsilon_0 c^3}\left[\vec{a}^2-(\vec{a}\times\vec{\beta})^2\right] \tag{10.3.555}$$

as:

$$E=\gamma m_0 c^2 \tag{10.3.556}$$

can be written:

$$P_T \cong \frac{q^2E^6}{6\pi m^6\varepsilon_0 c^{15}}\left[\vec{a}^2-(\vec{a}\times\vec{\beta})^2\right] \tag{10.3.557}$$

The killer for CERN is that E^6 factor because if we double the energy of a particle, it radiates much more times the equivalent received energy. In the case of electrons, this very quickly becomes such a high power that the accelerator can't accelerate any more – the electrons radiate away their energy quicker than it can be pumped in. For protons of the same energy, because of the m^6 factor at the denominator the E^6 factor is 10^{19} times smaller (as $m_p/m_e \cong 1836$), so radiate much less. This is why the LHC is so big, and uses protons rather than electrons. There are plans to build an even bigger LHC, unimaginatively named the "Very Large Hadron Collider", or to accelerate electrons in a straight line so that they radiate much less energy at the proposed International Linear Collider. Both of these propositions are very expensive though, and very large, so there is much interest in smaller accelerators like plasma accelerators.

We can also make appear the influence of the radius of the accelerator. Indeed, starting from:

$$P_T \cong \frac{q^2E^6}{6\pi m^6\varepsilon_0 c^{15}}\left[\|\vec{a}\|^2-\|\vec{a}\times\vec{\beta}\|^2\right] \tag{10.3.558}$$

Remember that we have seen in the section of Classical Mechanics that for a uniform circular motion:

$$\vec{a}=-\omega^2\begin{pmatrix}R\sin(\omega t)\\ R\cos(\omega t)\end{pmatrix}=-\omega^2\vec{r} \tag{10.3.559}$$

Therefore it follows:

$$\|\vec{a}\|^2=\omega^4R^2=\left(\frac{v}{R}\right)^4R^2=\frac{v^2}{R^2} \tag{10.3.560}$$

Hence:

$$P_T \propto \frac{q^2E^6v^2}{6\pi m^6\varepsilon_0 c^{15}R^2} \tag{10.3.561}$$

We therefore understand that the bigger is the radius, the smaller is the radiated power. This is why linear accelerator (considers as infinite curvature radius[6]) are much more interesting than circular accelerator (but more difficult to build as we need to find and large enough area to build them...).

10.3.5.3.1 Larmor's equation (non-relativistic derivation)

Maxwell's equations imply that all classical electromagnetic radiation is generated by accelerating electrical charges. It is possible to derive the intensity and angular distribution of the radiation from a point charge (a charged particle) subject to an arbitrary but small acceleration $\Delta v/\Delta t$ via Maxwell's equations, but the complicated math we have seen above obscures the physical interpretation that remains clear in J. J. Thomson's illuminating derivation below for the non-relativistic case (see [**<empty citation>**]).

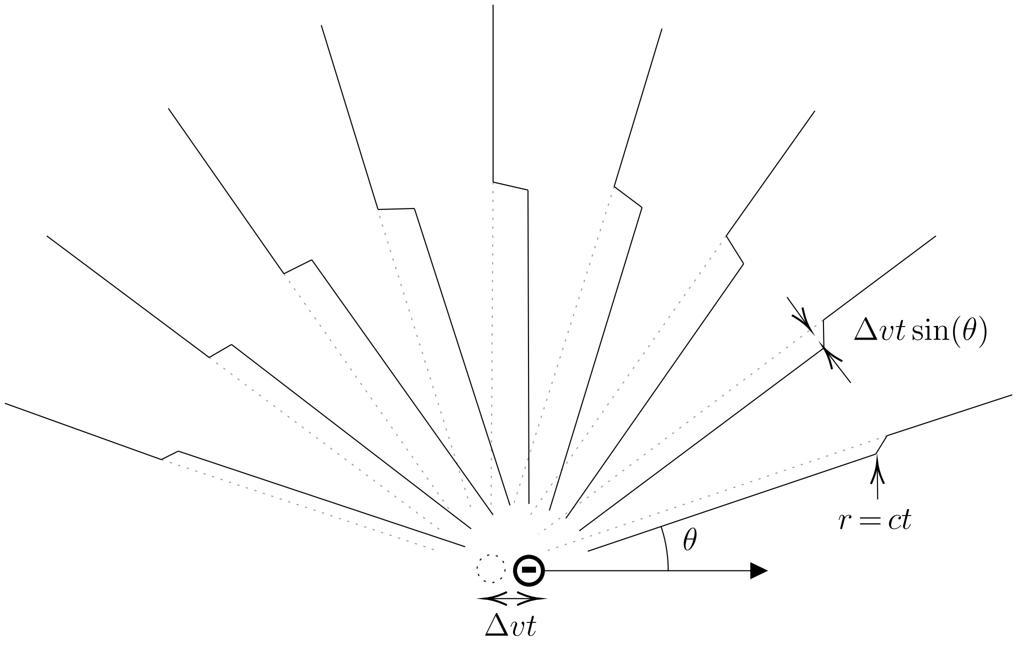
---

[6] And obviously for linear accelerator: $\|\vec{a}\times\vec{\beta}\|^2=0$ as the acceleration is collinear to the speed.

If a particle with electrical charge q is at rest or moving with a constant velocity, its electric field lines are purely radial: $|\vec{E}| = E_r$. Suppose a charged particle initially at rest is accelerated to a small velocity $\Delta v \ll c$ in a short time Δt. This disturbs the lines of force, and the disturbance travels outward at the speed of light c. The figure below shows that at time t after the acceleration, the disturbance will have propagated to $r = ct$ and the perpendicular component of the electric field will have magnitude:

$$\frac{E_\perp}{E_r} = \frac{\Delta vt\sin(\theta)}{c\Delta t} \qquad (10.3.562)$$

where θ is the angle between the acceleration vector and the line of sight connecting the charge to the observer.



In the above figure the electric field lines from an accelerated electron. The dotted circle shows the initial position of the electron, and the dotted lines are the radial lines of force emanating from that position. At time t after a small acceleration $\Delta v/\Delta t$, the electron position has moved by Δvt and its lines of force have shifted transversely by $\Delta vt\sin(\theta)$. Coulomb's law for the radial component E_r of the electric field (electric force per unit charge) a distance r from a stationary charge q is:

$$E_r = \frac{1}{4\pi\varepsilon_0}\frac{q}{r^2} \qquad (10.3.563)$$

Substituting r/c for t in the prior-previous relation and using Coulomb's law to eliminate E_r gives:

$$E_\perp = \frac{1}{4\pi\varepsilon_0}\frac{q}{r^2}\left(\frac{\Delta v}{\Delta t}\right)\frac{r\sin(\theta)}{c^2} \qquad (10.3.564)$$

and:

$$E_\perp = \frac{1}{4\pi\varepsilon_0}\frac{q\dot{v}\sin(\theta)}{rc^2} \qquad (10.3.565)$$

where:

$$\dot{v} \equiv \lim_{\Delta t \to 0} \left(\frac{\Delta v}{\Delta t} \right) \tag{10.3.566}$$

The above relation of $E_\perp$ valid for any small acceleration, not just a sinusoidal acceleration at a single frequency. The transverse field $E_\perp$ at $r = ct$ mimics the acceleration at $t = 0$. Thus a sinusoidal acceleration would result in a sinusoidal variation of $E_\perp$ with the same frequency.

Notice that $E_\perp \propto r^{-1}$ falls more slowly with distance r than $E_r \propto r^{-2}$. Far from the charged particle, only $E_\perp$ will contribute significantly to the observed electric field. From a distant observer's point of view, only the "visible" component of acceleration perpendicular to the line of sight $(\dot{v}\sin(\theta))$ contributes to the radiated electric field; the "invisible" component of acceleration parallel to the line of sight $\dot{v}\cos(\theta))$ does not appear to radiate! Likewise, the radiated electric field is linearly polarized in the direction parallel to the component of acceleration perpendicular to the line of sight.

How much power is radiated in each direction? The Poynting flux, or power per unit area is given by (see page 4156):

$$\bar{S} = \frac{\hat{E}^2}{2\mu_0 c} = \frac{c\varepsilon_0 \hat{E}^2}{2} \tag{10.3.567}$$

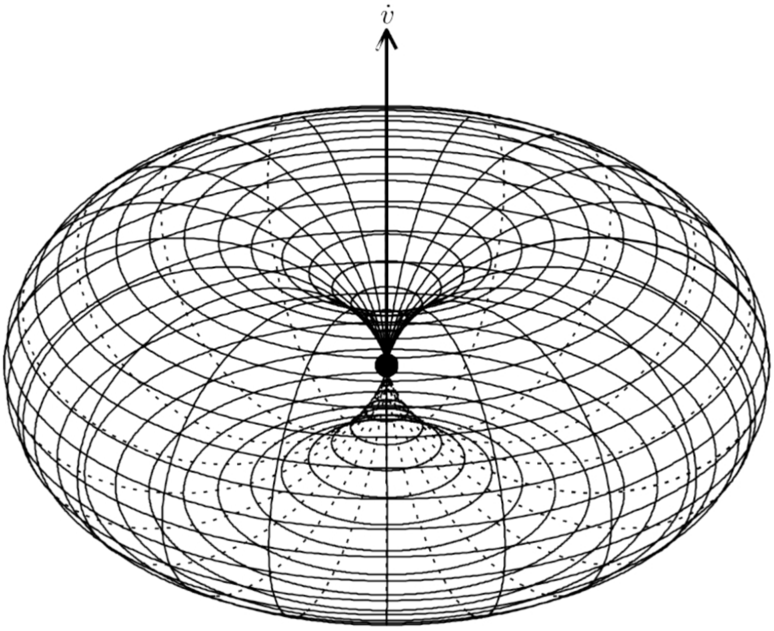
Inserting:

$$E_\perp = \frac{1}{4\pi\varepsilon_0} \frac{q\dot{v}\sin(\theta)}{rc^2} \tag{10.3.568}$$

into $\bar{S}$ gives:

$$\bar{S} = \frac{c\varepsilon_0}{2} \left(\frac{1}{4\pi\varepsilon_0} \frac{q\dot{v}\sin(\theta)}{rc^2} \right)^2 = \left(\frac{q^2\dot{v}^2}{32\varepsilon_0\pi^2 c^3} \right) \frac{\sin^2(\theta)}{r^2} \tag{10.3.569}$$

The accelerated charge radiates then with a dipolar power pattern $\propto \sin^2(\theta)$ shaped like a doughnut whose axis is parallel to the acceleration $\dot{v}$:



In the figure above the power pattern of Larmor radiation from a charged particle shown for an acceleration vector $\dot{v}$ tilted 60 degrees from the line of sight. The power received in any direction is proportional to the component of $\dot{v}$ perpendicular to the line of sight.

The total power emitted is the integral of $\bar{S}$ on a spherical surface of radius r:

$$P=\int\limits_{\text{sphere}}\bar{S}\mathrm{d}A=\frac{q^2\dot{v}^2}{32\varepsilon_0\pi^2c^3}2\int\limits_{\phi=0}^{2\pi}\int\limits_{\theta=0}^{\pi}\frac{\sin^2(\theta)}{r^2}r^2\sin(\theta)\mathrm{d}\theta\mathrm{d}\phi=\frac{q^2\dot{v}^2}{8\varepsilon_0\pi c^3}\int\limits_{\theta=0}^{\pi}\sin^3(\theta)\mathrm{d}\theta \quad (10.3.570)$$

The integral $\int_{\theta=0}^{\pi}\sin^3(\theta)\mathrm{d}\theta=4/3$, so the total power emitted by the accelerated charged particle is:

$$P=\frac{q^2\dot{v}^2}{8\varepsilon_0\pi c^3}\frac{4}{3}=\frac{q^2\dot{v}^2}{6\varepsilon_0\pi c^3}=\frac{q^2a^2}{6\varepsilon_0\pi c^3} \quad (10.3.571)$$

So we fall back on the classical Larmor's equation but without the complicated maths!

10.3.5.3.2 Abraham-Lorentz force

In the physics of electromagnetism, the "Abraham–Lorentz force" is an approximated recoil force on an accelerating charged particle caused by the particle emitting[7] electromagnetic radiation outside of a Quantum Mechanics framework. It is also named the "radiation reaction force" or "radiation damping force" or even the "self-force" or... "radiation resistance".

The formula - then we will derive further below in a special case - predates the theory of Special Relativity and is not valid at velocities on the order of the speed of light. Its relativistic generalization is named the "Abraham–Lorentz–Dirac force". Both of these are in the domain of classical physics, not quantum physics, and therefore may not be valid at distances of roughly the Compton wavelength or below. There is, however, an analogue of the formula that is both fully quantum and relativistic, named the "Abraham–Lorentz–Dirac–Langevin equation".

As we will see it, force is proportional to the square of the object's charge, times the jerk (rate of change of acceleration) that it is experiencing. The force points in the direction of the jerk. For example, in a cyclotron, where the jerk points opposite to the velocity, the radiation reaction is directed opposite to the velocity of the particle, providing a braking action. The Abraham–Lorentz force is also the source of the radiation resistance of a radio antenna radiating radio waves.

Remark

There seem to be pathological solutions of the Abraham–Lorentz–Dirac equation in which a particle accelerates in advance of the application of a force, so-named "pre-acceleration solutions". Since this would represent an effect occurring before its cause (retro-causality), some theories have speculated that the equation allows signals to travel backward in time, thus challenging the physical principle of causality. One resolution of this problem was discussed by Arthur D. Yaghjian and is further discussed by Fritz Rohrlich and Rodrigo Medina.

---

[7] The formula may also give an approximation when photons are absorbed.

The simplest non-rigorous derivation (in the engineer way of life...) for the self-force is found for periodic motion from the Larmor equation (see section Electrodynamics page 4192) for the power radiated from a point charge:

$$P_T=-\frac{q^2}{6\pi\varepsilon_0 c^3}\vec{a}^2 \tag{10.3.572}$$

If we assume the motion of a charged particle is periodic, then the average work done on the particle by the Abraham–Lorentz force is the Larmor power integrated over one period from τ_1 to τ_2:

$$\int\limits_{\tau_1}^{\tau_2}\vec{F}_{\text{rad}}\circ\vec{v}\mathrm{d}t=\int\limits_{\tau_1}^{\tau_2}P\mathrm{d}t=-\int\limits_{\tau_1}^{\tau_2}\frac{q^2}{6\pi\varepsilon_0 c^3}\vec{a}^2\mathrm{d}t=-\int\limits_{\tau_1}^{\tau_2}\frac{q^2}{6\pi\varepsilon_0 c^3}\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}\circ\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}\mathrm{d}t \tag{10.3.573}$$

The above expression can be integrated by parts. If we assume that there is periodic motion, the boundary term in the integral by parts disappears:

$$\int\limits_{\tau_1}^{\tau_2}\vec{F}_{\text{rad}}\circ\vec{v}\mathrm{d}t=-\frac{q^2}{6\pi\varepsilon_0 c^3}\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}\circ\vec{v}\bigg|_{\tau_1}^{\tau_2}+\int\limits_{\tau_1}^{\tau_2}\frac{q^2}{6\pi\varepsilon_0 c^3}\frac{\mathrm{d}^2\vec{v}}{\mathrm{d}t^2}\circ\vec{v}\mathrm{d}t=-0+\int\limits_{\tau_1}^{\tau_2}\frac{q^2}{6\pi\varepsilon_0 c^3}\dot{\vec{a}}\circ\vec{v}\mathrm{d}t \tag{10.3.574}$$

Clearly, we can identify:

$$\boxed{\vec{F}_{\text{rad}}=\frac{q^2}{6\pi\varepsilon_0 c^3}\dot{\vec{a}}} \tag{10.3.575}$$

It should be noted that already in 11905 (holocene calendar), Abraham clearly stated that this result cannot be always correct! A more rigorous derivation, which does not require periodic motion, was found using an Effective Field Theory formulation. An alternative derivation, finding the fully relativistic expression, was found by Dirac.

Here $\vec{F}_{\text{rad}}$ is the force, $\dot{\vec{a}}$ is the derivative of acceleration, or the third derivative of displacement, also named "jerk".

Physically, an accelerating charge emits radiation (according to the Larmor formula), which carries momentum away from the charge. Since momentum is conserved, the charge is pushed in the direction opposite to the direction of the emitted radiation.

10.3.6 Dipole antenna radiation pattern derivation (Hertz Electric Dipole)

Now that we have acquire a quite good knowledge of Maxwell's equations, potential vector, power emission and retarded potential, we can finally study a simple antenna configuration.

Given a current distribution on an antenna, the problem is one of determining the $\vec{E}$ and $\vec{H}$ fields due to this current distribution which satisfies all four of Maxwell's equations along with the boundary conditions, if any.

In the vector potential approach (a very clever one and sadly we don't know who was the first who found that very clever trick) we carry out the solution to this problem in second steps by defining intermediate potential functions. In the first step, we determine the potential function due to the current distribution in sinusoidal regime and in the second step we solve the geometric problem under some approximations.

In the analysis that follows, the relationships between the vector potential and the current distribution as well as the $\vec{E}$ and H fields are derived. All four of Maxwell's equations are embedded in these relationships.

Let us start with the second Maxwell's equations:

$$\vec{\nabla}\circ\vec{B}=0 \tag{10.3.576}$$

Since the curl of a vector field is divergence-free (vector identity: $\vec{\nabla}\circ(\vec{\nabla}\times\vec{A})=0$), the magnetic intensity $\vec{B}$ can be expressed as a curl of an arbitrary vector field, $\vec{A}$ as we already now it! Thus:

$$\mu\vec{H}=\vec{B}=\vec{\nabla}\times\vec{A} \tag{10.3.577}$$

or:

$$\vec{H}=\frac{1}{\mu}\vec{\nabla}\times\vec{A} \tag{10.3.578}$$

Substituting this into the third Mawell's equation:

$$\vec{\nabla}\times\vec{E}=-\frac{\partial\vec{B}}{\partial t} \tag{10.3.579}$$

in sinsuoidal regime and phasor notation:

$$\vec{\nabla}\times\vec{E}=-\frac{\partial\vec{B}}{\partial t}=-\mathrm{i}\omega\vec{B}=-\mathrm{i}\omega\mu\vec{H}=-\mathrm{i}\omega(\vec{\nabla}\times\vec{A}) \tag{10.3.580}$$

Or:

$$\vec{\nabla}\times(\vec{E}+\mathrm{i}\omega\vec{A})=\vec{0} \tag{10.3.581}$$

Since as we know that the curl of a gradient function is zero (vector identity: $\vec{\nabla}\times\vec{\nabla}\cdot U=0$ as proved in the section of Vector Calculus page 1912), the previous relation suggests that the quantity in brackets can be replaced by the gradient of a scalar function. Specifically, a scalar potential function U is defined such that:

$$\vec{E}+\mathrm{i}\omega\vec{A}=-\vec{\nabla}\cdot U \tag{10.3.582}$$

Using this we relate the $\vec{E}$ field to the potential functions as:

$$\vec{E}=-(\vec{\nabla}\cdot U+\mathrm{i}\omega\vec{A}) \tag{10.3.583}$$

The following relations:

$$\vec{H}=\frac{1}{\mu}\vec{\nabla}\times\vec{A} \qquad \vec{E}=-(\vec{\nabla}\cdot U+\mathrm{i}\omega\vec{A}) \tag{10.3.584}$$

relate the $\vec{H}$ and $\vec{E}$ fields to the potential functions $\vec{A}$ and $\vec{U}$.

Now, to satisfy the fours Maxwell's equation:

$$\vec{\nabla}\times\vec{H}=\vec{j}+\varepsilon\frac{\partial\vec{E}}{\partial t} \tag{10.3.585}$$

in sinusoidal (harmonic) regime in phasor notation:

$$\vec{\nabla}\times\vec{H}=\vec{j}+\mathrm{i}\varepsilon\omega\vec{E} \tag{10.3.586}$$

we substitute the expression for the $\vec{E}$ and $\vec{H}$ fields in therms of the potentials functions:

$$\frac{1}{\mu}\vec{\nabla}\times(\vec{\nabla}\times\vec{A})=-\mathrm{i}\varepsilon\omega(\vec{\nabla}\cdot U+\mathrm{i}\omega\vec{A})+\vec{j} \tag{10.3.587}$$

which is valid for a homogeneous medium. Expanding the left hand side using the vector identity proved in the section of Vector Calculus:

$$\vec{\nabla}\times(\vec{\nabla}\times\vec{A})=\vec{\nabla}\cdot(\vec{\nabla}\circ\vec{A})-\vec{\nabla}^2\vec{A} \tag{10.3.588}$$

We have (after rearranging):

$$\vec{\nabla}^2\vec{A}+\omega^2\mu\varepsilon\vec{A}=-\mu\vec{j}+\vec{\nabla}\cdot(\vec{\nabla}\circ\vec{A}+\mathrm{i}\omega\mu\varepsilon U) \tag{10.3.589}$$

So far we have satisfied three of Maxwell's four equations. Note that only the curl of $\vec{A}$ is defined so far. Since the curl and divergence are two independent parts of any vector field, we can now define the divergence of $\vec{A}$. We define $\vec{\nabla}\circ\vec{A}$ so as to relate $\vec{A}$ and U as well as simplify the previous relation by eliminating the second term on the right hand side of the equality. We relate $\vec{A}$ and U by the relation:

$$\vec{\nabla}\circ\vec{A}=-\mathrm{i}\omega\mu\varepsilon U \tag{10.3.590}$$

This empirical choice (relation) is as we already known, named the "Lorentz gauge". With this the magnetic vector potential $\vec{A}$ satisfies the vector wave equation (Helmoltz inhomogenous equation):

$$\vec{\nabla}^2\vec{A}+k^2\vec{A}=-\mu\vec{j} \tag{10.3.591}$$

where $k=\omega\sqrt{\mu\varepsilon}$ is the "propagation constant" (in radian per meter) in the medium.

Now, to satisfy the last remaining Maxwell's equation:

$$\vec{\nabla}\circ\vec{E}=\frac{\rho_Q}{\varepsilon} \tag{10.3.592}$$

For this purpose we substitute:

$$\vec{E}=-(\vec{\nabla}\cdot U+\mathrm{i}\omega\vec{A})=-\vec{\nabla}\cdot U-\mathrm{i}\omega\vec{A} \tag{10.3.593}$$

in it to get:

$$\vec{\nabla}\circ(-\vec{\nabla}\cdot U-\mathrm{i}\omega\vec{A})=\frac{\rho_Q}{\varepsilon} \tag{10.3.594}$$

Or:

$$\vec{\nabla}^2U+\mathrm{i}\omega(\vec{\nabla}\circ\vec{A})=-\frac{\rho_Q}{\varepsilon} \tag{10.3.595}$$

Eliminating $\vec{A}$ from this equation using the Lorentz gauge:

$$\vec{\nabla}^2U+k^2U=-\frac{\rho_Q}{\varepsilon} \tag{10.3.596}$$

Thus, both $\vec{A}$ and U must satisfy the wave equation, the source function being the current density for the magnetic vector potential, $\vec{A}$, and the charge density for the electric scalar potential function U.

Let us seek now a solution to:

$$\vec{\nabla}^2U+k^2U=-\frac{\rho_Q}{\varepsilon} \tag{10.3.597}$$

Consider a spherically symmetric charge distribution of finite volume V, centered on the origin. Our goal is to compute the scalar potential $U(x,y,z)$ (or $U(r,\theta,\phi)$) due to this source, which is the solution of the in-homogeneous wave equation as given by above. Since the charge is spherically symmetric, we will solve the wave equation in the spherical coordinate system.The Laplacian $\vec{\nabla}^2U$ in the spherical coordinate system is written as proved in the section of Vector Calculus (see page 1899) by:

$$\vec{\nabla}^2U=\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial U}{\partial r}\right)+\frac{1}{r^2\sin(\theta)}\frac{\partial}{\partial U}\left(\sin(\theta)\frac{\partial\theta}{\partial\theta}\right)+\frac{1}{r^2\sin^2(\theta)}\frac{\partial^2U}{\partial\phi^2} \tag{10.3.598}$$

The scalar potential $U(r,\theta,\phi)$, produced by a spherically symmetric charge distribution is independent of θ and ϕ. Therefore, the wave equation reduces to:

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial U}{\partial r}\right)+k^2U=-\frac{\rho_Q}{\varepsilon} \tag{10.3.599}$$

The right hand side of this equation is zero everywhere except at the source itself. Therefore, in the source-free region, U satisfies the homogeneous wave equation:

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial U}{\partial r}\right)+k^2U=0 \tag{10.3.600}$$

The solutions for U are the scalar spherical waves given by (or the sum of them!):

$$\boxed{U(r)=U_0^{\pm}\frac{e^{\mp ikr}}{r}} \tag{10.3.601}$$

where U_0^+ is a complex amplitude constant and $e^{-\text{i}kr}/r$ is a spherical wave travelling in the $+r$-direction. U_0^- is the complex amplitude of the scalar spherical wave $e^{+\text{i}kr}/r$ travelling in the $-r$-direction. By substituting this in the wave equation, it can be shown that it satisfies the homogeneous wave equation!

Consider a static point charge q kept at a point with position vector $\vec{r}\,'$. The electric potential, U, at a point (r,θ,ϕ) (or in cartesian coordinates $P(x,y,z)$), with the position vector $\vec{r}$ is given by:

$$U(r,\theta,\phi)=\frac{q}{4\pi\varepsilon R}\;[\text{J}\cdot\text{C}^{-1}] \tag{10.3.602}$$

(equivalently given in Volts [V]) where R is the distance between the charge and the observation point:

$$R=\|\vec{R}\|=\|\vec{r}-\vec{r}\,'\| \tag{10.3.603}$$

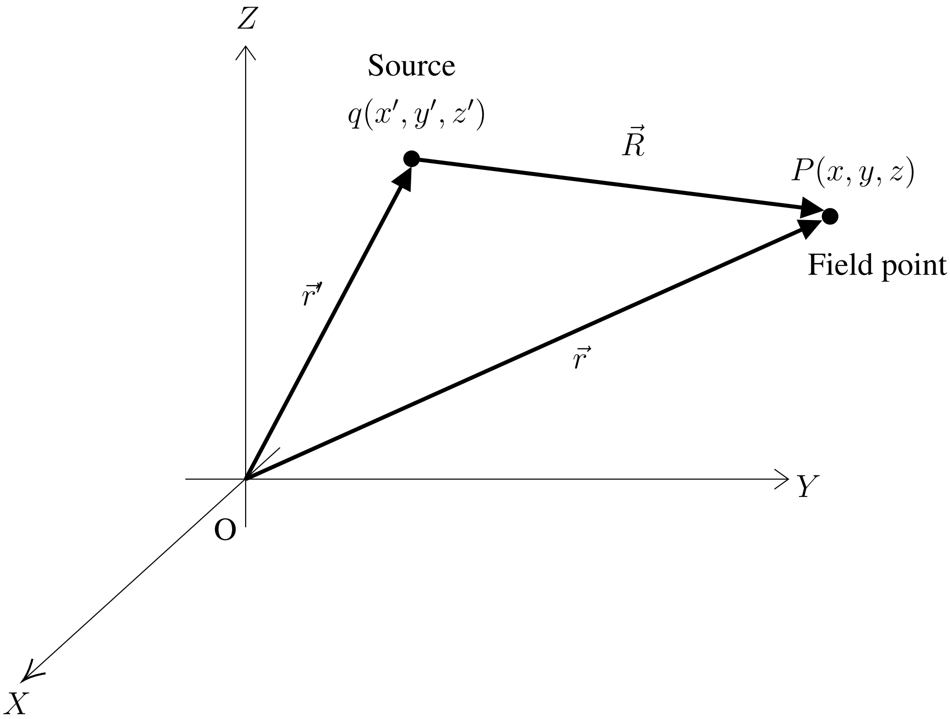


Figure 10.81: Position vectors of source and field points

If there are more than one point charges, the potential is obtained by the superposition principle, i.e., summing the contributions of all the point charges. If the source is specified as a charge density distribution over a volume, the potential at any field point is obtained by integration over the source volume. To do this, we first consider a small volume $\mathrm{d}V$ centered on $\vec{r}\,'$.

The charge contained in this volume is then $\rho(\vec{r}^{'})\mathrm{d}V$, where $\rho(\vec{r}^{'})$ is the volume charge density distribution function. So we can compute the potential at any field point $\vec{r}$ due to charge contained in the volume $\mathrm{d}V$ using:

$$\mathrm{d}U(r,\theta,\phi)=\frac{\rho \mathrm{d}V}{4\pi\varepsilon R} \tag{10.3.604}$$

Now let us recall the solution we get in a sinusoidal regime for a spherical symmetry configuration:

$$U(r)=U_0^{\pm}\frac{e^{\mp \mathrm{i}kr}}{r} \tag{10.3.605}$$

So by analogy we may write:

$$\mathrm{d}U(r,\theta,\phi)=\frac{\rho e^{-\mathrm{i}kr}\mathrm{d}V}{4\pi\varepsilon R} \tag{10.3.606}$$

The potential at point (r,θ,ϕ) due to a charge distribution $\rho(x',y',z')$ is obtained by integrating the previous relation over the source distribution:

$$U(r,\theta,\phi)=\frac{1}{4\pi\varepsilon}\oint_V\frac{\rho e^{-\mathrm{i}kR}\mathrm{d}V}{4\pi R} \tag{10.3.607}$$

This must be compared with the couple of relations we had proved earlier during our study of the Bremsstrahlung (see section Electrodynamics page 4163):

$$\begin{aligned}U(\vec{R},t)&=\frac{1}{4\pi\varepsilon_0}\oint_V\frac{\rho(\vec{r},t')\mathrm{d}V}{\|\vec{R}-\vec{r}\|}\\ \vec{A}(\vec{R},t)&=\frac{\mu_0}{4\pi}\oint_V\frac{\vec{J}(\vec{r},t')\mathrm{d}V}{\|\vec{R}-\vec{r}\|}\end{aligned} \tag{10.3.608}$$

Then the same developments, lead us to write:

$$\vec{A}(\vec{R},t)=\frac{\mu}{4\pi}\oint_V\frac{\vec{J}(\vec{r},t')e^{-\mathrm{i}kR}\mathrm{d}V}{\|\vec{R}-\vec{r}\|} \tag{10.3.609}$$

Now, let us consider a dipole antenna centered on the origin and oriented along the Z-axis with length L. We want to find the radiation pattern equation in polar coordinates (as the configuration is quite symmetrical!).

The current on the antenna will be approximately sinusoidal, with zeros at the ends $(L/2)$ of the antenna (hence a "harmonic" oscillator), represented by:

$$\vec{I}(z')=I_0\sin\left(k\left(\frac{L}{2}-|z'|\right)\right)\vec{a}_z \tag{10.3.610}$$

where:

$$k=\frac{2\pi}{\lambda}\qquad \lambda=\frac{c}{f}\qquad |z'|\leq\frac{L}{2} \tag{10.3.611}$$

The results we will derive starting from now only in the situation where the antenna is short, i.e., $L\ll\lambda$. That assumption allow us to say that the current in the antenna is independent of position along the antenna, depending only on time!

We use the potential vector expression found earlier above for a sinusoidal regime in a spherical symmetry configuration to find the Z-component of the vector potential:

$$\vec{A}_z=\frac{\mu}{4\pi}\int\limits_{-L/2}^{+L/2}\frac{\vec{I}(z')e^{-\mathrm{i}k\|\vec{R}\|}\mathrm{d}z'}{\|\vec{R}\|} \tag{10.3.612}$$

where:

$$\vec{R}=\vec{r}-z'\vec{a}_z \tag{10.3.613}$$

and the norm of $\vec{R}$ can be approximated as (the last row is a Maclaurin series):

$$\begin{aligned}\|\vec{R}\|&=\sqrt{(\vec{r}-z'\vec{a}_z)\circ(\vec{r}-z'\vec{a}_z)}=\sqrt{\vec{r}^2+(z'\vec{a}_z)^2-2\vec{r}\circ(z'\vec{a}_z)}\\&=r\sqrt{1-\frac{2\vec{r}\circ(z'\vec{a}_z)}{r}-\left(\frac{z'a_z}{r}\right)^2}\cong r\sqrt{1-\frac{2\vec{r}\circ(z'\vec{a}_z)}{r}}\\&\cong r\left(1-\frac{\vec{r}\circ(z'\vec{a}_z)}{r}\right)=r-z'\cos(\theta)\end{aligned} \tag{10.3.614}$$

Keep in mind that θ is the angle between the radius vector of the point of interest and the longitudinal axes of the antenna!

Substituting yields:

$$A_z\cong\mu\int\limits_{-L/2}^{+L/2}\frac{I_0\sin\left(k\left(\frac{L}{2}-|z'|\right)\right)e^{-\mathrm{i}k(r-z'\cos(\theta))}}{4\pi(r-z'\cos(\theta))}\mathrm{d}z' \tag{10.3.615}$$

As $r\gg z'\cos(\theta)$, the term $z'\cos(\theta)$ can be neglected in the denominator. However, it cannot be neglected in the exponential as it is a phase offset:

$$A_z\cong\frac{\mu I_0}{4\pi}\int\limits_{-L/2}^{+L/2}\frac{\sin\left(k\left(\dfrac{L}{2}-|z'|\right)\right)e^{-\mathrm{i}kr}e^{\mathrm{i}kz'\cos(\theta)}}{r}\mathrm{d}z' \tag{10.3.616}$$

Rearranging yields:

$$A_z\cong\frac{\mu I_0e^{-\mathrm{i}kr}}{4\pi r}\int\limits_{-L/2}^{+L/2}\sin\left(k\left(\frac{L}{2}-|z'|\right)\right)e^{\mathrm{i}kz'\cos(\theta)}\mathrm{d}z' \tag{10.3.617}$$

We eliminate the absolute value by splitting into two integrals:

$$A_z\cong\frac{\mu I_0e^{-\mathrm{i}kr}}{4\pi r}\left[\int\limits_{-L/2}^{0}\sin\left(k\left(\frac{L}{2}+z'\right)\right)e^{\mathrm{i}kz'\cos(\theta)}\mathrm{d}z'+\int\limits_{0}^{+L/2}\sin\left(k\left(\frac{L}{2}-z'\right)\right)e^{\mathrm{i}kz'\cos(\theta)}\mathrm{d}z'\right] \tag{10.3.618}$$

Flip limits on the first integral and combine:

$$A_z \cong \frac{\mu I_0 e^{-\mathrm{i}kr}}{4\pi r}\int\limits_0^{+L/2} \sin\left(k\left(\frac{L}{2}-z'\right)\right)\left(e^{-\mathrm{i}kz'\cos(\theta)}+e^{\mathrm{i}kz'\cos(\theta)}\right)\mathrm{d}z' \tag{10.3.619}$$

Substitute $e^{\mathrm{i}x}+e^{-\mathrm{i}x}=2\cos(x)$:

$$A_z \cong \frac{\mu I_0 e^{-\mathrm{i}kr}}{2\pi r}\int\limits_0^{+L/2} \sin\left(k\left(\frac{L}{2}-z'\right)\right)\cos(kz'\cos(\theta))\mathrm{d}z' \tag{10.3.620}$$

Now, integrate it, setting aside the constants and limits temporarily:

$$\alpha = \int \sin\left(k\left(\frac{L}{2}-z'\right)\right)\cos(kz'\cos(\theta))\mathrm{d}z' \tag{10.3.621}$$

Integrate by parts:

$$\int u\mathrm{d}v = uv - \int v\mathrm{d}u \tag{10.3.622}$$

with:

$$\begin{aligned}
u &= \sin\left(k\left(\frac{L}{2}-z'\right)\right)\\
\mathrm{d}u &= -k\cos\left(k\left(\frac{L}{2}-z'\right)\right)\\
v &= \frac{\sin(kz'\cos(\theta))}{k\cos(\theta)}\\
\mathrm{d}v &= \cos(kz'\cos(\theta))
\end{aligned} \tag{10.3.623}$$

We have then:

$$\alpha = \sin\left(k\left(\frac{L}{2}-z'\right)\right)\frac{\sin(kz'\cos(\theta))}{k\cos(\theta)} + \int \cos\left(k\left(\frac{L}{2}-z'\right)\right)\frac{\sin(kz'\cos(\theta))}{\cos(\theta)}\mathrm{d}z' \tag{10.3.624}$$

And again integration by part for the second term above:

$$\begin{aligned}
u &= \cos\left(k\left(\frac{L}{2}-z'\right)\right)\\
\mathrm{d}u &= k\sin\left(k\left(\frac{L}{2}-z'\right)\right)\\
v &= -\frac{\cos(kz'\cos(\theta))}{k\cos^2(\theta)}\\
\mathrm{d}v &= \frac{\sin(kz'\cos(\theta))}{\cos(\theta)}
\end{aligned} \tag{10.3.625}$$

Let us simplify the result:

$$\begin{aligned}\alpha = &\overbrace{\sin\left(k\left(\frac{L}{2}-z'\right)\right)\frac{\sin(kz'\cos(\theta))}{k\cos(\theta)} - \cos\left(k\left(\frac{L}{2}-z'\right)\right)\frac{\cos(kz'\cos(\theta))}{k\cos^2(\theta)}}^{\beta} + \\ &\underbrace{\int \sin\left(k\left(\frac{L}{2}-z'\right)\right)\frac{\cos(kz'\cos(\theta))}{\cos^2(\theta)}\mathrm{d}z'}_{=\alpha/\cos^2(\theta)}\end{aligned} \tag{10.3.626}$$

Time for some algebra:

$$\begin{aligned}\alpha &= \int \sin\left(k\left(\frac{L}{2}-z'\right)\right)\cos(kz'\cos(\theta))\mathrm{d}z' \\ \beta &= \sin\left(k\left(\frac{L}{2}-z'\right)\right)\frac{\sin(kz'\cos(\theta))}{k\cos(\theta)} - \cos\left(k\left(\frac{L}{2}-z'\right)\right)\frac{\cos(kz'\cos(\theta))}{k\cos^2(\theta)} \\ \alpha &= \beta + \frac{\alpha}{\cos^2(\theta)} \\ \alpha\cos^2(\theta) &= \beta\cos^2(\theta) + \alpha \\ \alpha &= \beta\frac{\cos^2(\theta)}{\cos^2(\theta)-1}\end{aligned} \tag{10.3.627}$$

So:

$$\alpha = \left[\sin\left(k\left(\frac{L}{2}-z'\right)\right)\frac{\sin(kz'\cos(\theta))}{k\cos(\theta)} - \cos\left(k\left(\frac{L}{2}-z'\right)\right)\frac{\cos(kz'\cos(\theta))}{k\cos^2(\theta)}\right]\frac{\cos^2(\theta)}{\cos^2(\theta)-1} \tag{10.3.628}$$

Now substitute we substitute the famous trigonometric identity $\cos^2(\theta)-1=-\sin^2(\theta)$ to get:

$$\alpha = \frac{1}{k\sin^2\theta}\left[\cos\left(k\left(\frac{L}{2}-z'\right)\right)\cos(kz'\cos(\theta)) - \sin\left(k\left(\frac{L}{2}-z'\right)\right)\sin(kz'\cos(\theta))\cos(\theta)\right] \tag{10.3.629}$$

and plug in the limits $z'=0$ and $z'=L/2$ and bring back the constants:

$$\begin{aligned}A_z \cong \frac{\mu I_0 e^{-\mathrm{i}kr}}{2\pi rk\sin^2(\theta)}\Bigg\{\Bigg[&\cos\left(k\left(\frac{L}{2}-\frac{L}{2}\right)\right)\cos\left(k\frac{L}{2}\cos(\theta)\right) - \\ &\sin\left(k\left(\frac{L}{2}-\frac{L}{2}\right)\right)\sin\left(k\frac{L}{2}\cos(\theta)\right)\cos(\theta)\Bigg] - \Bigg[\cos\left(k\left(\frac{L}{2}-0\right)\right)\cos(k_0\cos(\theta)) - \\ &\sin\left(k\left(\frac{L}{2}-0\right)\right)\sin(k_0\cos(\theta))\cos(\theta)\Bigg]\Bigg\}\end{aligned} \tag{10.3.630}$$

After simplification we get:

$$A_z \cong \frac{\mu I_0 e^{-\mathrm{i}kr}}{2\pi rk\sin^2(\theta)}\left[\cos\left(\frac{kL}{2}\cos(\theta)\right) - \cos\left(\frac{kL}{2}\right)\right] \tag{10.3.631}$$

In the section of Vector Calculus (see page 1849) we have proved that the change of coordinates between rectangular and spherical vector components is given by:

$$\begin{pmatrix} A_r \\ A_\theta \\ A_\phi \end{pmatrix} = \begin{bmatrix} \sin(\theta)\cos(\phi) & \sin(\theta)\sin(\phi) & \cos(\theta) \\ \cos(\theta)\cos(\phi) & \cos(\theta)\sin(\phi) & -\sin(\theta) \\ -\sin(\phi) & \cos(\phi) & 0 \end{bmatrix} \begin{pmatrix} A_x \\ A_y \\ A_z \end{pmatrix} \tag{10.3.632}$$

As A_x and A_y are zero (vector potential has the same orientation as current!), then we have:

$$A_\theta = -A_z \sin(\theta) \tag{10.3.633}$$

Therefore:

$$A_\theta \cong -\frac{\mu I_0 e^{-\mathrm{i}kr}}{2\pi r k \sin(\theta)}\left[\cos\left(\frac{kL}{2}\cos(\theta)\right) - \cos\left(\frac{kL}{2}\right)\right] \tag{10.3.634}$$

Now we want to focus on the electric field only (as it is curiously the main point of interest of people scared of mobile antennas). For this purpose we know that:

$$\vec{\nabla} \times \vec{H} = \vec{j} + \mathrm{i}\varepsilon\omega\vec{E} \tag{10.3.635}$$

And in the region outside of where lies the electric current, this reduces to:

$$\vec{\nabla} \times \vec{H} = \mathrm{i}\varepsilon\omega\vec{E} \tag{10.3.636}$$

Hence:

$$\vec{E} = -\frac{\mathrm{i}}{\omega\varepsilon}\vec{\nabla} \times \vec{H} = -\frac{\mathrm{i}}{\omega\varepsilon}\vec{\nabla} \times \left(\frac{1}{\mu}\vec{\nabla} \times \vec{A}\right) = -\frac{\mathrm{i}}{\omega\mu\varepsilon}\vec{\nabla} \times \left(\vec{\nabla} \times \vec{A}\right) \tag{10.3.637}$$

As we have proved in the section of Vector Calculus (see 1898), the curl in spherical coordinates is given by:

$$\vec{\nabla} \times \vec{f} = \begin{pmatrix} \dfrac{1}{r\sin(\theta)}\dfrac{\partial}{\partial\theta}(\sin(\theta)f_\phi) - \dfrac{1}{r\sin(\theta)}\dfrac{\partial f_\theta}{\partial\phi} \\ \dfrac{1}{r\sin(\theta)}\dfrac{\partial f_r}{\partial\phi} - \dfrac{1}{r}\dfrac{\partial}{\partial r}(rf_\phi) \\ \dfrac{1}{r}\dfrac{\partial}{\partial r}(rf_\theta) - \dfrac{1}{r}\dfrac{\partial f_r}{\partial\theta} \end{pmatrix} \tag{10.3.638}$$

As in our case as $A_\phi = A_r = 0$ and A_θ doesn't depends on ϕ we get:

$$\vec{\nabla} \times \vec{A} = \begin{pmatrix} 0 \\ 0 \\ \dfrac{1}{r}\dfrac{\partial}{\partial r}(rA_\theta) \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ \dfrac{\mathrm{i}\mu I_0 e^{\mathrm{i}kr}}{2\pi r\sin(\theta)}\left[\cos\left(\dfrac{kL}{2}\cos(\theta)\right) - \cos\left(\dfrac{kL}{2}\right)\right] \end{pmatrix} \tag{10.3.639}$$

And again:

$$\vec{\nabla} \times (\vec{\nabla} \times \vec{A}) = \begin{pmatrix} 0 \\ 0 \\ \dfrac{1}{r}\dfrac{\partial}{\partial r}(r(\vec{\nabla} \times \vec{A})) \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ \dfrac{\mu I_0 k e^{-\mathrm{i}kr}}{2\pi r\sin(\theta)}\left[\cos\left(\dfrac{kL}{2}\cos(\theta)\right) - \cos\left(\dfrac{kL}{2}\right)\right] \end{pmatrix} \tag{10.3.640}$$

Therefore focusing only on the remaining non-null component:

$$\begin{aligned}E_\theta &\cong -\frac{\mathrm{i}}{\omega\mu\varepsilon}\vec{\nabla}\times\left(\vec{\nabla}\times\vec{A}\right)=-\frac{\mathrm{i}\mu I_0 k e^{-\mathrm{i}kr}}{2\pi\omega\mu\varepsilon r\sin(\theta)}\left[\cos\left(\frac{kL}{2}\cos(\theta)\right)-\cos\left(\frac{kL}{2}\right)\right]\\ &=-\frac{\mathrm{i}I_0 k e^{-\mathrm{i}kr}}{2\pi\omega\varepsilon r\sin(\theta)}\left[\cos\left(\frac{kL}{2}\cos(\theta)\right)-\cos\left(\frac{kL}{2}\right)\right]\end{aligned} \tag{10.3.641}$$

As $k=2\pi/\lambda$ and $\omega=2\pi f=2\pi c/\lambda$:

$$E_\theta\cong-\frac{\mathrm{i}I_0 k e^{-\mathrm{i}kr}}{2\pi\varepsilon c r\sin(\theta)}\left[\cos\left(\frac{kL}{2}\cos(\theta)\right)-\cos\left(\frac{kL}{2}\right)\right] \tag{10.3.642}$$

Therefore we get the "far-fields for a dipole antenna in harmonic regime of length L":

$$\boxed{E_\theta\cong\frac{-\mathrm{i}I_0 e^{-\mathrm{i}kr}}{2\pi\varepsilon c r\sin(\theta)}\left[\cos\left(\frac{kL}{2}\cos(\theta)\right)-\cos\left(\frac{kL}{2}\right)\right]} \tag{10.3.643}$$

This equation for E_θ (that should be denoted $\hat{E}_\theta$ rigorously!) is the general form for the θ component in spherical coordinates of the far-field $\vec{E}$ field of a dipole antenna of any length oriented along the z-axis. The r component is zero due to the far-field assumption and the ϕ component is zero due to the electric field's orientation along the z-axis!

For the Hertz dipole (or "Hertzian dipole"), the magnetic field has only ϕ-component and the electric field does not have the ϕ-component. The electric field lies in the (r,θ) plane.

The electrostatic field is inversely proportional to the frequency. As the frequency of the current approaches zero, this field diverges to infinity. This field is essentially due to the accumulation of charges on the tip of the antenna. When the current flows in the dipole, the opposite charges get accumulated on the tips of the antenna giving a dipole. With the reversal of the current (every half cycle) dipole reverses its polarity giving an oscillating dipole. The electrostatic field is due to this oscillating dipole. As the frequency decreases, the accumulated charge for a given current increases and therefore the electrostatic field increases.

Here is a MATLAB® script to reproduce the 2D electric field radiation pattern of the Hertz dipole antenna:

Listing 10.1: **MATLAB® code for 2D Hertz dipole antenna**

```
n=377;
Io=1;
r=10;
lambda=0.3;
k=(2*pi)/lambda;
L=lambda/2;

theta=0:0.01:2*pi;
E=j*n*Io*exp(-j*k*r)*(1/(2*pi*r))*((cos(k*L*cos(theta)/2)
-cos(k*L/2))./sin(theta));
polar(theta, abs(E))
```

Here are the three corresponding plots[8] for $L=\lambda/2$ (left), $L=3\lambda$ (right) and $L=6\lambda$ (bottom):

---

[8] Notice the interesting fact that the maximum of the electric field radiation is not always at $\pi/2$...!

Figure 10.82: **Plot of some 2D Hertz dipole radiation pattern with MATLAB® 2019b**

Note that this picture is only a 2D slice of a 3D pattern. So here is the corresponding MATLAB® script to get a 3D view of the electric field radiation pattern:

Listing 10.2: **MATLAB® code for 3D Hertz dipole antenna**

```
theta=[0:0.1:2*pi];
phi=[0:0.1:2*pi];
n=377;
Io=1;
r=10;
lambda=20;
k=(2*pi)/lambda;
L=lambda*1.5;
E=j*n*Io*exp(-j*k*r)*(1/(2*pi*r))*((cos(k*L*cos(theta)/2)-cos(k*L/2
   ))./sin(theta));
udb=10*log10(abs(E));

%normalizing in order to make U vector positive
minu=min(udb);
u=udb-minu;
```

```

%expanding theta,phi,u to span entire space
u(1,1)=0;
for n=1:length(phi)
    theta(n,:)=theta(1,:);
end
phi=phi';
for m=1:length(phi)
    phi(:,m)=phi(:,1);
end
for k=1:length(u);
    u(k,:)=u(1,:);
end
[x,y,z]=sph2cart(phi,theta,u);
surf(x,y,z);
title('3D radiation pattern of dipole antenna');
```

Therefore we get for $L=\lambda/2$ (left) and $L=1.5\lambda$ (right):

Figure 10.83: Plot of some 3D Hertz dipole radiation pattern with MATLAB® 2019b

10.3.6.1 The $L=\lambda/2$ (half-wave) far-field resonant antenna

As $k=2\pi/\lambda$ and $\omega=2\pi f=2\pi c/\lambda$ and that many textbooks like to take $L=\lambda/2$ (therefore $\cos(kL/2)=\cos(2\pi L/(2\cdot 2L)=0)$, and that also $\mu=1/(c^2\varepsilon)$, you can find the last relation:

$$E_\theta \cong \frac{-\mathrm{i}I_0e^{-ikr}}{2\pi\varepsilon cr\sin(\theta)}\left[\cos\left(\frac{kL}{2}\cos(\theta)\right)-\cos\left(\frac{kL}{2}\right)\right] \tag{10.3.644}$$

sometimes under the following form:

$$E_\theta \cong \frac{-\mathrm{i}I_0e^{-ikr}}{2\pi\varepsilon cr}\frac{\cos\left(\frac{\pi}{2}\cos(\theta)\right)}{\sin(\theta)} \tag{10.3.645}$$

Numerically it can be shown that:

$$\frac{\cos\left(\dfrac{\pi}{2}\cos(\theta)\right)}{\sin(\theta)} \cong \sin(\theta) \tag{10.3.646}$$

such that we fall back on a famous relation that we can find in many textbooks:

$$\boxed{E_\theta \cong \frac{-\mathrm{i}I_0 e^{-\mathrm{i}kr}}{2\pi\varepsilon cr}\sin(\theta)} \tag{10.3.647}$$

The radiating pattern of the $\lambda/2$ resonant far-field antenna with this last approximation looks very similar to a normal dipole. As we can illustrate it again with the previous MATLAB® script.

Let us calculate the total emitted power by integrating P/S on the surface of sphere of radius r. We have then:

$$\frac{P}{S} = \frac{\varepsilon c}{2}\hat{E}^2 = \frac{\varepsilon c}{2}\left(\frac{-\mathrm{i}I_0}{2\pi\varepsilon cr}\sin(\theta)\right)^2 = \frac{\varepsilon c}{2}\frac{I_0^2}{4\pi^2\varepsilon^2c^2r^2}\sin^2(\theta) \tag{10.3.648}$$

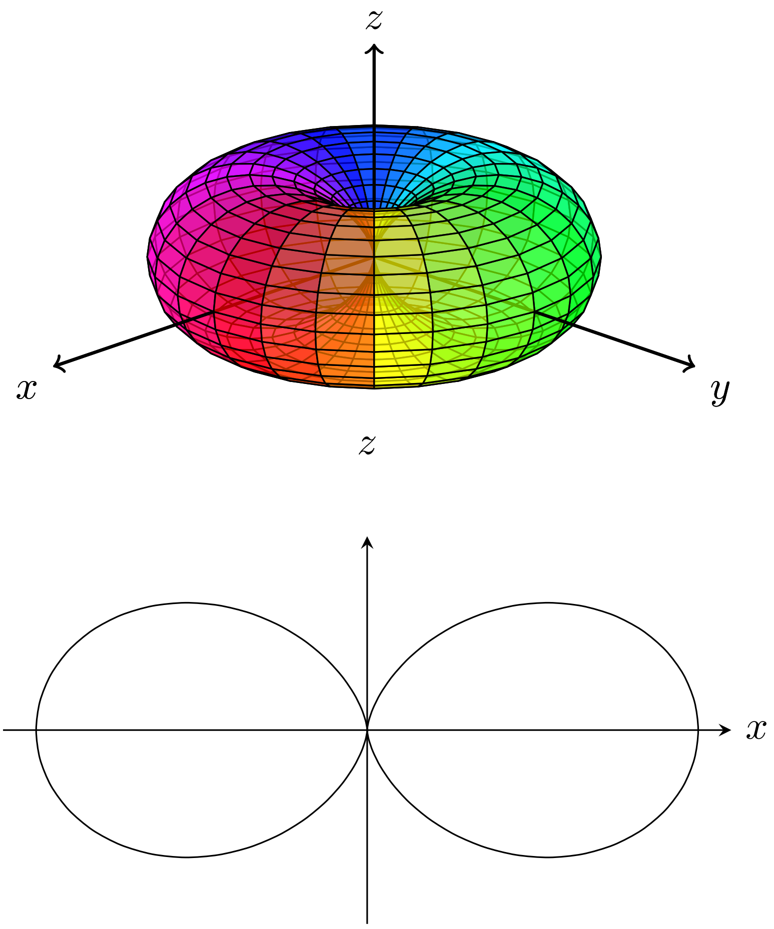

Figure 10.84: **Power radiation Hertzian dipole 2d and 3d**

And as we have already proved it, the surface element of the sphere is:

$$\mathrm{d}S=2\pi r^2\sin(\theta)\mathrm{d}\theta \tag{10.3.649}$$

Therefore the total emitted power is given by:

$$\begin{gathered}P\cong\oint_\Sigma\frac{P}{S}\mathrm{d}S=\int\limits_0^\pi\frac{\varepsilon c}{2}\frac{I_0^2\sin^2(\theta)}{4\pi^2\varepsilon^2c^2r^2}2\pi r^2\sin(\theta)\mathrm{d}\theta=\frac{I_0^2}{4\pi\varepsilon c}\int\limits_0^\pi\sin^3(\theta)\mathrm{d}\theta\\=\frac{I_0^2}{2\pi\varepsilon c}\int\limits_0^{\pi/2}\sin^3(\theta)\mathrm{d}\theta=\frac{I_0^2}{2\pi\varepsilon c}\frac{2}{3}=\frac{I_0^2}{3\pi\varepsilon c}\end{gathered} \tag{10.3.650}$$

Now let's see something for the fun. As we have proved it in the section of Electrical Engineering (see page 8451) we have:

$$\bar{p}=U_{\text{eff}}I_{\text{eff}}=\frac{U_0}{\sqrt{2}}\frac{I_0}{\sqrt{2}} \tag{10.3.651}$$

Therefore:

$$\bar{p}=RI_{\text{eff}}^2=R\left(\frac{I_0}{\sqrt{2}}\right)^2=\frac{RI_0^2}{2} \tag{10.3.652}$$

Therefore for our $L=\lambda/2$ far-field resonant antenna we get the value of a theoretical resistance that summarize the antenna Joule effect:

$$R\cong\frac{2\bar{p}}{I_0^2}=\frac{2\dfrac{I_0^2}{3\pi\varepsilon c}}{I_0^2}=\frac{2}{3\pi\varepsilon c}\cong 80\;[\Omega] \tag{10.3.653}$$

Remark

The natural electric field of the Earth refers to the planet Earth having a natural direct current (DC) electric field or potential gradient from the ground upwards to the ionosphere. The static fair-weather electric field in the atmosphere is $\sim 150\,[\mathrm{V}\cdot\mathrm{m}^{-1}]$ near the Earth's surface, but it drops exponentially with height to under $1\,[\mathrm{V}\cdot\mathrm{m}^{-1}]$ at 30 [km] altitude, as the conductivity of the atmosphere increases. Keep also in mind that at the Earth's surface, the energy surfacic density is approximately $1,000\,[\mathrm{W}\cdot\mathrm{m}^{-1}]$ for a surface perpendicular to the Sun's rays at sea level on a clear day.

Some readers may ask themselves if we could build antenna that emit in the range of the visible light 400 to 800 [THz]? The answer is that with traditional circuitry then answer is likely NO. At such high frequencies there are no good conductors so it would be very hard to drive such an antenna. We probably would need some waveguides rather than wires. And antenna size should be comparable to (or even slightly less than) wavelength, which further complicates things.

But such oscillators do exist. Consider LED diode, or still better - LASER. Both rely on electronic transitions. So we probably can't build oscillator in question, but we can use atoms, quantum wells and dots and many others acting as such oscillator.

Of the total power P_t (transmitted power) supplied to the antenna, a part, P_{rad}, is radiated out into space, and the remainder, P_{loss} is dissipated as heat in the antenna structure. The "radiation efficiency" ξ is defined as:

$$\xi=\frac{P_{\text{rad}}}{P_t} \tag{10.3.654}$$

The "gain of an antenna", in a given direction, is defined as the ratio between the power per unit area radiated in the chosen direction and the power per unit area that would radiate an isotropic (hypothetical) antenna that would radiate the same total power :

$$G=\frac{\left(\dfrac{P}{S}\right)_{\text{ant}}}{\left(\dfrac{P}{S}\right)_{\text{iso}}} \tag{10.3.655}$$

We put all these terms conditional because the isotropic antenna does not exist (or at least is quite difficult to develop at the day we write these lines). We can, if necessary, build a network of antennas whose radiation is almost isotropic!

When we talk about the gain of an antenna without specifying in which direction, it is the gain in the direction where it is maximum.

Let's calculate the gain of an elementary dipole of antenna note. The best direction is for $\theta=\pi/2$ when $L=\lambda/2$. Then:

$$\left(\frac{P}{S}\right)_{\text{ant}}=\frac{\varepsilon c}{2}\frac{I_0^2}{4\pi^2\varepsilon^2c^2r^2}\sin^2(\theta)=\frac{I_0^2}{8\pi^2\varepsilon c r^2} \tag{10.3.656}$$

And for the isotrope:

$$\left(\frac{P}{S}\right)_{\text{iso}}=\frac{\dfrac{RI_0^2}{2}}{4\pi r^2}=\frac{RI_0^2}{8\pi r^2} \tag{10.3.657}$$

Then:

$$G=\frac{\left(\dfrac{P}{S}\right)_{\text{ant}}}{\left(\dfrac{P}{S}\right)_{\text{iso}}}=\frac{\dfrac{I_0^2}{8\pi^2\varepsilon c r^2}}{\dfrac{RI_0^2}{8\pi r^2}}=\frac{1}{R\pi\varepsilon c} \tag{10.3.658}$$

But as:

$$R\cong\frac{2}{3\pi\varepsilon c}\cong 80\;[\Omega] \tag{10.3.659}$$

We then have:

$$G=\frac{1}{R\pi\varepsilon c}=\frac{3}{2}=1.5=1.76\;[\text{dB}] \tag{10.3.660}$$

Remark

For anyone wishing to deepen the subject of antennas, we strongly recommend the lecture of the master piece *Electromagnetic Waves and Antennas* ([428]) that also contains numerous MATLAB® scripts!

10.4. Electrokinetics

THE DEVELOPMENT of electrodynamics has enabled a part of the humanity to significantly change its life quality. We know almost all today what we have thanks to it: fridge, radio, TV, computers, scanners, cars, trams, trains, planes, robots, smartphones, tablets, and other wonderful things and also sometimes less wonderful...

Before you start studying electrokinetics (engineers speak of "electronics" or "electrotechniques"), that is to say the structures involving electric charges in movement, we will define the two fundamental laws (the term "law" is a misnomer, as the first one was proved in the section Electrostatics and the second one in the section of Electrodynamics but anyway...) of the study of electrokinetic and the basic terminology/jargon of electrical circuits or equipment (practical cases being studied in the section Electrical Engineering at page 8437). Even if some elements in the beginning of this section will perhaps not immediately be understood by the reader (especially industrial applications), they will become trivial as the progress of reading of the section.

Definitions (#10.4.479):

D1. An electrical circuit is constituted by a set of devices named "dipole", interconnected by a conductive wire. If the dipole is a source of energy we speak of "active dipole" other in the opposite case its a "passive dipole".

D2. A "node" of a circuit is an interconnection where three or more conductor wire are connected together.

D3. A "branch" is a circuit section between two nodes.

D4. A "mesh" is a set of branches forming a closed loop[9].

D5. A "floating ground[10]" is a type of ground in which the ground doesn't have a physical connection to the earth; it simply serves as a type of 0 [V] reference line that serves as a return path for current back to the negative side of the power supply.

D6. An "earth ground" is when a circuit has a physical connection to the earth (ground), in order to sink electrons through to a ground connected to the earth for safety reasons.

---

[9] A mesh is a closed path which further can't be divided into any other closed path whereas loop is a closed path which can or can not be divided further into closed path a mesh is a loop but it is not necessary that a loop will be a mesh it will only be a mesh when further division is not possible.

[10] I think in automobile DC circuits, floating ground is also referred to as "chassis ground". The chassis is connected to the negative battery terminal and, thus, provides the infrastructure for closing the DC circuit.

Remark

It is very important to understand what will follow! Some developments will be reused in the section of Special Relativity, Quantum Field Theory, etc. Furthermore, the reader should also read in parallel the section of Special Relativity to better understand the ins and outs of certain results and the provenance of some mathematical tools.

The dipole is characterized by the response in a current I by (most of time) a difference of electric potential U between its terminals. That is to say i.e. by the characteristic curve:

$$I = f(U) \tag{10.4.1}$$

Obviously some dipoles reacts on radiations difference, or on rotation difference, on pressure, on humidity and son on...

We shall see that in any conductor, the presence of a resistivity (see below the concept) causes a voltage drop and, strictly speaking, it is the same for the wires (made of conductor material). But these latter being connected in series with other dipoles, we neglect usually in small circuits the resistance of wires relatively to those of the dipoles. Therefore, the wires located between two dipoles of a small circuit are supposed to be equipotentials (the potential is the same on the two terminals).

10.4.1 Kirchhoff's laws

If you connect lots of passive or active elements together in a complicated network, then currents will flow through all the various elements so as to insure that charge is conserved, energy is conserved, and Ohm's Law is satisfied for each resistor.

Simultaneously satisfying all these conditions will give you exactly one solution. The method for writing down equations to represent these conservation laws is named "Kirchhoff's Laws" (not to be confused with those of the thermodynamics and optics bearing the same name!) and express the physical properties of the charge and the electric field and are at the number of 2 (one law for each property).

Briefly:

1. The total current flowing towards a node is equal to the total current flowing from that node
2. In a closed circuit, the algebraic sum of the products of the current and the resistance of each part of the circuit is equal to the resultant electromotive force in the circuit.

They will enable us without using the heavy mathematical artillery implicitly hidden behind just to get highly relevant results.

10.4.1.1 Mesh law (Kirchhoff's Loop Law)

The "mesh law" (implicitly it is simply the conservation of energy), also named "Kirchoff's loop law" or "Kirchoff's voltage law" (KVL), expresses the fact that when a charge browse a closed circuit (closed path), the energy it loses in by browsing a part of the circuit is equal to the energy it gains in the other. Thus, the algebraic sum of the potentials along a mesh is zero such that:

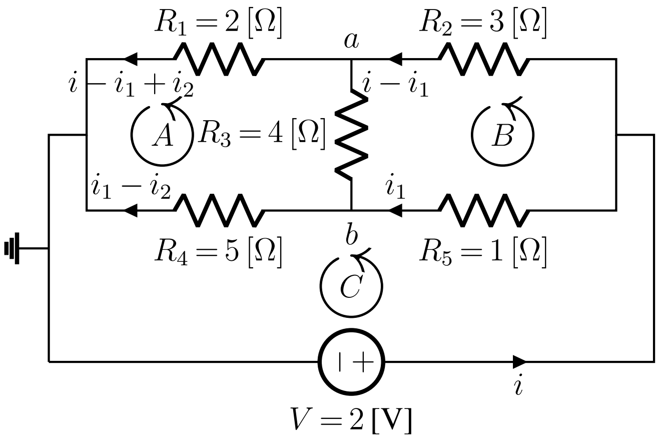
$$\boxed{\sum_{\text{mesh}} U_k = 0} \tag{10.4.2}$$

For this, we must arbitrarily choose a direction of travel of the mesh and agree that the tensions whose arrow points in the direction of travel are counted as positive and others as negative.

Remark

This law simply expresses the fact that the electric field (Coulomb) is a conservative vector field as we have seen in the section of Electrostatic.

In mesh analysis, Kirchhoff's voltage law $\sum V = 0$ (using the LaTeX Circuitikz package notation) is written for each independent loop, and a system of equation is solved. The number of independent loops can be determined by finding the minimum number of wire cuts needed such that there are no loops.



We have three independent loops, labelled as A, B, C, which gives the system of three equations:

$$0=-i_2R_3-(i-i_1+i_2)R_1+(i_1-i_2)R_4 \tag{10.4.3}$$

$$0=-(i-i_1)R_2+i_2R_3+i_1R_5 \tag{10.4.4}$$

$$0=V-i_1R_5-(i_1-i_2)R_4 \tag{10.4.5}$$

Solving this system gives:

$$(i,i_1,i_2)=\left(-\frac{144}{181},\frac{82}{181},\frac{26}{181}\right) \tag{10.4.6}$$

which can be used to determine the currents in all resistors and the associated voltages.

10.4.1.2 Nodes law (Kirchhoff's Point Law)

The "nodes law" (implicitly it is simply the current conservation law), also named "Kirchoff's point law" or "Kirchoff's current law" (KCL), expresses the conservation of charge, which means that the sum of currents leaving a node (a node can be seen as a separator of field lines - in extenso volumes connected by a same surface) is equal to the sum of currents entering the node. In other words, the algebraic sum of the currents is zero at every node of a circuit such that:

$$\boxed{\sum_{\text{node}} I_k=0} \tag{10.4.7}$$

This is also often denoted (if we denote by a the charges arriving in the node and by d those departing):

$$\sum_a\left(n_a\frac{\Delta q}{\Delta t}\right)=\sum_d\left(n_d\frac{\Delta q}{\Delta t}\right)\Leftrightarrow\sum_a i_a=\sum_d i_d \tag{10.4.8}$$

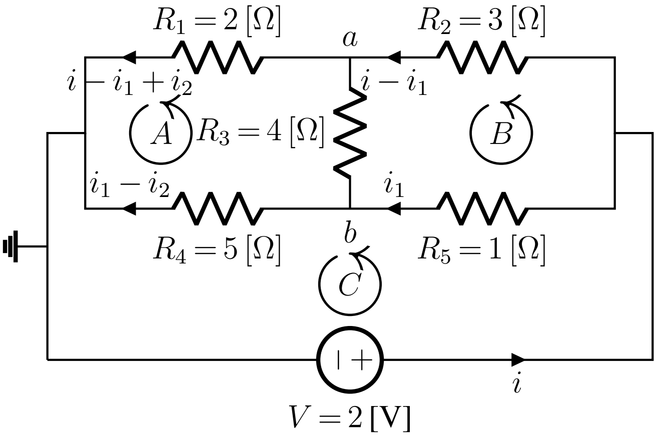
For this, we must choose a sign for incoming currents and the opposite sign for outgoing currents (as we do in Thermodynamics with the mass).

Remark

This law simply expresses the charge conservation equation (or equivalently the law continuity of the charge) that we have proved in the section Electrodynamics.

Figure 10.86: **Try to apply Kirchhoff's law...**

In nodal analysis, we deal with the potentials at each node and write out Kirchhoff's current law $\sum I = 0$ for the current leaving (or alternatively, entering) each node for each node where the potential is unknown. Let the nodes labelled a and b have potentials V_a and V_b in the figure below:



$R_1 = 2\,[\Omega]$
a
$R_2 = 3\,[\Omega]$
$i - i_1 + i_2$
$i - i_1$
A
$R_3 = 4\,[\Omega]$
B
$i_1 - i_2$
i_1
$R_4 = 5\,[\Omega]$
b
$R_5 = 1\,[\Omega]$
C
i
$V = 2\,[\text{V}]$

Then we have:

$$0 = \frac{V_a - V}{R_2} + \frac{V_a - V_b}{R_3} + \frac{V_a - 0}{R_1} \tag{10.4.9}$$

$$0=\frac{V_b-V}{R_5}+\frac{V_b-V_a}{R_3}+\frac{V_b-0}{R_4} \tag{10.4.10}$$

which after solving, gives:

$$(V_a,V_b)=\left(\frac{176}{181},\frac{280}{181}\right) \tag{10.4.11}$$

which can be easily confirmed via the mesh analysis done earlier above.

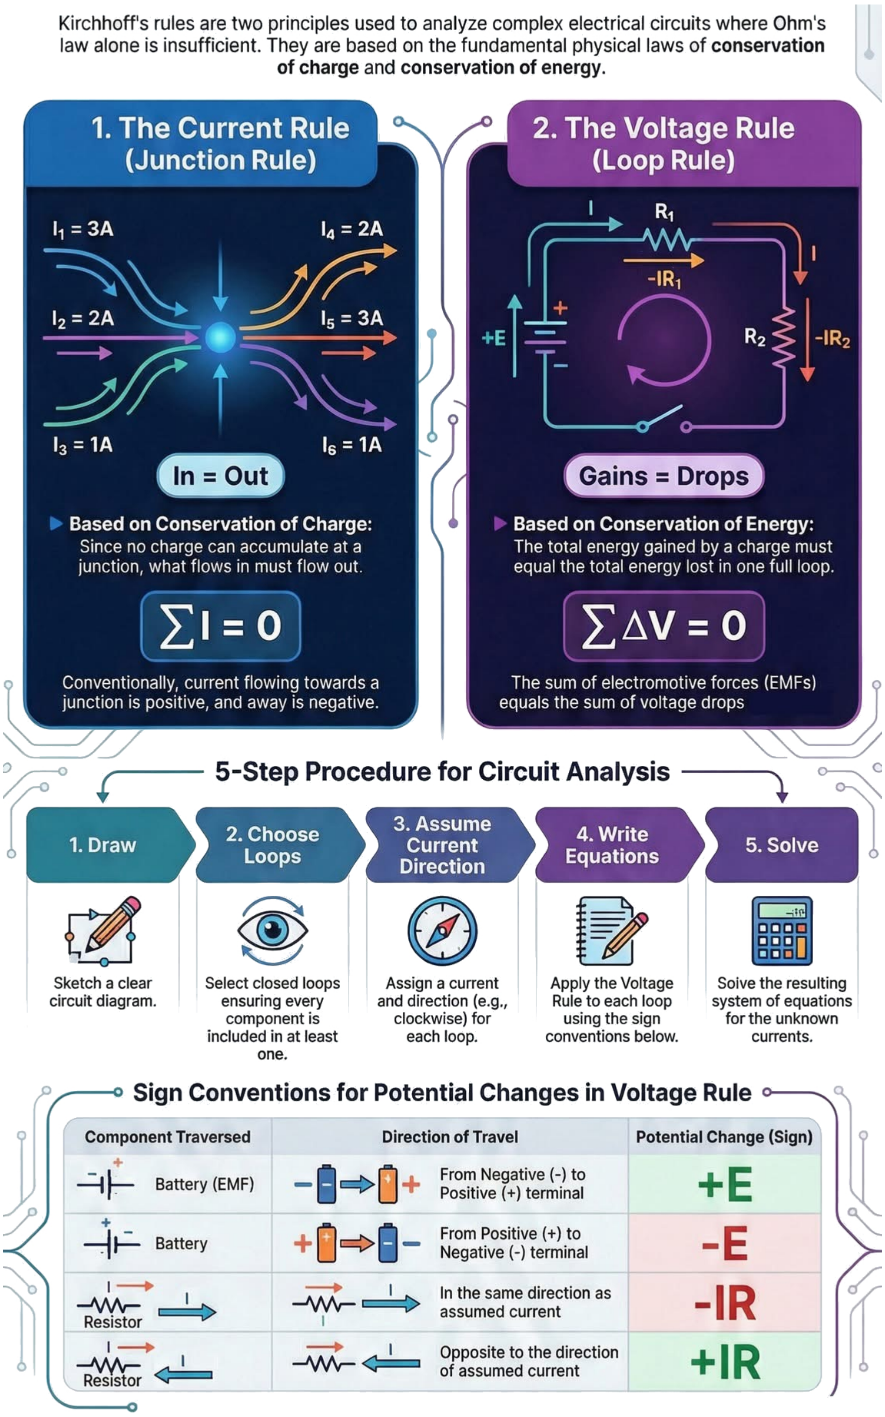
Figure 10.87: Example of a real non-trivial electric circuit (source: `https://320volt.com`)

Circuits such as the above one can also be analysed with the KVL and KCL. It just take more than a day for an average human to do the whole analysis on a sheet of paper...



Kirchhoff's rules are two principles used to analyze complex electrical circuits where Ohm's law alone is insufficient. They are based on the fundamental physical laws of **conservation of charge** and **conservation of energy.**

1. The Current Rule (Junction Rule)

In = Out

Based on Conservation of Charge: Since no charge can accumulate at a junction, what flows in must flow out.

$$\sum I = 0$$

Conventionally, current flowing towards a junction is positive, and away is negative.

2. The Voltage Rule (Loop Rule)

Gains = Drops

Based on Conservation of Energy: The total energy gained by a charge must equal the total energy lost in one full loop.

$$\sum \Delta V = 0$$

The sum of electromotive forces (EMFs) equals the sum of voltage drops

5-Step Procedure for Circuit Analysis

1. **Draw** Sketch a clear circuit diagram.
2. **Choose Loops** Select closed loops ensuring every component is included in at least one.
3. **Assume Current Direction** Assign a current and direction (e.g., clockwise) for each loop.
4. **Write Equations** Apply the Voltage Rule to each loop using the sign conventions below.
5. **Solve** Soive the resulting system of equations for the unknown currents.

Sign Conventions for Potential Changes in Voltage Rule

Component Traversed	Direction of Travel	Potential Change (Sign)
Battery (EMF)	From Negative (-) to Positive (+) terminal	+E
Battery	From Positive (+) to Negative (-) terminal	-E
I Resistor I	In the same direction as assumed current	-IR
I Resistor I	Opposite to the direction of assumed current	+IR

Figure 10.88: **Kirchoff's rules summary**

10.4.2 Drude model

The Drude model of electrical conduction will allow us to introduce the basic concepts of the electrokinetic. First, let us define inf what will follow the concept of "Electric Current", "electric current density", and "electric resistance".

An electrical conductor (we are not talking about semiconductors and superconductors at this level of our discussion) can be seen in a very simplified way as a pipe section $\vec{S}$ containing an electron gas of n elementary electric charges q per unit volume.

In the absence of electric field, each electron has a zero vector average speed because it remains in the vicinity of the atom.

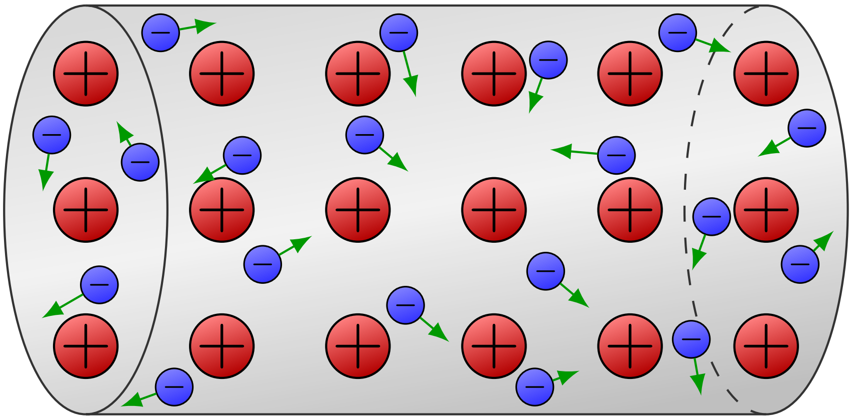


Figure 10.89: Typical conductor electrons behaviour without voltage (author: Izaak Neutelings)

Under the action of a constant and homogeneous electric field $\vec{E}$ (the case of direct current therefore!), some electrons are moved in a particular direction, until they collide with another atom (traditional aspect... not quantum one obviously!!!) where they take again an average vectorial zero speed drift and so on.

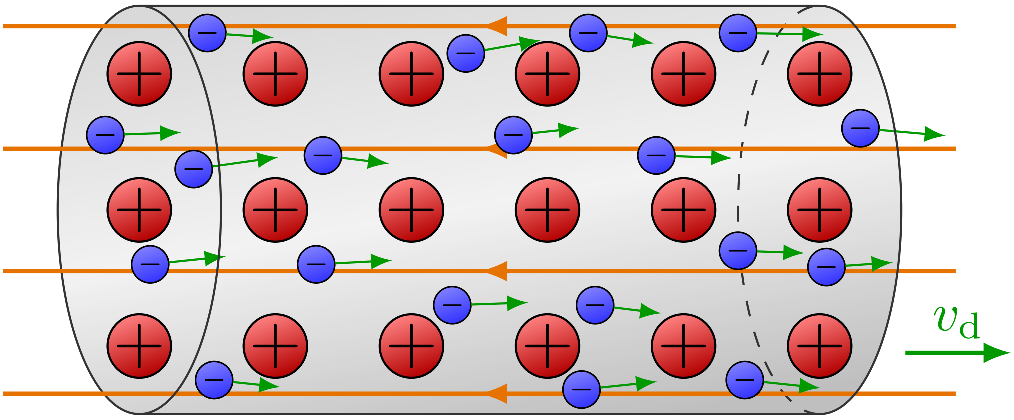

Figure 10.90: Typical conductor electrons behaviour with voltage (author: Izaak Neutelings)

This is the oldest model and the most basic one of the electric current. The bases were laid by Paul Drude in 11902 (holocene calendar), shortly after the discovery of the electron by Joseph John Thomson in 11897 (holocene calendar). Hence the name "Drude model".

Insufficient to conceive and develop most of the active electrical components that exists since the late 120th century (holocene calendar), the billiard balls model has nevertheless considerable interests:

- This is a useful tool to give to our limited mind a picture of phenomena we do not get any direct perception (at least at this day), since they take place in the infinitesimal world of atoms an elementary particles.
- The results, for the engineer, of more accurate modern theories, especially such as energy band theory, allow themselves to be formulated using the same concepts as those appearing in the "Billiard Balls" Drude model. Let us quote among them the "density number" and the "electron mobility" concepts (that we will introduce later rigorously further below in our study of energy band theory).
- Even if this approach is quite primitive, this model leads to a phenomenological interesting interpretation of the fundamental laws such as Ohm's law or the Joule's law. It binds together certain microscopic phenomena and observable quantities.

As it's friendly name suggests it, this model treats the electrons as tiny billiard balls. These particles are therefore considered as classical objects, simply governed by Newton's and Maxwell's laws proved in previous sections of this textbook. This corpuscular conception of the electron is also not totally opposed to the results of quantum physics (study in the next sections of this textbook), in which a wave packet can always be interpreted as a particle with its mass and speed (see the Ehrenfest's theorem in the section of Wave Quantum Physics at page 4870).

In a millimetre copper cube, we assume that the number of electrons is so high that it therefore does not matter then treat individually, which would also be irrelevant. It is the average behaviour of electrons that should be studied! Two types of interactions that determine behaviour are:

- The interaction of electrons with the material in which they operate, and to which they belong;
- The interaction of electrons with the electromagnetic field applied from the outside (all other interaction being neglected).

The distance λ travelled by an electron distance is named "electron mean free conduction path" and if τ is the time interval between two successive collisions then we have trivially:

$$\lambda = v\tau \qquad (10.4.12)$$

where v is obviously the mean electron velocity of the material.

The collision time is a random variable. All physical parameters maintained as constant, this random variable is stationary, its average value is named "mean collision time".

We suppose that:

$$v = a\tau \qquad (10.4.13)$$

the mean velocity, is therefore generated by the acceleration of the electric field (see section Electrostatic page 3969):

$$a = \frac{F}{m} = \frac{qE}{m} \tag{10.4.14}$$

We then get the "mean drift velocity" or simply electrons "drift velocity" given by:

$$v = \frac{qE}{m}\tau \tag{10.4.15}$$

This relation is so named because their initial speed is maintained due to the thermal excitation of the external environment and corresponds to the thermal velocity for which we have determined the expression in our study of the Maxwell-Boltzmann distribution in the section of Statistical Mechanics (we will calculate their further below in this section).

We admit, in the context of the billiard balls model, that electrons behave like atoms of an ideal gas. This is a gross approximation but enough satisfying for now!

The mean velocity is assumed to be identical for all the free electrons when a constant homogeneous electric field is applied, stationary, and directed along a single axis. It gives the possibility to define the "current intensity I" of electric current in the conductor.

Definition (#10.4.480): The "electric current" or "electric intensity", denoted by I, measures the charge $\mathrm{d}Q = nq$ that passes through the cross section S of a conductor per unit of time $\mathrm{d}t$ and is given according to what has been shown just before by:

$$\boxed{I = \frac{\mathrm{d}Q}{\mathrm{d}t}} \tag{10.4.16}$$

A slice of conductor, of volume $\mathrm{d}V = S\mathrm{d}L$ contains therefore the electric charge:

$$\mathrm{d}Q = \frac{nq}{V}\mathrm{d}V = \rho_q S\mathrm{d}L \tag{10.4.17}$$

It passes through the section S in a time $\mathrm{d}t$, such as:

$$\mathrm{d}L = v\mathrm{d}t \tag{10.4.18}$$

The current is therefore written:

$$I = \frac{\mathrm{d}Q}{\mathrm{d}t} = \rho_q S v \tag{10.4.19}$$

Remark

Attention to the usage of the latter relation in practice! If we consider a theoretical wire, the potential difference across the wire is zero. So there will be no gain / loss of kinetic energy of the electron and therefore no change in speed. If we now consider a real wire, resistive therefore, the potential difference across its terminals will be low but not zero, and the electron's potential drop will not be won in kinetic energy but dissipated as heat in the wire.

If I is seen as the flow of a "current density J" through the surface S, then we have:

$$I=\oint\limits_S J\mathrm{d}S=JS \tag{10.4.20}$$

the current density being assumed constant at each point of the surface.

We have therefore:

$$I=\rho_q Sv=JS \tag{10.4.21}$$

and after simplification:

$$J=\rho_q v \tag{10.4.22}$$

which is therefore the expression of the "current density" in the conductor.

As we know the expression of the velocity, this lead us to the famous "drift current" relation:

$$J=\frac{\rho_q q\tau}{m}E \tag{10.4.23}$$

Remark

That latter relation is often denoted:

$$J_{\text{drift}}=q\rho\mu E \tag{10.4.24}$$

where $\rho=\rho_q/m$ is the density of charges (for recall ρ_q was the massic density of charges) and μ is another notation of the mobility τ. Or this relation is also sometimes denoted:

$$J_{\text{drift}}=qn\mu E \tag{10.4.25}$$

And we define the "conductivity" by:

$$\sigma=\frac{\rho_q q\tau}{m}=\frac{nq^2\tau}{m}\;[\mathrm{kg}^{-1}\cdot\mathrm{m}^{-3}\cdot\mathrm{s}^3\cdot\mathrm{A}^2] \tag{10.4.26}$$

where this time n is not the number of electrons, but the number density of electrons! Notice that $[\mathrm{kg}^{-1}\cdot\mathrm{m}^{-3}\cdot\mathrm{s}^3\cdot\mathrm{A}^2]$ is the equivalent of $[\mathrm{kg}^{-1}\cdot\mathrm{m}^{-3}\cdot\mathrm{s}\cdot\mathrm{C}^2]$. Conductivity has in SI units (sadly) of "siemens" per metre $[\mathrm{S}\cdot\mathrm{m}^{-1}]$.

By definition, the "resistivity" (not to be confused with the resistance denoted R!!), is the inverse of the conductivity:

$$\boxed{\rho=\frac{1}{\sigma}=\frac{m}{\rho_q q\tau}\;[\mathrm{kg}\cdot\mathrm{m}^3\cdot\mathrm{s}^{-3}\cdot\mathrm{A}^{-2}]} \tag{10.4.27}$$

More commonly denoted:

$$\rho=\frac{1}{\sigma}\;[\Omega\cdot\mathrm{m}] \tag{10.4.28}$$

where Ω is the unit named "Ohm".

We notice that the conductivity contains the product of the number density of electron by their mobility. Therefore it is necessary that at least one of these variables has a high value for a material has a high conductivity.

The mobility is greater in the semiconductors than in metals. This characteristic however is completely masked by the ratio of the volumetric numbers of electrons: n is between $1,000,000$ to $100,000,000$ times lower in semiconductors than in metals, which explains the higher conductivity of these.

Following the relation:

$$\sigma=\frac{\rho_q q\tau}{m}=\frac{nq^2\tau}{m} \tag{10.4.29}$$

proved just earlier above, the conductivity depends on the electric field, through the collision time. Indeed, the more the electric field grows, the more the speed of the electrons increases. The distance between the points of possible shocks remaining the same, the collision time, and hence the conductivity should decrease (and thus the resistance increase!).

However, the independence of the conductivity (and respectively the resistance) with the electric field is an experimental fact established precisely with all usual conductors in normal civilian uses.

The origin of this contradiction lies in the large difference in the magnitudes of the thermal velocity given by the Maxwell-Boltzmann distribution (see section Statistical Mechanics page 3554):

$$\langle v_{\text{th}}\rangle=\sqrt{\langle v^2\rangle}=\sqrt{\frac{3kT}{m}} \tag{10.4.30}$$

and of the average speed drift seen above:

$$v=\frac{qE}{m}\tau \tag{10.4.31}$$

with the mean free path time that will be obtained using the expression:

$$\sigma=\frac{\rho_q q\tau}{m}=\frac{nq^2\tau}{m} \tag{10.4.32}$$

We have proved in the section of Statistical Mechanics that for an electron at room temperature:

$$\langle v_{\text{th}}\rangle\cong 1.2\cdot 10^5\;[\text{m}\cdot\text{s}^{-1}] \tag{10.4.33}$$

And let us calculate the drift velocity for copper with for this particular metal the following values:

$$\sigma=5.81\cdot 10^7\;[\Omega^{-1}]\qquad\text{and}\qquad n=1.16\cdot 10^{29}\;[\text{m}^{-3}] \tag{10.4.34}$$

This allows us to get the value:

$$\tau=\frac{\sigma m}{nq^2}=1.79\cdot 10^{-14}\;[\text{s}] \tag{10.4.35}$$

and therefore:

$$v=\frac{qE}{m}\tau=\frac{qE}{m}\frac{\sigma m}{nq^2}=\frac{qE}{m}\cdot(1.79\cdot 10^{-14}) \qquad (10.4.36)$$

Taking $E=0.32\,[\text{V}\cdot\text{m}^{-1}]$, which is considered as a high value since this field produces a current density of:

$$J=\frac{nq^2\tau}{m}E=1.86\cdot 10^7\,[\text{A}\cdot\text{m}^{-2}]=18.6\,[\text{A}\cdot\text{mm}^{-2}] \qquad (10.4.37)$$

we finally have:

$$v=\frac{qE}{m}\cdot(1.79\cdot 10^{-14})=1\cdot 10^{-3}\,[\text{m}\cdot\text{s}^{-1}] \qquad (10.4.38)$$

Therefore, even in a strong industrial electric field, the drift velocity is negligible compared to the thermal velocity!

As the thermal velocity depends only a little bit of the electric field, it turns out that in practice the electron velocity is independent of the electric field. In other words, establishing a current, even intense, has only a negligible effect on the speed of electrons!

It is therefore not the electrons that carry the energy, contrary to a falsely held belief, due to bad analogies (which are always bad equivalences as we already know...!) - typically the analogy of electrons that behaves like water flow in cables (good luck to explain with water flow basic AC circuits with capacitance, inductance or semiconductors) - as taught in the non-graduate degrees of the school education system!!!!

Remark

In the vast majority of cases, the conductor sizes are large, compared to the average distance that an electron travel between two consecutive shocks. The behaviour of the surface of the conductive electrons then are of secondary importance. This is why the conductive medium is often implicitly considered as infinite. The FET (Field-Effect Transistor) and MOST (Metal Oxide Semiconductor Transistor) are an important exception to this. The current circulates in a layer thin enough that the electron mobility is affected by electron scattering on surfaces defining this layer.

However, an important point to notice is the calculation of the mean free path of electrons in the classical Drude model. We have indeed:

$$l\cong v_{\text{th.}}\tau\cong 2\,[\text{nm}] \qquad (10.4.39)$$

which is much higher, at least an order of magnitude (factor of 10), to the inter-atomic distances. It results from this that successive collisions with atoms of the network is not responsible for Ohm's law (which we will see now) contrary to one of the initial assumptions of the Drude model but that it are the impurities and defects of the material involved in it that generates the collisions! We will see a further below in the theoretical model of energy bands that the mean free path is in fact still much greater!

Warning!!! This relation may suggest that since the mean free path is proportional to the thermal velocity and therefore proportional to the square root of the temperature, that the resistance decreases with temperature. But in fact it is not so! The Drude model is too simplistic because in reality it is the opposite that occurs for conductors (resistance increases with temperature because the time interval τ between collisions decreases faster than the speed increases). And then there is also an opposite problem ... almost at a temperature equal to the zero Kelvin (and over for some materials) the mean free path should be almost zero but superconductors show us that it is not the case! In short, without explicit relation depending on the temperature we are in total darkness!

The only thing we know how to do is to admit that to a given constant factor α (positive or negative), a temperature change requires a relative change in resistance by (first order Taylor development):

$$\frac{\Delta\rho}{\rho_0}=\alpha\Delta T \qquad (10.4.40)$$

hence:

$$\frac{\rho-\rho_0}{\rho_0}=\alpha(T-T_0) \qquad (10.4.41)$$

Then we get the relation know in high-schools (the same relation applies for resistance if the reader replaces ρ by R and ρ_0 by R_0):

$$\rho=\rho_0[1+\alpha(T-T_0)] \qquad (10.4.42)$$

Finally, let us notice that the fourth Maxwell equation (see section Electrodynamics page 4106) can then be written by the results obtained just previously:

$$\vec{\nabla}\times\vec{H}=\vec{j}+\frac{\mathrm{d}\vec{D}}{\mathrm{d}t}=\sigma\vec{E}+\frac{\mathrm{d}\vec{D}}{\mathrm{d}t} \qquad (10.4.43)$$

which then explicitly makes appear the conductivity coefficient.

10.4.3 Ohm's law

Ohm's law states that the current through a conductor between two points is directly proportional to the voltage across the two points. Introducing the constant of proportionality, the resistance.

From the relation proved just above:

$$J=\frac{\rho_q q\tau}{m}E \tag{10.4.44}$$

and taking the definition of "conductivity" by:

$$\sigma=\frac{\rho_q q\tau}{m}=\frac{nq^2\tau}{m} \tag{10.4.45}$$

We have finally:

$$\boxed{J=\sigma E} \tag{10.4.46}$$

which is the "local Ohm's law". We have already see it in differential form in the section of Statistical Mechanics and we already know therefore that it belongs in fact to the family of diffusion laws!

Type of Materials	**Electrical conductivity** σ $[\Omega\cdot\mathrm{m}^{-1}]$
Silver	$6.3\cdot 10^7$
Copper	$5.8\cdot 10^7$
Gold	$4.2\cdot 10^7$
Aluminum	$3.4\cdot 10^7$
Germanium	2.2
Silicon	$4.3\cdot 10^{-4}$
Polyethylene	10^{-14}
Diamond	10^{-14}

Table 10.4: **Table of some electrical conductivities at room temperature**

Remark

Since the conductivity is necessarily a scalar, the vector notation of Ohm's law implies that the electrostatic field lines also indicate the path taken by the electrical charges. Moreover, as the conductivity is a scalar necessarily positive in the traditional model, this implies that the current has the same direction as the electric field.

If we multiply the previous equality under scalar left and right by a length L we get:

$$J\cdot L=\sigma E\cdot L\Leftrightarrow I=\sigma\frac{S}{L}U=GU \tag{10.4.47}$$

Then we have:

$$I=G\cdot U \tag{10.4.48}$$

or:

$$U=\frac{1}{G}I \tag{10.4.49}$$

We define the inverse of conductivity as the "electric resistance", or more commonly simply named "resistance", defined by:

$$\boxed{R=\frac{1}{G}=\frac{1}{\sigma\dfrac{S}{L}}\;[\Omega]} \tag{10.4.50}$$

where in S.I. units $[\Omega]=[\mathrm{kg}\cdot\mathrm{m}^2\cdot\mathrm{s}^{-3}\cdot\mathrm{A}^{-2}]$.

Remark

It is important to notice that the electrical resistance is proportional to the length of the resistive element and inversely proportional to its sectional area. For example in high voltage cables, the resistance is given in ohms per kilometre, which permits then to calculates the power lost by kilometre and therefore the money lost by Joule loss.

Therefore, we can write Ohm's local law in its most commonly known form:

$$\boxed{U=RI} \tag{10.4.51}$$

whence (beware !!!) the potential U is the potential difference over the length of the resistive element (also named "resistive dipole") as we see it in the previous developments and not the total outside potential!

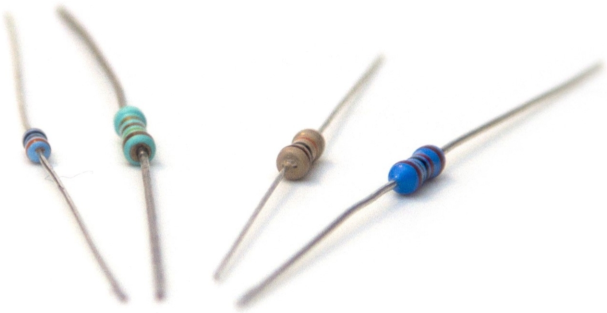

Figure 10.91: Some resistive dipoles (source: `http://www.e-style.ch`, author: Martin Bircher)

As for the capacitors seen in the section Electrostatics, resistors have also color codes that have as far as we know until know the same definitions:

Remark

This relation is valid only for ideal conductors under normal conditions of temperature and pressure and for which the Drude model applies. So semiconductors and superconductors are excluded.

Since U is the potential of the resistive element, then we often do reference in the field of electrical engineering to the "voltage drop" (indeed, beyond the resistive element the potential is not the same that at the point above this same resistive element).

For copper cables in typical non-industrial use, there is a very useful American table in practice giving with a relatively good accuracy the resistivity according to the diameter and the maximum permissible current. Here is a sample of this table:

AWG	Wire ∅ in [mm] with isolation	Resistance in $[\Omega \cdot \text{m}^{-1}]$	Max. theoretically eligible current in [A]	Max. theoretically eligible current in [A] outdoors
1	7.35	0.0040	211	119

HOW RESISTORS CONVERT ELECTRIC ENERGY TO HEAT

Resistors oppose the flow of electric current. The electrical energy supplied by a source is dissipated as **heat** due to collisions of charge carriers with the material's atoms.

1. CURRENT FLOWS THROUGH A RESISTOR

When a voltage V is applied across a resistor R, a current I flows through it.

2. COLLISIONS INSIDE THE RESISTOR

Electrons drift through the material but constantly collide with atoms. These collisions transfer kinetic energy to the atoms, increasing their vibrational motion.

- ● Electron (charge carrier)
- ● Atom of the resistive material
- ✸ Collision

3. ELECTRICAL ENERGY → HEAT

The increased atomic vibrations (lattice vibrations) appear to us as **heat**. The resistor's temperature rises and thermal energy is released to the surroundings.

THE POWER DISSIPATED AS HEAT

The rate at which electrical energy is converted to heat (power) is given by Joule's law.

$$P = VI = I^2 R = \frac{V^2}{R}$$

P = power dissipated (watts, W)
V = voltage across the resistor (volts, V)
I = current through the resistor (amperes, A)
R = resistance (ohms, Ω)

All the electrical energy supplied is ultimately **dissipated as heat** in an ideal resistor.

EXAMPLE

A 100 Ω resistor carries 0.20 A of current. How much power (heat) is dissipated?

$$P = I^2 R = (0.20)^2 \times 100 = 4.0 \ \mathbf{W}$$

So, 4.0 joules of energy are converted to heat every second.

MICROSCOPIC VIEW

Collisions randomize electron motion and increase the amplitude of atomic vibrations (phonons). This is the microscopic origin of heating.

● Electron ● Atom ~ Vibration

TEMPERATURE RISE

Power dissipated raises the temperature until the heat lost to the surroundings (conduction, convection, radiation) equals the power generated.

Steady state:
$P_{\text{dissipated}} = P_{\text{lost}}$

DEPENDENCE ON RESISTANCE

For a given voltage:

$$P = \frac{V^2}{R}$$

Higher resistance
→ lower current
→ **less power**

For a given current:

$$P = I^2 R$$

Higher resistance
→ **more power**

ENERGY VIEW

A resistor has no energy storage. It simply converts electrical energy into thermal energy, making it one of the most fundamental dissipative elements in electrical circuits.

This is why resistors feel warm or hot when power is dissipated in them.

10.4.3.1 Complex Conductivity

The "complex conductivity" is a simple result of a simple extension of the classical Drude model for the material conduction. In the Drude model it is assumed that in the conduction material there is a concentration n of electrons and that an electron has a probability $1/\tau$, where τ is named "scattering time" or "relaxation time", for scattering with the lattice for losing its momentum. The motion of the electrons can be described by Newton's law:

$$m\frac{\mathrm{d}v}{\mathrm{d}t}=-qE-\frac{mv}{\tau} \tag{10.4.52}$$

where m is the (effective) electron mass, v the mean electron velocity in field direction, and E is the electric field strength.

This relation is easy to derived. Indeed, consider the motion of an electron in an electric field of strength $E\,[\mathrm{V}\cdot\mathrm{m}^{-1}]$. The force on the electron is $-qE$. In the event of a collision between the electron and a gas molecule, energy is lost in the form of heat. The frictional or retarding force due to the collision is mv/τ, or $mv\nu$, where τ is the mean time between collision, ν is the frequency of collision and m is the effective mass of electron. Therefore, the net force on the electron is:

$$F=-qE-\frac{mv}{\tau} \tag{10.4.53}$$

Since the electron is moving with a velocity v, the force on the electron is equal to the rate of change of the momentum:

$$F=-qE-\frac{mv}{\tau}=m\frac{\mathrm{d}v}{\mathrm{d}t} \tag{10.4.54}$$

The term $-mv/\tau$ resembles a "friction term" in the equation of motion. Assuming sinusoid variation of the electric field, i.e.:

$$v\propto E\propto e^{-\mathrm{i}\omega t} \tag{10.4.55}$$

Thus from the differential equation above it follows:

$$-q\hat{E}e^{-\mathrm{i}\omega t}-\frac{m\hat{v}e^{-\mathrm{i}\omega t}}{\tau}=m\frac{\mathrm{d}(\hat{v}e^{-\mathrm{i}\omega t})}{\mathrm{d}t} \tag{10.4.56}$$

Therefore:

$$-q\hat{E}e^{-\mathrm{i}\omega t}-\frac{m\hat{v}e^{-\mathrm{i}\omega t}}{\tau}=-m\hat{v}\mathrm{i}\omega e^{-\mathrm{i}\omega t} \tag{10.4.57}$$

Simplifying:

$$-q\hat{E}-\frac{m\hat{v}}{\tau}=-m\hat{v}\mathrm{i}\omega \tag{10.4.58}$$

Hence:

$$\hat{v}=-\frac{q\hat{E}}{m}\frac{1}{\tau^{-1}-\mathrm{i}\omega} \tag{10.4.59}$$

This gives the current density:

$$\hat{J}=-nq\hat{v}=\frac{nq^2\hat{E}}{m}\frac{1}{1/\tau-\mathrm{i}\omega}=\frac{\rho_q q}{m}\frac{1}{\tau^{-1}-\mathrm{i}\omega}\hat{E} \tag{10.4.60}$$

and thus the complex material conductivity is defined as:

$$\boxed{\hat{\sigma}=\frac{nq_e^2}{m_e}\frac{1}{\tau^{-1}-\mathrm{i}\omega}} \tag{10.4.61}$$

The complex conductivity relates both the magnitude and the phase of the current density to the magnitude and phase of the applied electric field similar to the current and voltage in an alternative current circuit are related by the complex conductance. This can be most easily seen when you remember that only real parts of the complex values of current and electric field are used and you express the complex conductivity by the complex exponential $\sigma=|\hat{\sigma}|\exp(-\mathrm{i}\phi)$. Then you see that $|\hat{\sigma}|$ is the magnitude of the proportionality constant and φ is the current-field phase shift.

The real part of $\hat{\sigma}$ thus describes the convective current and the imaginary part corresponds to a displacement current (imaginary part indicates that the current lags behind the electrical field, which happens because the electrons need roughly a time τ to accelerate in response to a change in the electrical field).

Like radio waves, the electric field of the optical light acts on the electrons in a material and can cause them to move. But visible light has a much shorter wavelength than radio waves (about 10^6 shorter) and so it doesn't drive macroscopic currents. Moreover, the conductivity decreases, which we can see in the Drude Model:

$$\hat{\sigma}(\omega)=\frac{\sigma_0}{1+\mathrm{i}\omega\tau}=\frac{\sigma_0}{1+\omega^2\tau^2}-\mathrm{i}\omega\tau\frac{\sigma_0}{1+\omega^2\tau^2} \tag{10.4.62}$$

where for recall ω is the light frequency, τ is the relaxation time (due to scattering and related to the carrier density, temperature, etc.), and $\sigma_0=\frac{\rho_q q\tau}{m}$ is the "effective DC conductivity" (complex conductivity when $\omega=0$) also named "nominal conductivity" (n is the number density and m is an effective mass which can be different for electrons and holes depending on the material).

We can see that when the frequency ω is large (like for optical waves) the conductivity goes to zero. This happens because at really high frequencies the electrons do not have time to respond to the field and so they no longer (appreciably) move back and forth. Above this frequency the material becomes transparent (identical to the behaviour at the critical frequency in plasmas).

10.4.3.2 Simple (harmonic oscillator) model of dielectric and conductors (and plasmas)

As we have seen during our study of Rayleigh scattering (see section Nuclear Physics page 5102), a simple model for the dielectric properties of a material may be obtained by considering the motion of a bound electron in the presence of an applied electric field. As the electric field tries to separate the electron from the positively charged nucleus, it generates an electric dipole moment. Averaging this dipole moment over the volume of the material gives rise to a macroscopic dipole moment per unit volume.

A simple model for the dynamics of the displacement x of the bound electron is as follows (with $\dot{x}=\mathrm{d}x/\mathrm{d}t$):

$$m_e\ddot{x}=q_eE-kx-m_e\gamma\dot{x} \tag{10.4.63}$$

where we assumed that the electric field is acting in the x-direction and that there is a spring-like restoring force due to the binding of the electron to the nucleus, and a friction-type force proportional to the velocity of the electron.

The spring constant k is related to the resonance frequency of the spring via the relationship $\omega_0=\sqrt{k/m_e}$, or, $k=m_e\omega_0^2$. Therefore, we may rewrite the above relation as:

$$\ddot{x}+\gamma\dot{x}+\omega_0^2x=\frac{q_e}{m_e}E \tag{10.4.64}$$

The limit $\omega_0=0$ corresponds to unbound electrons and describes the case of good conductors. The frictional term $\gamma\dot{x}$ arises from collisions that tend to slow down the electron. The parameter y is a measure of the rate of collisions per unit time, and therefore, $\tau=1/\gamma$ will represent the mean-time between collisions.

In a typical conductor, τ is of the order of 10^{-14} seconds, for example, for copper, $\tau=2.4\cdot 10^{-14}$ [s] and $\gamma=4.1\cdot 10^{13}$ [s^{-1}]. The case of a tenuous, collisionless, plasma can be obtained in the limit $\gamma=0$. Thus, the above simple model can describe the following cases:

a. Dielectrics, $\omega_0\neq 0,\gamma\neq 0$

b. Conductors, $\omega_0=0,\gamma\neq 0$

c. Collisionless Plasmas, $\omega_0=0,\gamma=0$

The basic idea of this model is that the applied electric field tends to separate positive from negative charges, thus, creating an electric dipole moment. In this sense, the model contains the basic features of other types of polarization in materials, such as Ionic/molecular polarization arising from the separation of positive and negative ions by the applied field, or polar materials that have a permanent dipole moment.

10.4.3.2.1 Dielectrics

The applied electric field $E(t)$ above can have any time dependence. In particular, if we will assume it is sinusoidal with frequency ω, $E(t)=E_0e^{\mathrm{i}\omega t}$, then the above differential equation will have for solution as proved during our study of Rayleigh scattering (see section Nuclear Physics page 5102):

$$x=\frac{\frac{q_e}{m_e}E}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma} \tag{10.4.65}$$

The corresponding velocity of the electron will also be sinusoidal $v(t)=ve^{\mathrm{i}\omega t}$, where $v=\dot{x}=\mathrm{i}\omega x$. Thus, we have:

$$v=\mathrm{i}\omega x=\frac{\mathrm{i}\omega\frac{q_e}{m_e}E}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma} \tag{10.4.66}$$

From the both relations above we can find the polarization per unit volume P. We assume that there are N such elementary dipoles per unit volume. The individual electric dipole moment is $p=q_ex$ (see section Electrostatics page 3984). Therefore, the polarization per unit volume will be:

$$P=Np=Nq_ex=\frac{\frac{Nq_e^2}{m_e}E}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma}:=\varepsilon_0\chi(\omega)E \tag{10.4.67}$$

The electric flux density (see page 4108) will be then:

$$D=\varepsilon_0E+P=\varepsilon_0(1+\chi(\omega))E:=\varepsilon(\omega)E \tag{10.4.68}$$

where the "effective permittivity" $\varepsilon(\omega)$ is then defined by:

$$\varepsilon(\omega)=\varepsilon_0+\frac{\frac{Nq_e^2}{m_e}}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma} \tag{10.4.69}$$

This can be written in a more convenient form, as follows:

$$\boxed{\varepsilon(\omega)=\varepsilon_0+\frac{\varepsilon_0\omega_p^2}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma}} \tag{10.4.70}$$

where ω_p^2 is the so-named "plasma frequency" of the material defined by (we have already met this relation during our study of plasmas at page 3947):

$$\boxed{\omega_p^2=\frac{Nq_e^2}{\varepsilon_0m_e}} \tag{10.4.71}$$

The model defined by:

$$\varepsilon(\omega)=\varepsilon_0+\frac{\varepsilon_0\omega_p^2}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma} \tag{10.4.72}$$

is known as a "Lorentz dielectric". The corresponding susceptibility, defined through $\varepsilon(\omega)=\varepsilon_0(1+x(\omega))$, is:

$$\chi(\omega)=\frac{\omega_p^2}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma} \tag{10.4.73}$$

For a dielectric, we may assume $\omega_0 \neq 0$. Then, the low-frequency limit ($\omega = 0$) gives the "nominal dielectric constant":

$$\varepsilon(\omega) = \varepsilon_0 + \frac{\frac{Nq_e^2}{m_e}}{\omega_0^2 - \omega^2 + \mathrm{i}\omega\gamma} \Rightarrow \varepsilon(0) = \varepsilon_0 + \varepsilon_0\frac{\omega_p^2}{\omega_0^2} = \varepsilon_0 + \frac{Nq_e^2}{m_e\omega_0^2} \tag{10.4.74}$$

The real and imaginary parts of $\varepsilon(\omega)$ characterize by convention the refractive and absorptive properties of the material. By convention, we define the imaginary part with the negative sign (because we use $e^{\mathrm{i}\omega t}$ time dependence):

$$\varepsilon(\omega) = \varepsilon'(\omega) - \mathrm{i}\varepsilon''(\omega) \tag{10.4.75}$$

It follows from:

$$\varepsilon(\omega) = \varepsilon_0 + \frac{\varepsilon_0\omega_p^2}{\omega_0^2 - \omega^2 + \mathrm{i}\omega\gamma} \tag{10.4.76}$$

that:

$$\varepsilon'(\omega) = \varepsilon_0 + \frac{\varepsilon_0\omega_p^2\left(\omega_0^2 - \omega^2\right)}{\left(\omega^2 - \omega_0^2\right)^2 + \gamma^2\omega^2} \qquad \varepsilon''(\omega) = \frac{\varepsilon_0\omega_p^2\omega\gamma}{\left(\omega^2 - \omega_0^2\right)^2 + \gamma^2\omega^2} \tag{10.4.77}$$

The figure below shows a plot of $\varepsilon'(\omega)$ and $\varepsilon''(\omega)$. Around the resonant frequency ω_0, the real part $\varepsilon'(\omega)$ behaves in an anomalous manner, that is, it drops rapidly with frequency to values less than ε_0 and the material exhibits strong absorption. The term "normal dispersion" refers to an $\varepsilon'(\omega)$ that is an increasing function of ω, as is the case to the far left and right of the resonant frequency:

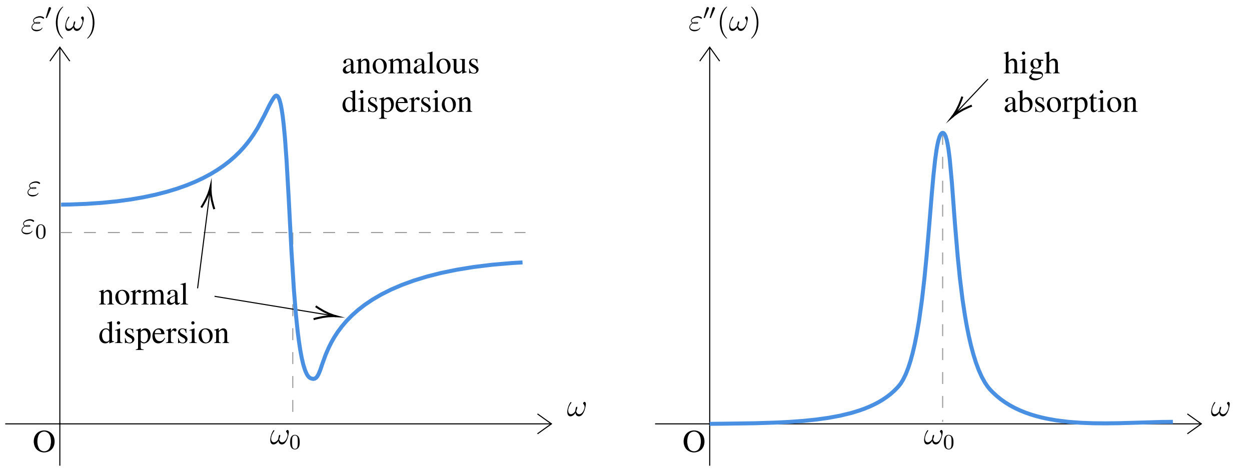

Figure 10.94: **Real and imaginary parts of the effective permittivity $\varepsilon(\omega)$**

Real dielectric materials exhibit, of course, several such resonant frequencies corresponding to various vibrational modes and polarization mechanisms (e.g., electronic, ionic, etc.). The permittivity becomes the sum of such terms:

$$\varepsilon(\omega) = \varepsilon_0 + \varepsilon_0\sum_i \frac{N_i q_{e,i}^2/m_{e,i}\varepsilon_0}{\omega_i^2 - \omega^2 + \mathrm{i}\omega\gamma_i} \tag{10.4.78}$$

Remark

A more correct quantum-mechanical treatment leads essentially to the same relation:

$$\varepsilon(\omega)=\varepsilon_0+\varepsilon_0\sum_{j>i}\frac{f_{ji}\left(N_i-N_j\right)q_e^2/m_e\varepsilon_0}{\omega_{ji}^2-\omega^2+\mathrm{i}\omega\gamma_{ji}} \tag{10.4.79}$$

where ω_{ji} are transition frequencies between energy levels, that is, $\omega_{ji}=\left(E_j-E_i\right)/h$ and N_i, N_j are the populations of the lower, E_i, and upper, E_j, energy levels. The quantities f_{ji} are named "oscillator strengths." For example, for a two-level atom we have:

$$\varepsilon(\omega)=\varepsilon_0+\varepsilon_0\frac{f\omega_p^2}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma} \tag{10.4.80}$$

where we defined:

$$\omega_0=\omega_{21}, \qquad f=f_{21}\frac{N_1-N_2}{N_1+N_2}, \qquad \omega_p^2=\frac{\left(N_1+N_2\right)e^2}{m\varepsilon_0} \tag{10.4.81}$$

Normally, lower energy states are more populated, $N_i>N_j$, and the material behaves as a classical absorbing dielectric. However, if there is population inversion, $N_i<N_j$ then the corresponding permittivity term changes sign. This leads to a negative imaginary part, $\varepsilon''(\omega)$, representing a gain.

As:

$$n^2(\omega)=\frac{c}{v_n}=\sqrt{\varepsilon_r\mu_r}=\sqrt{\varepsilon(\omega)/\varepsilon_0} \tag{10.4.82}$$

For a material have and relative permeability equal to 1 (vacuum) then:

$$n^2(\omega)=\sqrt{\varepsilon_r}=\sqrt{\varepsilon(\omega)/\varepsilon_0} \tag{10.4.83}$$

Therefore:

$$\varepsilon(\omega)=\varepsilon_0+\varepsilon_0\sum_i\frac{N_iq_{e,i}^2/m_{e,i}\varepsilon_0}{\omega_i^2-\omega^2+\mathrm{i}\omega\gamma_i} \tag{10.4.84}$$

can be written in the following form, known as the "Sellmeier equation" (where the B_i are constants):

$$\boxed{n^2(\omega)=1+\sum_i\frac{B_i\omega_i^2}{\omega_i^2-\omega^2+\mathrm{i}\omega\gamma_i}} \tag{10.4.85}$$

In practice the relation above is applied in frequency ranges that are far from any resonance so that one can effectively set $\gamma_i=0$:

$$n^2(\omega)=1+\sum_i\frac{B_i\omega_i^2}{\omega_i^2-\omega^2}=1+\sum_i\frac{B_i\lambda^2}{\lambda^2-\lambda_i^2} \tag{10.4.86}$$

or:

$$n_\lambda=\sqrt{1+\sum_i\frac{B_i\lambda^2}{\lambda^2-\lambda_i^2}} \tag{10.4.87}$$

where λ,λ_i denote the corresponding free-space wavelengths (e.g., $\lambda=2\pi c/\omega$). In practice, refractive index data are fitted to the relation above using $2-4$ terms over a desired frequency range. For example, fused silica (SiO_2) is very accurately represented over the range $0.2\leq\lambda\leq 3.7\;[\mu\text{m}]$ by the following formula where λ and λ_i are in units of μ:

$$n_\lambda^2=1+\frac{0.6961663\lambda^2}{\lambda^2-(0.0684043)^2}+\frac{0.4079426\lambda^2}{\lambda^2-(0.1162414)^2}+\frac{0.8974794\lambda^2}{\lambda^2-(9.896161)^2} \tag{10.4.88}$$

Remark

The previous relation:

$$n^2(\omega)=1+\sum_i\frac{B_i\omega_i^2}{\omega_i^2-\omega^2} \tag{10.4.89}$$

Can be found in some textbook for the first term ($i=0$) under the following form:

$$n^2\approx 1+\chi_e(0)\frac{\omega_{0,e}^2}{\omega_{0,e}^2-\omega^2}=1+\chi_e(0)\frac{1}{1-\omega^2/\omega_{0,e}^2}\approx 1+\chi_e(0)\left(1+\frac{\omega^2}{\omega_{0,e}^2}\right) \tag{10.4.90}$$

Therefore:

$$n^2\approx 1+\chi_e(0)+\frac{\chi_e(0)}{\omega_{0,e}^2}\left(\frac{2\pi c}{\lambda_0}\right)^2=A+\frac{B}{\lambda_0^2}\quad\text{and}\quad n\approx\left(A+\frac{B}{\lambda_0^2}\right)^{1/2} \tag{10.4.91}$$

A et B being two constants.When the dispersion is low, $B/\left(\lambda_0^2A\right)\ll 1$, we fall back on the well-known "Cauchy's formula":

$$n\approx n_0+\frac{C}{\lambda_0^2} \tag{10.4.92}$$

This relationship is well verified for dielectrics used in optics. However the constants n_0 and C are determined experimentally because the simple model adopted here does not take into account the complexity of the electronic properties of materials.

10.4.3.2.2 Conductors

We will see now that using the first results above we can fall back on relation of the complex conductivity we get at page 4238.

The conductivity properties of a material are described by Ohm's law. To derive this law from our simple model, we use the relationship $J=\rho v$, where the volume density of the conduction charges is $\rho=Nq_e$. It follows from above that:

$$J=\rho v=Nq_ev=\frac{\mathrm{i}\omega\frac{Nq_e^2}{m}E}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma}:=\sigma(\omega)E \tag{10.4.93}$$

and therefore, we identify the conductivity $\sigma(\omega)$:

$$\sigma(\omega)=\frac{\mathrm{i}\omega\frac{Nq_e^2}{m}}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma}=\frac{\mathrm{i}\omega\varepsilon_0\omega_p^2}{\omega_0^2-\omega^2+\mathrm{i}\omega\gamma} \tag{10.4.94}$$

We note that $\sigma(\omega)/\mathrm{i}\omega$ is essentially the electric susceptibility considered above. Indeed, we have:

$$J = Nq_e v = Nq_e \mathrm{i}\omega x = \mathrm{i}\omega P \tag{10.4.95}$$

and thus, $P = J/\mathrm{i}\omega = (\sigma(\omega)/\mathrm{i}\omega)E$. It follows that $\varepsilon(\omega) - \varepsilon_0 = \sigma(\omega)/\mathrm{i}\omega$, and:

$$\varepsilon(\omega) = \varepsilon_0 + \frac{\varepsilon_0\omega_p^2}{\omega_0^2 - \omega^2 + \mathrm{i}\omega\gamma} = \varepsilon_0 + \frac{\sigma(\omega)}{\mathrm{i}\omega} \tag{10.4.96}$$

since in a metal the conduction charges are unbound, we may take $\omega_0 = 0$. After cancelling a common factor of $\mathrm{i}\omega$, we get:

$$\boxed{\sigma(\omega) = \frac{\varepsilon_0\omega_p^2}{\gamma + \mathrm{i}\omega} = \frac{\varepsilon_0\omega_p^2}{\tau^{-1} + \mathrm{i}\omega}} \tag{10.4.97}$$

So we fall back on the expected result. The nominal conductivity is obtained at the low-frequency limit as we know, $\omega = 0$:

$$\sigma = \frac{\varepsilon_0\omega_p^2}{\gamma} = \frac{Nq_e^2}{m_e\gamma} \tag{10.4.98}$$

✍**Example:**

Copper has a mass density of $8.9\cdot 10^6\;[\text{gr}\cdot\text{m}^{-3}]$ and atomic weight of $63.5\;[\text{gr}\cdot\text{mole}^{-1}]$. Using Avogadro's number of $6\cdot 10^{23}$ atoms per mole, and assuming one conduction electron per atom, we find for the volume density N :

$$N = \frac{6\cdot 10^{23}\frac{\text{atoms}}{\text{mole}}}{63.54\frac{\text{gr}}{\text{mole}}}\left(8.9\cdot 10^6\,\frac{\text{gr}}{\text{m}^3}\right)\left(1\frac{\text{electron}}{\text{atom}}\right) = 8.4\cdot 10^{28}\;[\text{electrons}\cdot\text{m}^{-3}]$$

It follows that:

$$\sigma = \frac{Nq_e^2}{m_e\gamma} = \frac{(8.4\cdot 10^{28})\,(1.6\cdot 10^{-19})^2}{(9.1\cdot 10^{-31})\,(4.1\cdot 10^{13})} = 5.8\cdot 10^7\;[\Omega^{-1}\cdot\text{m}^{-1}] = 5.8\cdot 10^7\;[\text{Siemens}\cdot\text{m}^{-1}]$$

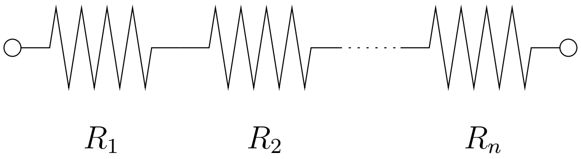
where we used $q_e = 1.6\cdot 10^{-19}$ [C], $m_e = 9.1\cdot 10^{-31}$ [kg], $\gamma = 4.1\cdot 10^{13}\;[\text{s}^{-1}]$. The plasma frequency of copper can be calculated by:

$$f_P = \frac{\omega_\text{P}}{2\pi} = \frac{1}{2\pi}\sqrt{\frac{Nq_e^2}{m_e\varepsilon_0}} = 2.6\cdot 10^{15}\;[\text{Hz}]$$

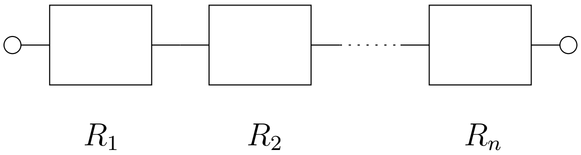
which lies in the ultraviolet range. For frequencies such that $\omega \ll \gamma$, the conductivity may be considered to be independent of frequency and equal to the de value of $\sigma = Nq_e^2/m_e\gamma$. This frequency range covers most present-day RF applications. For example, assuming $\omega \leq 0.1\gamma$, we find $f \leq 0.1\gamma/2\pi = 653$ [GHz].

10.4.3.3 Equivalent Resistance

We can now study the entire length of an electric field line collinear with a constant current I supposed to be constant at any point (this is an approximation obviously...) to obtain total resistance if n resistive elements are put next to each other linearly:



Or using another typical symbol in electronics (the both are accepted and documented in *IEC 60617: Standard Graphic Symbols for Circuit Diagrams*):



The answer is relatively simple since if we denote by U_{n-1} the potential in the first extremity of the resistive element and U_n that of the other extremity. We then have (the reader will have notice that the use of the mesh law in the following relation logically without even necessarily be aware of it existence):

$$U=(U_0-U_1)+(U_1-U_2)+\ldots+(U_{n-1}-U_n)=R_1I+R_2I+\ldots+R_nI \tag{10.4.99}$$

that is to say, a result similar to that obtained by a single resistance whose value is approximately given by (if the electric current is constant throughout the wire) the "equivalent resistance of resistors in series":

$$\boxed{R_e\cong\sum_{i=1}^{n}R_i} \tag{10.4.100}$$

which is the arithmetic sum of the individual resistances.

Let us now consider n resistance in parallel all at a given voltage U (by law of mesh!) and alimented by an electric current I. The current then splits into n streams such that:

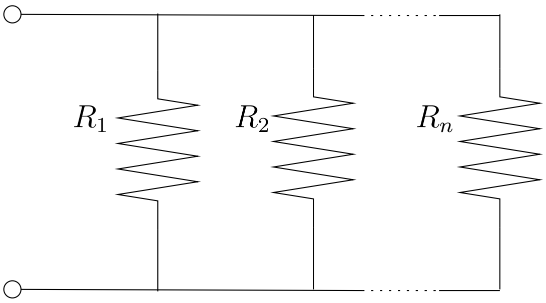
$$I_i=\frac{U}{R_i} \tag{10.4.101}$$

in each of the n mesh. Applying the node law, we have:

$$I_e=\sum_{i=1}^{n}I_i=\sum_{i=1}^{n}\frac{U}{R_i}=\frac{U}{R_e} \tag{10.4.102}$$

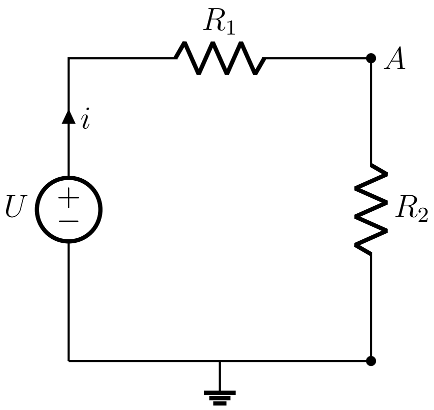
that is to say that the set of all the resistance put in parallel is analogous to an "equivalent resistance of resistors in parallel":

$$\boxed{\frac{1}{R_e}=\sum_{i=1}^{n}\frac{1}{R_i}\Leftrightarrow R_e=\frac{1}{\displaystyle\sum_{i=1}^{n}\frac{1}{R_i}}} \tag{10.4.103}$$



Plugging devices in parallel allows to always have the same voltage across them (neglecting the voltage drops). This is the way that the electrical outlets are installed in a domestic installation!

Therefore for a series circuit, we can calculate the equivalent resistance by adding them. Using the notation of the LaTeX Circuitikz package we have:



For this circuit, we have:

$$R_{\text{eq}}=R_1+R_2 \tag{10.4.104}$$

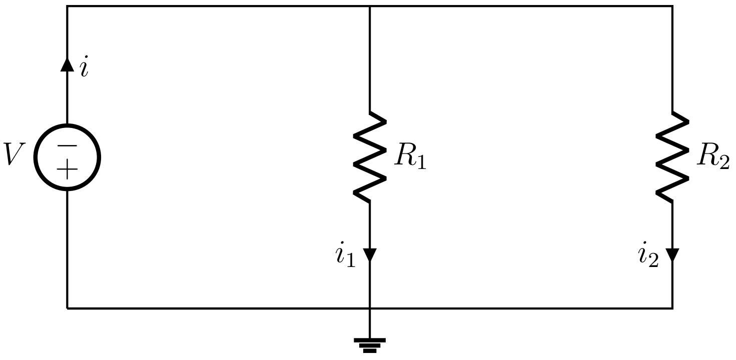
and the voltage:

$$U_A=\frac{R_2}{R_1+R_2}U \tag{10.4.105}$$

The current is given obviously by $I=\frac{U}{R_1+R_2}$ and the voltage at A is given by:

$$U_A=U-IR_1=U\left(1-\frac{R_1}{R_1+R_2}\right)=\frac{R_2}{R_1+R_2}U \tag{10.4.106}$$

For a parallel circuit, the effective resistance is the harmonic sum as proven earlier:



In this circuit, we have therefore:

$$R_{\text{eq}}=\left(\frac{1}{R_1}+\frac{1}{R_2}\right)^{-1}=\frac{R_1R_2}{R_1+R_2} \tag{10.4.107}$$

and the current in the branches is given by:

$$I_1=\frac{R_2}{R_1+R_2}I \tag{10.4.108}$$

Indeed, as the voltage drop across R_1 and R_2 must be the same, we have:

$$I_1R_1=I_2R_2 \tag{10.4.109}$$

We also have $I_2=I-I_1$, which gives:

$$I_1R_1=(I-I_1)R_2 \Longrightarrow I_1=\frac{R_2}{R_1+R_2}I \tag{10.4.110}$$

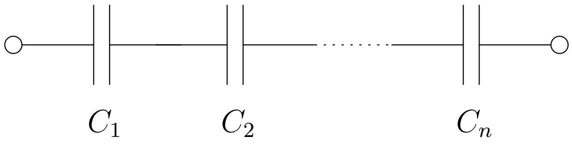
10.4.3.4 Equivalent Capacities

Even if this has nothing to do with the Ohm's law we can apply the previous reasoning to capacitor.

Let us recall that we defined in the section Electrostatics, the capacity given by:

$$C=\frac{Q}{U} \tag{10.4.111}$$

Let us consider, as well as resistors, n capacitors of capacity C_i in series set behind each other:



We put at potential U_0 and U_n the two extremities of the chain and we bring the charge Q on the whole system. The potential (voltage) across the total capacitor chain is then written simply:

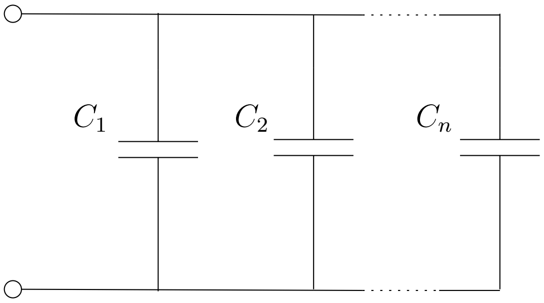
$$U=U_0-U_n=(U_0-U_1)+(U_1-U_2)+\ldots+(U_{n-1}-U_n)=\frac{Q_1}{C_1}+\frac{Q_2}{C_2}+\ldots+\frac{Q_n}{C_n}=Q\sum_{i=1}^{n}\frac{1}{C_i} \tag{10.4.112}$$

and therefore corresponds to that of a single capacitor C_e that is the "equivalent capacitance of capacitors in series":

$$\boxed{\frac{1}{C_{\text{eq}}}=\sum_{i=1}^{n}\frac{1}{C_i}\Leftrightarrow C_e=\frac{1}{\displaystyle\sum_{i=1}^{n}\frac{1}{C_i}}} \tag{10.4.113}$$

where we also find here a harmonic mean.

Now let us consider n capacitor of capacity C_i in parallel with the same potential U:



The electric charge of each is then imposed (by the mesh law) by the relation:

$$Q_i=C_iU \tag{10.4.114}$$

The total electrical load is simply:

$$Q=\sum_{i=1}^{n}Q_i=U\sum_{i=1}^{n}C_i \tag{10.4.115}$$

which corresponds to an "equivalent capacitance of capacitors in parallel":

$$\boxed{C_{\text{eq}}=\sum_{i=1}^{n}C_i} \tag{10.4.116}$$

which is the arithmetic sum of the individual capacities.

Finally to close this subject, let us recall that we have proved in the section of Electrostatics that:

$$i=C\frac{\mathrm{d}u}{\mathrm{d}t} \tag{10.4.117}$$

In the case where a capacity is alone in series with an AC sine generator (fairly typical case in the industrial world of the 119th and 120th century), then we have:

$$i=C\frac{\mathrm{d}}{\mathrm{d}t}U_0\sin(\omega t)=\omega CU_0\cos(\omega t)=\omega CU_0\sin\left(\omega t+\frac{\pi}{2}\right) \tag{10.4.118}$$

And therefore we get:

$$I_0=\omega CU_0 \tag{10.4.119}$$

That we will write in analogy with Ohm's law in the form:

$$U_0 = \frac{1}{\omega C} I_0 = X_C I_0 \tag{10.4.120}$$

hence:

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi f C} \tag{10.4.121}$$

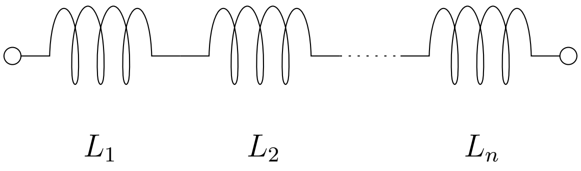
is named the "capacitive reactance". We notice that in the continuous case where the pulsation is zero, the capacitive reactance becomes infinite and that we find the known situation where the capacity does not pass current (at least in the ideal case ...).

Therefore, a capacitor connected to a circuit that changes over a given range of frequencies can be said to be "Frequency dependent".

10.4.3.5 Equivalent Inductance

Even if this has nothing to do with the Ohm's law we can apply the previous reasoning to inductance (see page 4261).

Let us consider the following circuit:



Since it is a series circuit, the flowing current will be the same through all inductors, while each of them may have different voltages across them.

The current in the circuit is:

$$i = i_1 = i_2 = i_3 = i_n \tag{10.4.122}$$

Using Kirchhoff's Voltage Law, the total voltage is:

$$u = u_1 + u_2 + u_3 + \ldots + u_n \tag{10.4.123}$$

Substituting:

$$u_i = L_i \frac{\mathrm{d}i}{\mathrm{d}t} \tag{10.4.124}$$

Results in:

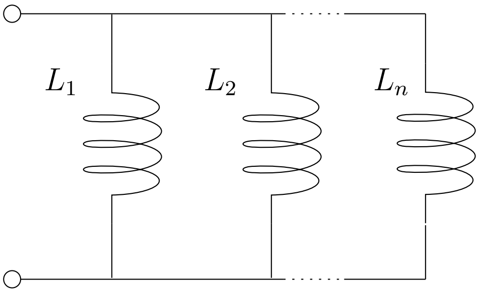
$$\begin{aligned} u &= L_1 \frac{\mathrm{d}i}{\mathrm{d}t} + L_2 \frac{\mathrm{d}i}{\mathrm{d}t} + L_3 \frac{\mathrm{d}i}{\mathrm{d}t} + \ldots + L_n \frac{\mathrm{d}i}{\mathrm{d}t} \\ &= (L_1 + L_2 + L_3 + \ldots + L_n) \frac{\mathrm{d}i}{\mathrm{d}t} \\ &= \left(\sum_{i=1}^{n} L_i \right) = L_{\text{eq}} \frac{\mathrm{d}i}{\mathrm{d}t} \end{aligned} \tag{10.4.125}$$

Therefore we have the "equivalent inductance of inductors in series":

$$\boxed{L_{\text{eq}}=\sum_{i=1}^{n}L_i} \tag{10.4.126}$$

In conclusion, the equivalent inductance of n inductors in series is (approximately because of heat dissipation) the sum of all the individual inductances.

For the parallel case, consider the circuit below consisting again of n inductors:



Since it is a parallel circuit, the voltage will be the same across all inductors, while each of them may have different current through them.

The voltage across the inductors are:

$$u=u_1=u_2=u_3=u_n \tag{10.4.127}$$

The total current in the circuit is:

$$i=i_1+i_2+i_3+\ldots+i_n \tag{10.4.128}$$

Substituting:

$$i_i=\frac{1}{L_i}\int_{t_0}^{t}v\mathrm{d}t+i_i\left(t_0\right) \tag{10.4.129}$$

Results in:

$$\begin{aligned}i&=\frac{1}{L_1}\int_{t_0}^{t}v\mathrm{d}t+i_1\left(t_0\right)+\frac{1}{L_2}\int_{t_0}^{t}v\mathrm{d}t+i_2\left(t_0\right)+\ldots+\frac{1}{L_n}\int_{t_0}^{t}v\mathrm{d}t+i_n\left(t_0\right)\\&=\left(\frac{1}{L_1}+\frac{1}{L_2}+\ldots+\frac{1}{L_n}\right)\int_{t_0}^{t}v\mathrm{d}t+i_1\left(t_0\right)+i_2\left(t_0\right)+\ldots+i_n\left(t_0\right)\\&=\sum_{i=1}^{n}\frac{1}{L_i}\int_{t_0}^{t}v\mathrm{d}t+\sum_{i=1}^{n}i_i(t_0)\\&=\frac{1}{L_{\text{eq}}}\int_{t_0}^{t}v\mathrm{d}t+i\left(t_0\right)\end{aligned} \tag{10.4.130}$$

Hence, the "equivalent inductance of inductors in parallel":

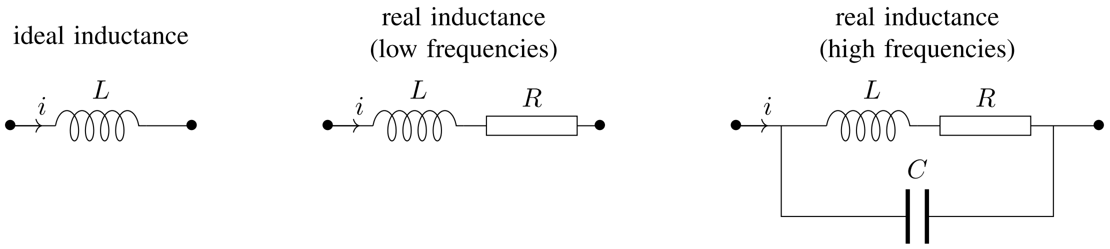
$$\boxed{\frac{1}{L_{\text{eq}}}=\sum_{i=1}^{n}\frac{1}{L_i}\Leftrightarrow L_{\text{eq}}=\frac{1}{\sum_{i=1}^{n}\frac{1}{L_i}}} \tag{10.4.131}$$

In conclusion, the equivalent inductance of n inductors in parallel is the reciprocal of the sum of all the individual inductances.

The total inductance of parallel inductors is always smaller than the smallest individual inductance in the calculation.

From the inductance formula in series and parallel above, we can conclude that the way we find equivalent inductance is the same as when we find equivalent resistance.

To finish on that topic, the reader must however keep in mind that as always... reality is a little bit more complex than idealized mathematical models. Relatively to inductances we can consider the following three cases:



ideal inductance
i
L
real inductance
(low frequencies)
i
L
R
real inductance
(high frequencies)
i
L
R
C

Figure 10.95: Different inductance models (author: Jimmy Roussel)

10.4.4 Electromotive Force

Given AB a portion of an electric circuit travelled by a constant current I from A to B. The existence of this current implies that the potential on A is greater (different) in absolute value than in B (in absolute value). This potential difference is reflected in the existence of the electrostatic field $\vec{E}$ producing a Coulomb force:

$$\vec{F}=q\vec{E} \tag{10.4.132}$$

capable of accelerating a charge q.

Then, given:

$$P_q=Fv \tag{10.4.133}$$

the power required to give a speed v to a any particle of charge q. Knowing that this in the conductor there is ρ_q electric charge per unit volume, the total power P in the circuit AB travelled by a current I is:

$$\begin{aligned}P&=\int\limits_V n_qP_q\mathrm{d}V=\int\limits_A^B\mathrm{d}l\int\limits_S n_qP_q\mathrm{d}S=\int\limits_A^B\mathrm{d}l\int\limits_S n_qFv\mathrm{d}S=\int\limits_A^B\mathrm{d}l\int_S(n_qqEv)\mathrm{d}S\\&=\int\limits_A^B(\rho_qv\mathrm{d}S)E\mathrm{d}l=\int\limits_S J\mathrm{d}S\int\limits_A^B E\mathrm{d}l=I\int\limits_A^B E\mathrm{d}l=I(U_A-U_B)=I\Delta U:=IU\end{aligned} \tag{10.4.134}$$

That is to say:

$$\boxed{P=UI} \tag{10.4.135}$$

where:

$$U=U_A-U_B>0 \tag{10.4.136}$$

This power is therefore the "electric power" available between A and B, simply because there flows a current I.

If we consider in this electric circuit $\overline{AB}$ a resistive for which we measure a potential difference:

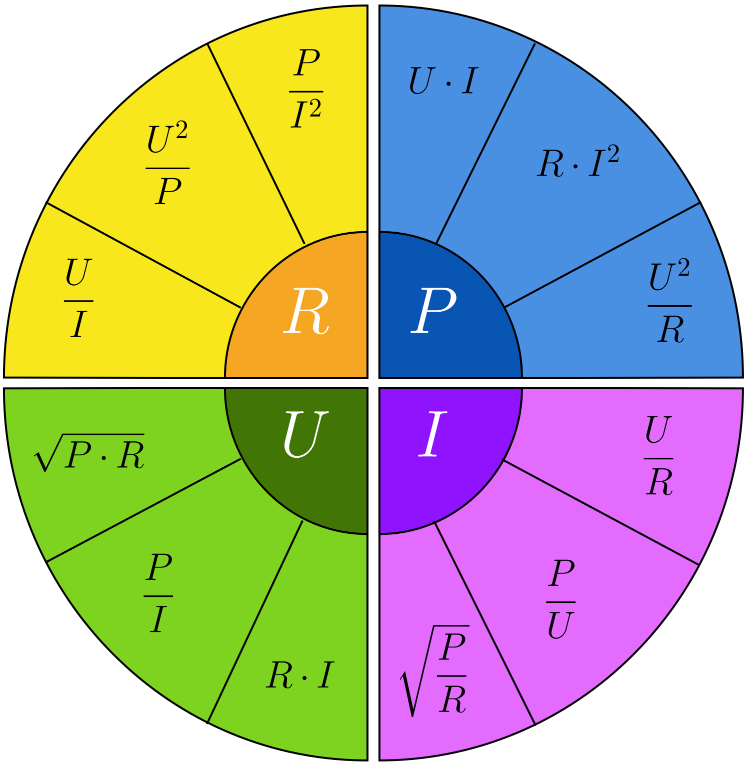
$$U=RI \tag{10.4.137}$$

then the power available inside thereof is given by the "Joule power":

$$\boxed{P_J=RI^2} \tag{10.4.138}$$

Thus, among this available power, a certain part is dissipated as heat (Joule effect) in a passive dipole such as a resistance. Obviously it is this power that charge (invoice) us our electricity provider and to know the corresponding energy consumed, we simply multiply the power of the device which is used by the functioning duration.

Now that we have the latter relation we can finally introduce the famous Ohm Circle that related the most important DC relations:



However..., something is wrong in our previous developments if we look more closely. Indeed, if we apply the reasoning in a closed circuit, that is to say, if we look at the total power supplied between A and A by the Coulomb force, we get (obviously because the Coulomb electrostatic field is conservative):

$$P=I\int_A^A E\mathrm{d}l=I(U_A-U_A)=I\cdot 0=0 \qquad (10.4.139)$$

that is to say null power ?! Eh yes! This means they can not be a steady state current in a closed loop and when there is a current, then this implies that the Coulomb force is not responsible for the global movement of charge carriers in a conductor!!

This is exactly what happens in an electric circuit. If we want that a permanent current flows, there must be a force other than the electrostatic force that enables the electric charges to close the path (this is a purely mathematical reasoning)! It is for this reason that we must involve an "artificial" external energy source such as an "electrical generator" which is then equivalent to the hydraulic pump for water.

The generator involve then as physical property that only when its circuit is open (the current I then being equal to zero) a "potential difference" is maintained between its terminals necessarily involving the presence of another force compensating the Coulomb attraction of the conductor. Thus, the total force acting on an electric charge q is written thus:

$$\vec{F}=q(\vec{E}_S+\vec{E}_M) \qquad (10.4.140)$$

with being $\vec{E}_S$ the electrostatic field and $\vec{E}_M$ the "electromotive field". In equilibrium and in the absence of current, we must have:

$$\vec{E}_S+\vec{E}_M=\vec{0} \qquad (10.4.141)$$

This means that the difference of potential across an open generator is then:

$$\vec{E}_S+\vec{E}_M=\vec{0}\Leftrightarrow\vec{E}_S=-\vec{E}_M\Leftrightarrow\int_A^B\vec{E}_S\circ\mathrm{d}\vec{l}=-\int_A^B\vec{E}_M\circ\mathrm{d}\vec{l}=U_A-U_B \quad (10.4.142)$$

We name and denote by:

$$e=\int_A^B\vec{E}_M\circ\mathrm{d}\vec{l}=U_B-U_A>0 \quad (10.4.143)$$

(somewhat abusively) the proper "electromotive force EMF" of the generator.

Since, inside the generator, we have:

$$\vec{E}_S=-\vec{E}_M\neq\vec{0} \quad (10.4.144)$$

at open circuit, this means that a generator is a non-conductive equipotential (or with "non-conservative field").

At equilibrium, but in the presence of a current I (generator set in a closed circuit), the charge carriers responsible for the current undergo additional force due to collisions occurring inside the conductor. For an ideal generator, these collisions are negligible and we get:

$$U_A-U_B=-e \quad (10.4.145)$$

However, for a non-ideal generator, such collisions occur and result in the existence of an internal resistance r (very small for generators that just go out of the factory!). Thus, the true electromotive force is given by:

$$\boxed{(U_A-U_B)+e=rI\Rightarrow U_A-U_B=rI-e} \quad (10.4.146)$$

The internal resistance of the generator introduces a voltage drop proportional to the current supplied, so it outputs a potential lower than that given by it electromotive force.

The latter relation is sometimes noted as follows:

$$U_B-U_A=e-rI \quad (10.4.147)$$

and often with the following writing:

$$U=\mathcal{E}-rI \quad (10.4.148)$$

What is measured with a voltmeter is however the generator electromotive force (GEF) since the generators have an internal resistance admit as infinite and therefore involve a current I almost equal to zero:

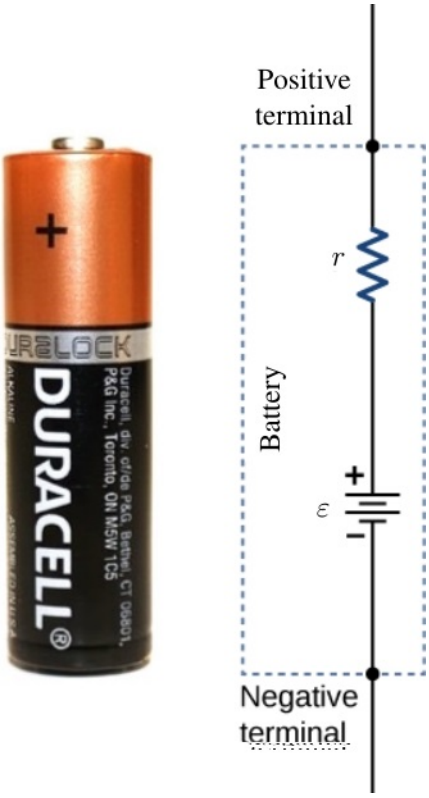


Figure 10.96: **Electromotive force schematic concept (source: OpenStax)**

Generators vary depending on the energy source used and the method of conversion of the latter into electrical energy (i.e., the nature of $\vec{E}_m$). We can then produce electrical energy from a battery (chemical energy), an electrostatic generator (mechanical energy), a dynamo (mechanical energy) a solar cell (radiation energy) or thermocouple (heat energy).

The total power P to be provided in steady state is therefore:

$$\begin{aligned}P&=\int_V n_q P_q \mathrm{d}V=\oint_{\text{circuit}}\mathrm{d}l\int_S n_q P_q \mathrm{d}S=\oint\mathrm{d}l\int_S n_q F v \mathrm{d}S=\oint_{\text{circuit}}\mathrm{d}l\int_S (n_q q v \mathrm{d}S)\frac{F}{q}\\&=\oint_{\text{circuit}}\frac{F\mathrm{d}l}{q}\int_S J\mathrm{d}S=I\oint_{\text{circuit}}\frac{F\mathrm{d}l}{q}=Ie\end{aligned}\qquad(10.4.149)$$

where:

$$e=\oint_{\text{circuit}}\frac{F}{q}\mathrm{d}l=\oint_{\text{circuit}}E_M\mathrm{d}l\qquad(10.4.150)$$

is the total EMF of the circuit. The integral being on the whole circuit, the total EMF is the sum of the EMF present along the circuit (if any). If they are located in dipoles, the expression becomes:

$$e=\sum_k e_k\qquad(10.4.151)$$

where the e_k are the algebraic values of the different EMF:

- $e_k > 0$ corresponds to "generators" devices (production of electrical energy)
- $e_k < 0$ corresponds to "receptors" devices (consumption of electrical energy)

We also have for the electric power:

$$P = Ie = \frac{e}{R+r}e = \frac{e^2}{R+r} \tag{10.4.152}$$

and for the Joule (resistive) Power:

$$P_J = RI^2 = R\left(\frac{e}{R+r}\right)^2 \tag{10.4.153}$$

A motor converts electrical energy into mechanical energy and therefore corresponds to a EMF receptor, we also say that it has a "counter-electromotive force" or CEMF.

10.4.4.1 Faraday's law of induction

Now that we have proved the necessity of the electromotive force, we will be able to prove the origin of the "Faraday's law" and also of the "Lenz's law" that we had used in the section of Electrodynamics to prove the third Maxwell equation.

The Determination of Faraday's law will also allow us to define the concept of inductance and study its properties.

Let us do the same approach as did Faraday and ask ourselves the following question: How do we generate an electric current?

An electric current is a moving set of electric charges in a conductive material. These electric charges are moved thanks to a difference of potential that is maintained by an electromotive force. Thus, a battery by converting the chemical energy during a time $\mathrm{d}t$ provides a power P modifying the kinetic energy of the $\mathrm{d}Q$ charge carriers producing then an electric current I.

Given P_q the power required to communicate a speed $\vec{v}$ to an electric charge particle q. Knowing that in a conductor, there is n charge carriers per unit volume, the total power P_q to be provided by the (ideal) generator is then (see above):

$$P=Ie \tag{10.4.154}$$

We therefore put that the ideal electromotive force of a circuit is:

$$e=\frac{P}{I}=\oint\limits_{\text{circuit}}\frac{F\mathrm{d}l}{q}=\oint\limits_{\text{circuit}}\frac{\vec{F}\circ\mathrm{d}\vec{l}}{q} \tag{10.4.155}$$

However, the Coulomb force is unable to produce an electromotive force as we have proved earlier. To generate a direct (continuous) electric current in a closed circuit, we therefore need an electromotive field which circulation along the circuit is not zero. The Faraday's experiment thus shows that it is the existence of the magnetic field that allows the creation of a current (!!!!). This means that the Lorentz force must be responsible for the creation of an electromotive force, that is to say:

$$e=\oint\limits_{\text{circuit}}\frac{q\left(\vec{E}+\vec{v}\times\vec{B}\circ\mathrm{d}\vec{l}\right)}{q}=\oint\limits_{\text{circuit}}\left(\vec{E}+\vec{v}\times\vec{B}\circ\mathrm{d}l\right)\circ\mathrm{d}\vec{l} \tag{10.4.156}$$

Therefore:

$$e=\oint\limits_{\text{circuit}}\left(\vec{E}+\vec{v}\times\vec{B}\circ\mathrm{d}l\right)\circ\mathrm{d}\vec{l}=\oint\limits_{\text{circuit}}\vec{E}\circ\mathrm{d}\vec{l}+\oint\limits_{\text{circuit}}(\vec{v}\times\vec{B})\circ\mathrm{d}\vec{l}=0+\oint\limits_{\text{circuit}}(\vec{v}\times\vec{B})\circ\mathrm{d}\vec{l} \tag{10.4.157}$$

The properties of the vector cross product (see section Vector Calculus 1830) giving us:

$$(\vec{x}\times\vec{y})\circ\vec{z}=-(\vec{x}\times\vec{z})\circ\vec{y} \tag{10.4.158}$$

We can then write:

$$e=\oint\limits_{\text{circuit}}\left(\vec{v}\times\vec{B}\right)\circ\mathrm{d}\vec{l}=-\oint\limits_{\text{circuit}}\left(\vec{v}\times\mathrm{d}\vec{l}\right)\circ\vec{B}=-\frac{\mathrm{d}t}{\mathrm{d}t}\oint\limits_{\text{circuit}}\left(\vec{v}\times\mathrm{d}\vec{l}\right)\circ\vec{B}=-\frac{1}{\mathrm{d}t}\oint\limits_{\text{circuit}}\left(\vec{v}\mathrm{d}t\times\mathrm{d}\vec{l}\right)\circ\vec{B} \tag{10.4.159}$$

A small remark is essential at this level. If $\vec{v}$ is the velocity vector of the charges q it cannot be the one which is collinear with $\mathrm{d}\vec{l}$ because otherwise we would have:

$$\vec{v}\mathrm{d}t\times\mathrm{d}\vec{l}=\vec{0} \tag{10.4.160}$$

and therefore e would be zero and this is not possible because it would contradict all the developments made so far! In fact, $\vec{v}$ is the speed of the whole circuit which brings with it all the charges at the same speed!

Thus, during a time $\mathrm{d}t$, the circuit moves by a distance:

$$\mathrm{d}\vec{r}=\vec{v}\mathrm{d}t \tag{10.4.161}$$

vector that is perpendicular to $\mathrm{d}\vec{l}$. Since then:

$$\mathrm{d}\vec{r}\times\mathrm{d}\vec{l} \tag{10.4.162}$$

is the surface (see the properties of the cross product in the section of Vector Calculus) described by the displacement of the element $\mathrm{d}\vec{l}$ on the distance $\mathrm{d}\vec{r}$ such that:

$$\mathrm{d}\vec{r}\times\mathrm{d}\vec{l}=\mathrm{d}^2\vec{S} \tag{10.4.163}$$

We then have:

$$e=-\frac{1}{\mathrm{d}t}\oint\limits_{\text{circuit}}\left(\vec{v}\mathrm{d}t\times\mathrm{d}\vec{l}\right)\circ\vec{B}=-\frac{1}{\mathrm{d}t}\oint\limits_{\text{circuit}}\vec{B}\circ\mathrm{d}^2\vec{S} \tag{10.4.164}$$

We recognize here the expression of the flux (named sometimes "cutted flux") through the elementary surface $\mathrm{d}^2\vec{S}$. Which brings us to write (there is a little bit of intuition - common sense - with the manipulation of differentials but hey that's also physics ...):

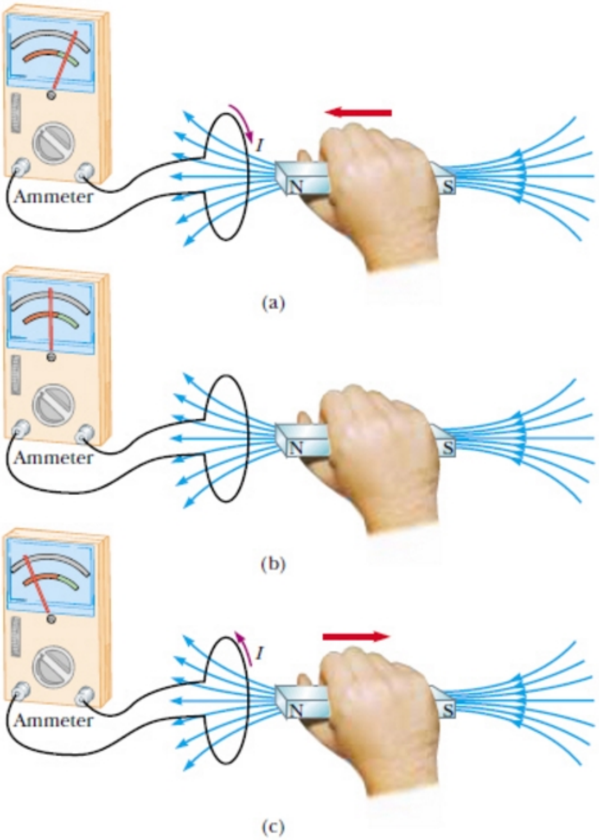
$$e=-\frac{1}{\mathrm{d}t}\oint\limits_{\text{circuit}}\vec{B}\circ\mathrm{d}^2\vec{S}=-\frac{1}{\mathrm{d}t}\oint\limits_{\text{circuit}}\mathrm{d}^2\Phi_c=-\frac{1}{\mathrm{d}t}\mathrm{d}\oint\limits_{\text{circuit}}\mathrm{d}\Phi_c=-\frac{\mathrm{d}\Phi_B}{\mathrm{d}t} \tag{10.4.165}$$

We have just proved the "Faraday's law of induction" in the case of a rigid circuit immersed in a variable magnetic field. We have seen the expression of the cut flux appears naturally. In fact, the only thing that matters is the existence of movement of the overall or a part of the circuit (review the proof to be convinced). Thus, the expression of the induced EMF:

$$\boxed{e=-\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}} \tag{10.4.166}$$

remains valid for a circuit deformed and / or displaced in a static magnetic field. This proof was made from the Lorentz force and is therefore a priori independent of the chosen reference system!

Phenomenologically this can be summarized into the following figure:



(a) When a magnet is moved toward a loop of wire connected to a sensitive ammeter, the ammeter deflects as shown, indicating that a current is induced in the loop.

(b) When the magnet is held stationary, there is no induced current in the loop, even when the magnet is inside the loop

(c) When the magnet is moved away from the loop, the ammeter deflects in the opposite direction, indicating that the induced current is opposite that shown in part (a). Changing the direction of the magnet's motion changes the direction of the current induced by that motion.

10.4.4.1.1 Lenz's law

The statement of "Lenz's law" is as follows: Induction produces effects which oppose the causes which gave rise to it.

This law is, like the rule of maximum flux, already contained in the equations and brings nothing more, except an intuition of the physical phenomena. In this case, Lenz's law is only the expression of the sign "$-$" contained in Faraday's law.

✍**Example:**

If we approach a circuit of the north pole of a magnet, the flux increases and therefore the induced EMF is negative. The induced current will then be negative and will itself produce an induced magnetic field opposite to that of the magnet. Two consequences:

- The increase in flux through the circuit is lessened.
- A negative Laplace force appears (see section Magnetostatics page 4063) $\vec{F}=I\mathrm{d}\vec{l}\times\vec{B}$, opposing to the approach of the magnet.

This sign "$-$" in Faraday's law (Lenz's law) describes the fact that under normal conditions, there is no possible runaway (example: current only increasing).

This is the reason why the Lenz's law is often named the "Lenz-Faraday law".

10.4.4.2 Inductance

So we have:

$$\Phi_B=\int\vec{B}\circ\mathrm{d}\vec{S} \tag{10.4.167}$$

But the Biot-Savart's law gives us (see section Magnetostatics page 4023):

$$\mathrm{d}\vec{B}=\frac{\mu_0}{4\pi}\frac{\mathrm{d}\vec{l}\times\vec{r}}{r^3}\Leftrightarrow\oint\limits_{\Gamma}\mathrm{d}\vec{B}=\frac{\mu_0}{4\pi}I\oint\limits_{\Gamma}\frac{\mathrm{d}\vec{l}\times\vec{r}}{r^3}=\vec{B} \tag{10.4.168}$$

Therefore:

$$\Phi_B=\int_S\left(\frac{\mu_0}{4\pi}I\oint\limits_{\Gamma}\frac{\mathrm{d}\vec{l}\times\vec{r}}{r^3}\right)\circ\mathrm{d}\vec{S}=I\left[\frac{\mu_0}{4\pi}\int_S\left(\oint\limits_{\Gamma}\frac{\mathrm{d}\vec{l}\times\vec{r}}{r^3}\right)\circ\mathrm{d}\vec{S}\right] \tag{10.4.169}$$

which we historically write in condensed form as follows:

$$\boxed{\Phi_B=I\cdot L} \tag{10.4.170}$$

where:

$$L=\frac{\mu_0}{4\pi}\int_S\left(\oint\limits_{\Gamma}\frac{\mathrm{d}\vec{l}\times\vec{r}}{r^3}\right)\circ\mathrm{d}\vec{S} \tag{10.4.171}$$

is named the "self-induction coefficient" or "self-inductance", or simply "self" or commonly "inductance", expressed in "Henry" [H]. It only depends on the geometric properties of the circuit and is necessarily positive.

Explicitly this unit can be written in various forms but the most common one are:

$$\mathrm{H}=\frac{\mathrm{kg}\cdot\mathrm{m}^2}{\mathrm{s}^2\cdot\mathrm{A}^2}=\frac{\mathrm{kg}\cdot\mathrm{m}^2}{\mathrm{C}^2}=\frac{\mathrm{J}}{\mathrm{A}^2}=\frac{\mathrm{T}\cdot\mathrm{m}^2}{\mathrm{A}}=\frac{\mathrm{V}\cdot\mathrm{s}}{\mathrm{A}} \tag{10.4.172}$$

With the laws that we have stated so far, we are able to study some variable regimes (also named "transcient regimes"). Indeed, all reasoning based on the notion of a field (electric or magnetic) constant over time can easily be applied to variable physical systems (time-dependent fields), provided that this variability takes place on long times scales compared to the characteristic adjustment time of the field in the corresponding materials.

Here is a concrete case:

Most laws of magnetostatics assume a permanent current, that is, the same throughout the circuit. When we close a switch, an electromagnetic signal propagates throughout the circuit and this is how a permanent current can be established: it takes a time of the order of l/c where l is the length of the circuit and c the speed of light. If we now have a sinusoidal voltage generator with period T (this is just an example ... taken randomly ...), then we can still use the relations deduced from magnetostatic if:

$$T\gg l/c \tag{10.4.173}$$

Thus, although the current is variable, the creation of a magnetic field will obey the Biot-Savart law as long as the above criterion remains satisfied. This type of variable regime is named "quasi static regime" in the sense that it is transient.

So, since we have:

$$e=-\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}\quad\text{and}\quad\Phi_B=LI \tag{10.4.174}$$

we then have if and only if the current is variable in the circuit:

$$\boxed{e=-\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}=-L\frac{\mathrm{d}i}{\mathrm{d}t}} \tag{10.4.175}$$

L being constant for a rigid circuit. The self therefore generates an electromotive force opposite to that generated by the current at its terminals. This electromotive force therefore has an opposite direction to that of the electric generator.

In the case where an inductor is alone in series with a sinusoidal alternating current generator (fairly typical case in the industrial world of the 119th and 120th century), then the conservation of the field will give:

$$u+e=0 \tag{10.4.176}$$

And therefore explicitly in the typical case of a sine regime:

$$U_0\sin(\omega t)-L\frac{\mathrm{d}i}{\mathrm{d}t}=0 \tag{10.4.177}$$

And therefore:

$$\mathrm{d}i=\frac{U_0}{L}\sin(\omega t)\mathrm{d}t \tag{10.4.178}$$

To get the current, we integrate:

$$i(t)=\frac{U_0}{L}\int\sin(\omega t)=-\frac{U_0}{\omega L}\sin\left(\omega t-\frac{\pi}{2}\right) \tag{10.4.179}$$

So in this special case, the current is behind the voltage (or the voltage is ahead of the current) by a quarter of a period. It is also customary to write:

$$I_0=\frac{U_0}{\omega L} \tag{10.4.180}$$

Therefore:

$$U_0=\omega L I_0=X_L I_0 \tag{10.4.181}$$

where by analogy with pure resistance, the expression:

$$X_L=\omega L \tag{10.4.182}$$

is named "inductive reactance".

Remark

We see well in the relation obtained above that in stationary regime, if the current is constant, then the electromotive force is zero and the self then behaves like a simple equipotential!

We must now give an important and simple example of Lenz's law at the same time by applying it to the calculation of the inductance of a solenoid of radius r (the inductance of a toric solenoid with circular section having already been treated in the section of Magnetostatics). We proved in the section of Magnetostatics that the magnetic field in a solenoid was given by:

$$B=\mu\frac{IN}{\ell} \tag{10.4.183}$$

where as a reminder N is the number of turns and l is the length of the solenoid. We saw above that Faraday's law of induction was given by:

$$e=-\frac{1}{\mathrm{d}t}\mathrm{d}\oint\limits_{\text{circuit}}\mathrm{d}\Phi_c=-\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}=-L\frac{\mathrm{d}i}{\mathrm{d}t} \tag{10.4.184}$$

and in the case of a turn we will travel N times the path of the integral. It then comes:

$$e=-N\frac{\mathrm{d}\Phi}{\mathrm{d}t}=-L\frac{\mathrm{d}i}{\mathrm{d}t} \tag{10.4.185}$$

We saw above that the flux of the magnetic field was given by (if the field is perpendicular to the crossed surface):

$$\Phi=B\cdot S \tag{10.4.186}$$

Therefore:

$$\Phi=B\cdot S=\left(\mu\frac{IN}{\ell}\right)S=\frac{\mu SN}{\ell}I \tag{10.4.187}$$

Remark

Caution!! The flux in a solenoid is not equal to the flux in a turn multiplied by the number of turns of the solenoid!

The rate of change of the magnetic flux is found by derivation, that is:

$$N\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}=N\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\mu SN}{\ell}I\right)=\frac{\mu SN^2}{I}\frac{\mathrm{d}I(t)}{\mathrm{d}t}=\frac{\mu SN^2}{\ell}\frac{\mathrm{d}i}{\mathrm{d}t} \tag{10.4.188}$$

Or in the case of circular turns:

$$N\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}=\frac{\mu SN^2}{l}\frac{\mathrm{d}i}{\mathrm{d}t}=\frac{\mu(2\pi R^2)N^2}{\ell}\frac{\mathrm{d}i}{\mathrm{d}t} \tag{10.4.189}$$

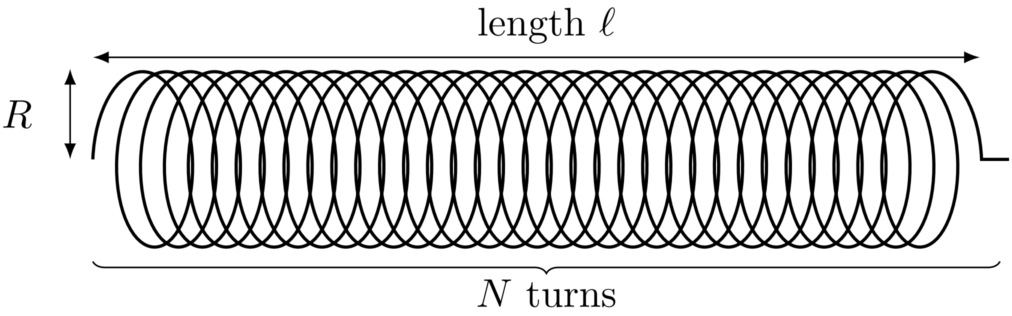


Figure 10.98: **Simple solenoid (author: Izaak Neutelings)**

The electromotive force generated is then:

$$e=-N\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}=-L\frac{\mathrm{d}i}{\mathrm{d}t}=-\left(\frac{\mu(\pi R^2)N^2}{\ell}\right)\frac{\mathrm{d}i}{\mathrm{d}t} \tag{10.4.190}$$

and therefore by correspondence in vacuum:

$$L=\frac{\mu(\pi r^2)N^2}{l}\cong 4\pi^2\cdot 10^{-7}\frac{N^2r^2}{l} \tag{10.4.191}$$

Now calculate the instantaneous power received by a coil. We have proved above that we still have in our case study and if we modelize the inductance as a non-ideal dipole:

$$p=\Delta u\cdot i=u\cdot i=(r\cdot i-e)i=r\cdot i^2-e\cdot i \tag{10.4.192}$$

where the lowercase letters indicate as always that we are in a non-constant regime:

$$p=r\cdot i^2-e\cdot i=r\cdot i^2-\left(-L\frac{\mathrm{d}i}{\mathrm{d}t}\right)i=r\cdot i^2+L\frac{\mathrm{d}i}{\mathrm{d}t}i=p_j+\frac{\mathrm{d}\left(\dfrac{1}{2}Li^2\right)}{\mathrm{d}t} \tag{10.4.193}$$

At the contrary to the development which we had made in the section of Electrostatics for the same calculation with regard to the capacitor, we have not neglected here the dissipation of energy by Joule effect. But the reader must be aware that in most cases this term is also neglected!

So by integration in a given time interval from 0 to t we have for the second term:

$$E_L=\frac{1}{2}Li^2 \tag{10.4.194}$$

This energy is therefore always positive and is stored in electrostatic form in the inductance.

Or explicitly in the case of a circular solenoid:

$$E_L=\frac{1}{2}Li^2\cong\frac{1}{2}\left(4\pi^2\cdot 10^{-7}\frac{N^2R^2}{\ell}\right)i^2 \tag{10.4.195}$$

And since for a Solenoid $B=\mu NI/\ell$, we have in vacuum:

$$E_L=\frac{1}{2}\left(\frac{\mu_0 N^2}{\ell}\pi R^2\right)\left(\frac{B\ell}{\mu_0 N}\right)^2=\frac{1}{2}\frac{1}{\mu_0}\left(\pi R^2\ell\right)B^2 \tag{10.4.196}$$

When i decreases, the coil restores this energy. So we cannot store energy in an isolated coil unlike a capacitor.

Under a sinusoidal regime, the average power will be zero. We can generalize this by admitting that a perfect inductance does not dissipate any power by the Joule effect.

Let us now determine the inductance of a coaxial structure (similarly as we did of the capacitance of such a cable at page 3997) as shown in the figure below:

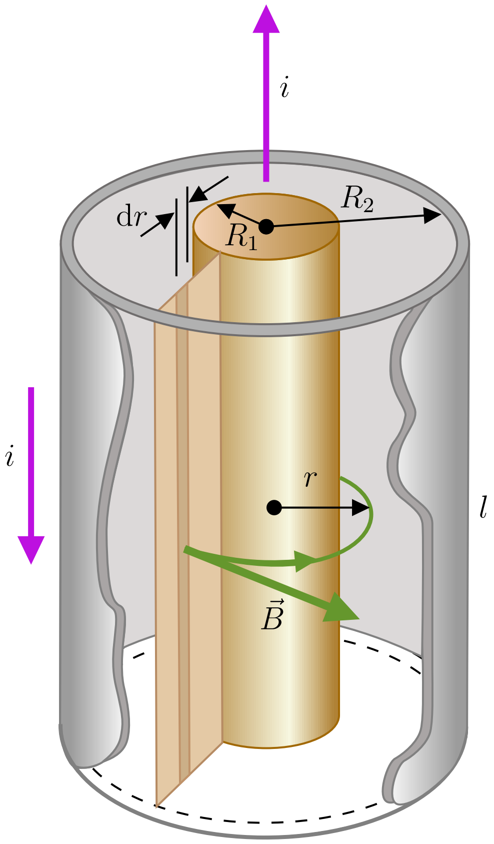

Figure 10.99: **Section of a long coaxial cable**

where the inner and outer conductors carry equal currents in opposite directions.

The inductance of this structure is of interest for a number of reasons – in particular, for determining the characteristic impedance of coaxial transmission line.

We must find the magnetic flux through the light gold rectangle in the figure above. Ampère's law tells us that the magnetic field in the region between the conductors is due to the inner conductor alone and that its magnitude is:

$$B=\frac{\mu i}{2\pi r} \tag{10.4.197}$$

where r is measured from the common center of the cylinders. A sample circular field line is shown in the figure above, along with a field vector tangent to the field line.

The magnetic field is perpendicular to the light gold rectangle of length l, and width R_2-R_1, the cross section of interest.

Because the magnetic field varies with radial position across this rectangle, we must use calculus to find the total magnetic flux.

Divide the light gold rectangle into strips of width $\mathrm{d}r$ such as the darker strip in the figure above. We evaluate the magnetic flux through such a strip:

$$\mathrm{d}\Phi=B\mathrm{d}S=Bl\mathrm{d}r \tag{10.4.198}$$

Substitute for the magnetic field and integrate over the entire light gold rectangle gives us:

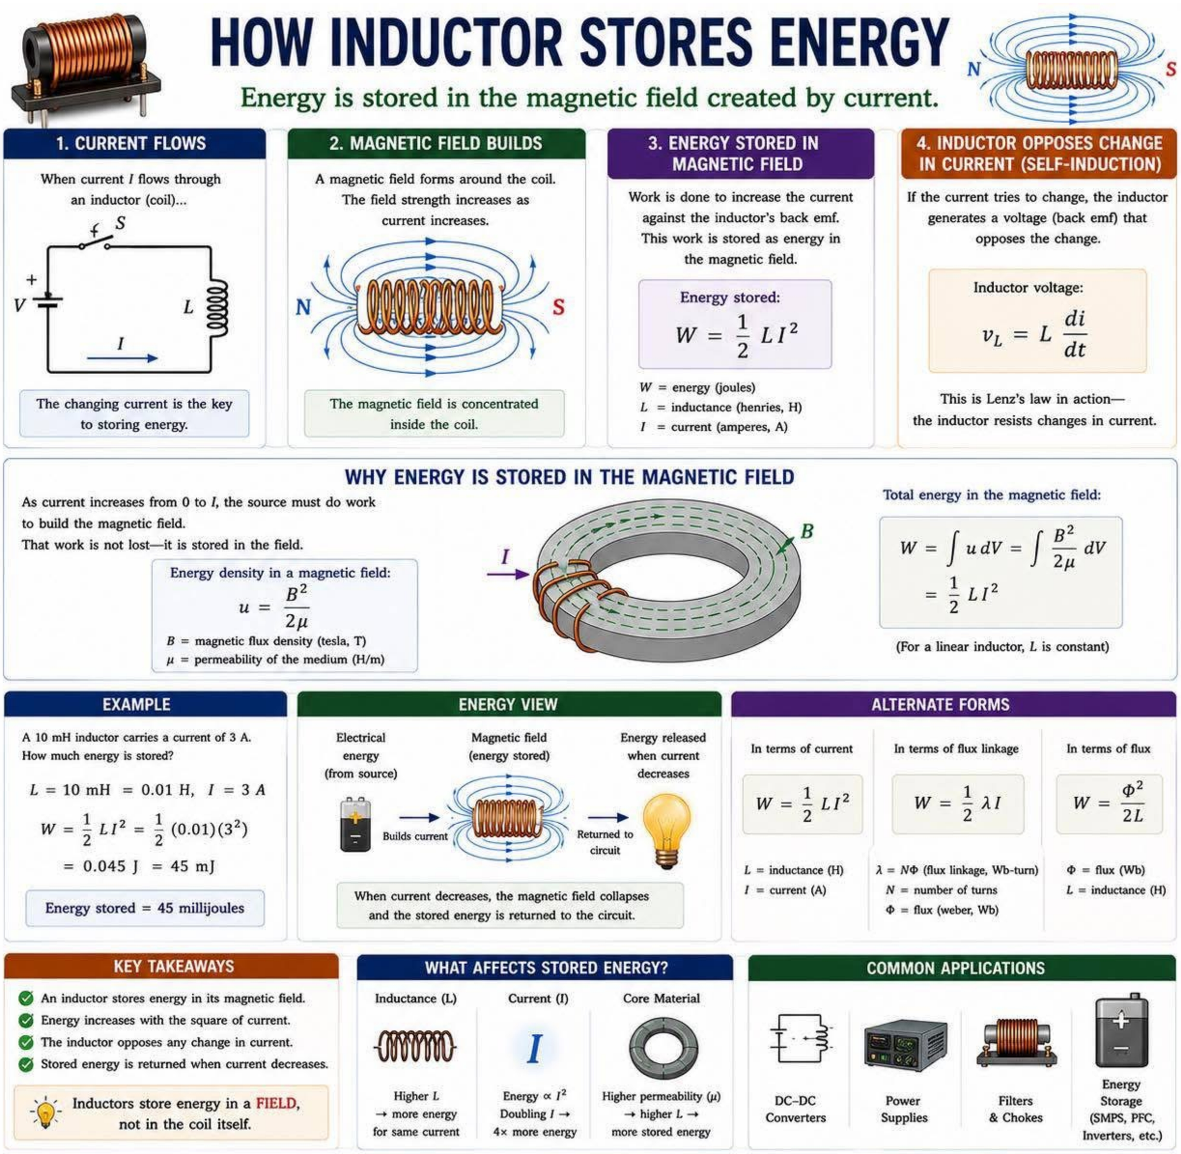
$$\Phi=\int\limits_{R_1}^{R_2}\frac{\mu i}{2\pi r}l\mathrm{d}r=\frac{\mu il}{2\pi r}\int\limits_{R_1}^{R_2}\frac{1}{r}\mathrm{d}r=\frac{\mu il}{2\pi r}\ln\left(\frac{R_2}{R_1}\right) \tag{10.4.199}$$

Using the definition of inductance we then get:

$$\boxed{L=\frac{\Phi_B}{i}=\frac{\mu l}{2\pi r}\ln\left(\frac{R_2}{R_1}\right)} \tag{10.4.200}$$

and therefore we can also define the "coaxial inductance per unit length":

$$L=\frac{\Phi_B}{I}=\frac{\mu}{2\pi r}\ln\left(\frac{R_2}{R_1}\right) \tag{10.4.201}$$



HOW INDUCTOR STORES ENERGY

Energy is stored in the magnetic field created by current.

1. CURRENT FLOWS

When current I flows through an inductor (coil)...

The changing current is the key to storing energy.

2. MAGNETIC FIELD BUILDS

A magnetic field forms around the coil. The field strength increases as current increases.

The magnetic field is concentrated inside the coil.

3. ENERGY STORED IN MAGNETIC FIELD

Work is done to increase the current against the inductor's back emf. This work is stored as energy in the magnetic field.

Energy stored:

$$W = \frac{1}{2} L I^2$$

W = energy (joules)
L = inductance (henries, H)
I = current (amperes, A)

4. INDUCTOR OPPOSES CHANGE IN CURRENT (SELF-INDUCTION)

If the current tries to change, the inductor generates a voltage (back emf) that opposes the change.

Inductor voltage:

$$v_L = L \frac{di}{dt}$$

This is Lenz's law in action—the inductor resists changes in current.

WHY ENERGY IS STORED IN THE MAGNETIC FIELD

As current increases from 0 to I, the source must do work to build the magnetic field.
That work is not lost—it is stored in the field.

Energy density in a magnetic field:

$$u = \frac{B^2}{2\mu}$$

B = magnetic flux density (tesla, T)
μ = permeability of the medium (H/m)

Total energy in the magnetic field:

$$W = \int u \, dV = \int \frac{B^2}{2\mu} \, dV = \frac{1}{2} L I^2$$

(For a linear inductor, L is constant)

EXAMPLE

A 10 mH inductor carries a current of 3 A. How much energy is stored?

$$L = 10 \text{ mH} = 0.01 \text{ H}, \quad I = 3 \ A$$

$$W = \frac{1}{2} L I^2 = \frac{1}{2} (0.01)(3^2)$$

$$= 0.045 \text{ J} = 45 \text{ mJ}$$

Energy stored = 45 millijoules

ENERGY VIEW

Electrical energy (from source) → Builds current → Magnetic field (energy stored) → Returned to circuit → Energy released when current decreases

When current decreases, the magnetic field collapses and the stored energy is returned to the circuit.

ALTERNATE FORMS

In terms of current	In terms of flux linkage	In terms of flux
$W = \frac{1}{2} L I^2$	$W = \frac{1}{2} \lambda I$	$W = \frac{\Phi^2}{2L}$
L = inductance (H) I = current (A)	$\lambda = N\Phi$ (flux linkage, Wb-turn) N = number of turns Φ = flux (weber, Wb)	Φ = flux (Wb) L = inductance (H)

KEY TAKEAWAYS

- ✓ An inductor stores energy in its magnetic field.
- ✓ Energy increases with the square of current.
- ✓ The inductor opposes any change in current.
- ✓ Stored energy is returned when current decreases.

Inductors store energy in a FIELD, not in the coil itself.

WHAT AFFECTS STORED ENERGY?

Inductance (L)	Current (I)	Core Material
Higher L → more energy for same current	Energy ∝ I^2 Doubling I → 4× more energy	Higher permeability (μ) → higher L → more stored energy

COMMON APPLICATIONS

- DC–DC Converters
- Power Supplies
- Filters & Chokes
- Energy Storage (SMPS, PFC, Inverters, etc.)

10.4.5 Electromagnetic Waves in Conductors

The study of electromagnetic waves in conductors is very important as it helps to understand and model some effects of current propagation in real life common conductors that are a priori not intuitive like:

1. The fact that the current and the propagation of an electric field along a standard conductor line are the two faces of a same coin
2. Understand why the current is concentrated mainly near the surface of the (standard) conductor and not at its center
3. The fact the amplitude of an incident electromagnetic wave entering in a standard conductor is quickly attenuated.
4. The very low phase and group velocity of an electromagnetic wave inside a standard conductor that carry the electrons of the current.

OK let's start with the maths!

10.4.5.1 Skin effect

The "skin effect" or "pellicular effect" (or, more rarely, "Kelvin effect") is an electromagnetic phenomenon which makes that at high frequency a current tends to circulate only at the surface of the conductors. This phenomenon of electromagnetic origin exists for all the conductors traversed by alternating currents. It causes the current density to decrease as one moves away from the periphery of the conductor. This results in an increase in the resistance of the conductor.

This effect can be used to lighten the weight of high frequency transmission lines by using tubular conductors, or even pipes, without (too much) current loss. It is also used in the electromagnetic shielding of the coaxial wires by surrounding them with a thin metal case which keeps the currents induced by the high ambient frequencies on the outside of the cable.

What we would now like to determine is the attenuation of the electric field (or an attenuation coefficient) in the material of a solid cylindrical conductive cable of conductivity σ and permeability ε:

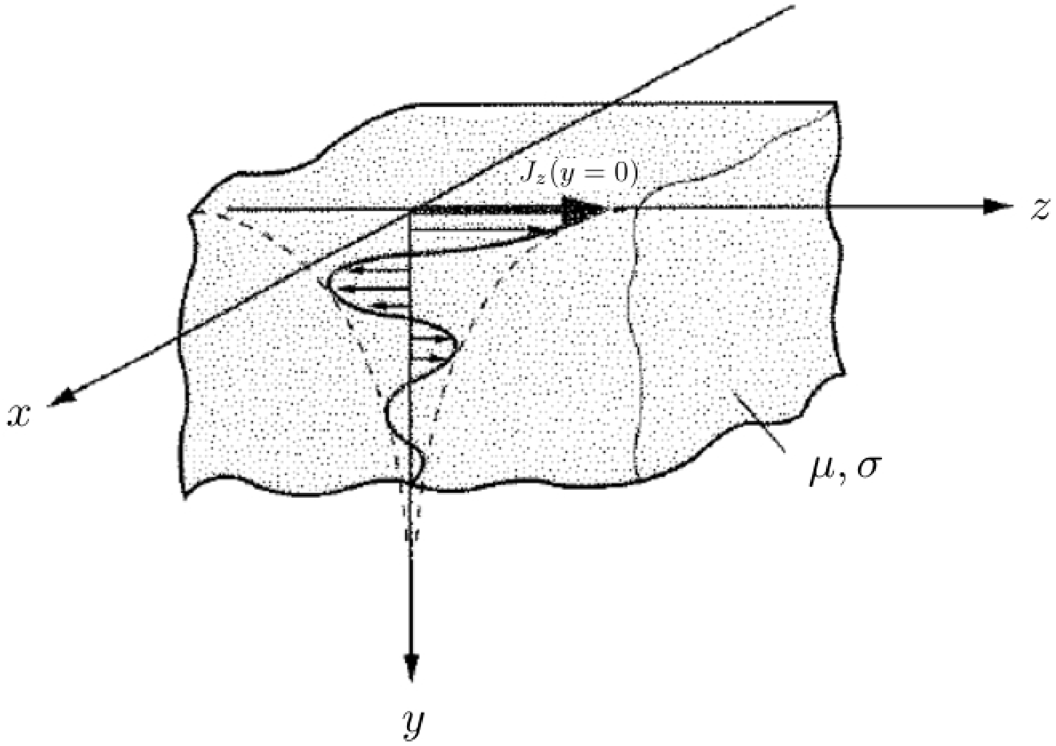


Figure 10.100: **Configuration study for skin effect (source: Introductory Electromagnetics, Z. and B.D. Popovic**

and assuming that the current density vector is parallel to the boundary surface, and that is has a single component, for example, $\vec{J} = J_z \vec{e}_z$, depending on the coordinate y (the distance from the interface) only. We wish to determine the distribution of current in the conducting half-space.

To do this, we take the fourth Maxwell's equation in the form given previously:

$$\vec{\nabla} \times \vec{H} = \vec{j} + \frac{\mathrm{d}\vec{D}}{\mathrm{d}t} = \sigma \vec{E} + \frac{\mathrm{d}\vec{D}}{\mathrm{d}t} \qquad (10.4.202)$$

and we assume to work with a conductor which has no capacitive effect (i.e. no displacement current), contrary to the general case demonstrated in the Electrodynamics section, the latter relation then reduces to:

$$\vec{\nabla} \times \vec{H} = \frac{1}{\mu} \vec{\nabla} \times \vec{B} = \sigma \vec{E} \qquad (10.4.203)$$

and if we associate it with Maxwell's third equation (see section Electrodynamics page 4101), and assuming a harmonic excitation, we have for recall:

$$\vec{\nabla} \times \vec{E} = -\frac{\partial \vec{B}}{\partial t} = -\mathrm{i}\omega \vec{B} \qquad (10.4.204)$$

Therefore, from that latter:

$$\vec{\nabla} \times \vec{j} = -\mathrm{i}\omega\sigma \vec{B} \qquad (10.4.205)$$

So we have so far:

$$\vec{\nabla} \times \vec{j} = -\mathrm{i}\omega\sigma \vec{B} \qquad \vec{\nabla} \times \vec{B} = \mu \vec{j} \qquad (10.4.206)$$

We assumed the current density vector has only a z component, which depends only on y. From the Biot-Savart law and symmetry it therefore follows that there is only an x component of the vector $\vec{B}$ (the reader can request we put the details of the section of Magnetism here again if necessary). According to the expression for the curl in a rectangular coordinates system, the both previous relations become:

$$\frac{\mathrm{d}j_z}{\mathrm{d}y}=-\mathrm{i}\omega\sigma B_x \qquad -\frac{\mathrm{d}B_x}{\mathrm{d}y}=\mu j_z \tag{10.4.207}$$

where we use ordinary derivatives (not partial) because j_z and B_x depend only on y. From the both relations above we can eliminate B_x to get an equation in j_z:

$$\frac{\mathrm{d}^2 j_z}{\mathrm{d}y^2}=\mathrm{i}\omega\mu\sigma j_z \tag{10.4.208}$$

Let us place ourselves in the important case of a harmonic regime:

$$j_z(y,t)=j_0(y)\cos(ky-\omega t) \tag{10.4.209}$$

and let us use temporarily the phasors notation:

$$j_z(y,t)=j_0e^{\mathrm{i}(ky-\omega t)}=j_0e^{\mathrm{i}ky}e^{-\mathrm{i}\omega t} \tag{10.4.210}$$

We then have:

$$\begin{aligned}\frac{\partial^2 j_z}{\partial y^2}&=\frac{\partial\left(j_0e^{\mathrm{i}ky}\right)}{\partial y^2}e^{-\mathrm{i}\omega t}\\ \frac{\partial j_z}{\partial t}&=-\mathrm{i}\omega j_0e^{\mathrm{i}ky}e^{-\mathrm{i}\omega t}\end{aligned} \tag{10.4.211}$$

By injecting this into the previous differential equation and simplifying, we then get:

$$\frac{\partial^2 e^{\mathrm{i}ky}}{\partial y^2}=-\mathrm{i}\omega\sigma\mu e^{\mathrm{i}ky} \tag{10.4.212}$$

Thus:

$$-k^2=-\mathrm{i}\omega\sigma\mu \tag{10.4.213}$$

and therefore:

$$k=\pm\sqrt{\mathrm{i}\omega\sigma\mu} \tag{10.4.214}$$

remembering (see section Numbers page 243) that:

$$\sqrt{\mathrm{i}}=\sqrt{e^{\mathrm{i}\frac{\pi}{2}}}=\left(e^{\mathrm{i}\frac{\pi}{2}}\right)^{\frac{1}{2}}=e^{\mathrm{i}\frac{\pi}{4}}=\cos\left(\frac{\pi}{4}\right)-\mathrm{i}\sin\left(\frac{\pi}{4}\right)=\frac{1-\mathrm{i}}{\sqrt{2}} \tag{10.4.215}$$

it comes:

$$k=\pm\frac{1-\mathrm{i}}{\sqrt{2}}\sqrt{\omega\sigma\mu}=\pm(1-\mathrm{i})\sqrt{\frac{\omega\sigma\mu}{2}} \tag{10.4.216}$$

Therefore:

$$j_z(y,t)=j_0(y)e^{\mathrm{i}ky}e^{-\mathrm{i}\omega t}=j_0e^{\pm(1-\mathrm{i})\sqrt{\frac{\omega\sigma\mu}{2}}y}e^{-\mathrm{i}\omega t}=j_0e^{\pm(\mathrm{i}+1)\sqrt{\frac{\omega\sigma\mu}{2}}y}e^{-\mathrm{i}\omega t} \tag{10.4.217}$$

Thus:

$$j_z(y,t)=j_0e^{\pm\sqrt{\frac{\omega\sigma\mu}{2}}y}e^{\mathrm{i}\left(\pm\sqrt{\frac{\omega\sigma\mu}{2}}y-\omega t\right)} \tag{10.4.218}$$

We must reject for physical reasons (conservation of energy) the solution:

$$k=+\sqrt{\mathrm{i}\omega\sigma\mu} \tag{10.4.219}$$

Therefore it remains:

$$\boxed{j_z(y,t)=j_0e^{-\sqrt{\frac{\omega\sigma\mu}{2}}z}e^{-\mathrm{i}\left(\sqrt{\frac{\omega\sigma\mu}{2}}y+\omega t\right)}} \tag{10.4.220}$$

that physicists write:

$$j_z(y,t)=j_0e^{-\frac{y}{\delta}}e^{\mathrm{i}\left(-\frac{y}{\delta}-\omega t\right)} \tag{10.4.221}$$

because the units of δ are meters (parameter that is zero if the electric field is constant) and is assimilated to the "attenuation coefficient" that we had set ourselves to determine at the beginning:

$$\delta=\sqrt{\frac{2}{\omega\sigma\mu}}=\sqrt{\frac{2\sigma}{\omega\mu}} \tag{10.4.222}$$

For a copper conductor, we have according to Wikipedia the following values:

Frequency	**δ [mm]**
50 [Hz]	9.38
60 [Hz]	8.57
10 [kHz]	0.66
100 [kHz]	0.21
1 [MHz]	0.066
10 [MHz]	0.021

Table 10.6: **Somme attenuation skin effect factor for Copper (source: Wikipedia)**

10.4.5.2 Phase and group velocity of EM waves inside conductors (modified Maxwell equations)

Let us remind that three of the Maxwell equations are:

$$\vec{\nabla}\circ\vec{D}=\rho \quad \vec{\nabla}\circ\vec{B}=0$$
$$\vec{\nabla}\times\vec{E}=-\frac{\partial\vec{B}}{\partial t} \tag{10.4.223}$$

And in conductors the fourth Maxwell equation is written:

$$\vec{\nabla}\times\vec{B}=\mu\vec{j}+\mu\varepsilon\frac{\partial\vec{E}}{\partial t} \tag{10.4.224}$$

If we explicit the first term on the right of the quality using Ohm's law:

$$\vec{\nabla}\times\vec{B}=\mu\sigma\vec{E}+\mu\varepsilon\frac{\partial\vec{E}}{\partial t} \tag{10.4.225}$$

Or even more explicit assuming $\mu_r=1$:

$$\vec{\nabla}\times\vec{B}=\mu_0\sigma\vec{E}+\mu_0\varepsilon_r\varepsilon_0\frac{\partial\vec{E}}{\partial t} \tag{10.4.226}$$

Let us take the curl of:

$$\vec{\nabla}\times\vec{E}=-\frac{\partial\vec{B}}{\partial t} \tag{10.4.227}$$

Therefore (we use on the right term the identity proved in the section of Vector Calculus page 1911):

$$\vec{\nabla}\times(\vec{\nabla}\times\vec{E})=-\frac{\partial}{\partial t}(\vec{\nabla}\times\vec{B})=\vec{\nabla}(\vec{\nabla}\circ\vec{E})-\vec{\nabla}^2\vec{E} \tag{10.4.228}$$

Taking the gradient of :

$$\vec{\nabla}\circ\vec{D}=\rho\Rightarrow\vec{\nabla}\rho_c=\varepsilon_r\varepsilon_0\vec{\nabla}(\vec{\nabla}\circ\vec{E})=\vec{0} \tag{10.4.229}$$

Hence under this assumption:

$$\vec{\nabla}(\vec{\nabla}\circ\vec{E})=\vec{0} \tag{10.4.230}$$

Therefore:

$$\vec{\nabla}\times(\vec{\nabla}\times\vec{E})=-\frac{\partial}{\partial t}(\vec{\nabla}\times\vec{B})=\cancel{\vec{\nabla}(\vec{\nabla}\circ\vec{E})}-\vec{\nabla}^2\vec{E} \tag{10.4.231}$$

Hence:

$$\vec{\nabla}^2\vec{E}=\frac{\partial}{\partial t}(\vec{\nabla}\times\vec{B}) \tag{10.4.232}$$

Injecting in the latter:

$$\vec{\nabla}\times\vec{B}=\mu\sigma\vec{E}+\mu\varepsilon\frac{\partial\vec{E}}{\partial t} \tag{10.4.233}$$

we get :

$$\vec{\nabla}^2\vec{E}=\frac{\partial}{\partial t}(\vec{\nabla}\times\vec{B})=\mu_0\varepsilon_r\varepsilon_0\frac{\partial^2\vec{E}}{\partial t^2}+\mu_0\sigma\frac{\partial\vec{E}}{\partial t} \tag{10.4.234}$$

Hence we have the "modified wave equation":

$$\boxed{\vec{\nabla}^2\vec{E}=\mu_0\varepsilon_r\varepsilon_0\frac{\partial^2\vec{E}}{\partial t^2}+\mu_0\sigma\frac{\partial\vec{E}}{\partial t}} \tag{10.4.235}$$

As $\sigma\rightarrow 0$, we recover the wave equation for linear media as we would expect.

Remark

Respectively from $\vec{\nabla}\times(\vec{\nabla}\times\vec{B})$ we get:

$$\vec{\nabla}^2\vec{B}=\mu\varepsilon\frac{\partial^2\vec{B}}{\partial t^2}+\mu\sigma\frac{\partial\vec{B}}{\partial t} \tag{10.4.236}$$

The solution can be written as an attenuated plane wave:

$$E_x=E_0e^{\mathrm{i}(\beta z-\omega t)}e^{-\alpha z}=E_0e^{\mathrm{i}((\beta+\mathrm{i}\alpha)z-\omega t)}=E_0e^{\mathrm{i}(kz-\omega t)} \tag{10.4.237}$$

Remark

If an electromagnetic wave hits a conductor (starting in air or vacuum, say), the wave will attenuate as it penetrates the conductor with a characteristic distance. The attenuation length in a conductor is known as the "skin depth" and defined by:

$$\delta=\frac{1}{\alpha}$$

The skin depth refers therefore to the point at which the field reaches approximately 37% (i.e. $1/e$) of its nominal value. Where did the missing corresponding energy go? Part of it was reflected (high conductivity materials reflect most of the energy) and part of it was absorbed and turned into heat. (Heating occurs because the electromagnetic field accelerates electrons, and those electrons lose energy through resistance, that is, collisions with other particles.)

In geophysics, skin depth is primarily applied in two techniques: electromagnetic conductivity surveys and ground-penetrating radar (GPR).

Where therefore:

$$k:=\beta+\mathrm{i}\alpha \tag{10.4.238}$$

Substituting $E_0e^{\mathrm{i}(\beta z-\omega t)}e^{-\alpha z}$ back into the modified wave equation:

$$(\mathrm{i}\beta-\alpha)^2E_0=\mu_0\varepsilon_r\varepsilon_0(-\mathrm{i}\omega)^2E_0+\mu_0\sigma(-\mathrm{i}\omega)E_0 \tag{10.4.239}$$

Expanded, rearranged and simplified:

$$(-\beta^2-2\mathrm{i}\beta\alpha+\alpha^2)=-\mu_0\varepsilon_r\varepsilon_0\omega^2-\mathrm{i}\mu_0\sigma\omega \tag{10.4.240}$$

Equating the real and imaginary parts:

$$-\beta^2+\alpha^2=-\mu_0\varepsilon_r\varepsilon_0\omega^2 \qquad -2\beta\alpha=-\mu_0\sigma\omega \tag{10.4.241}$$

Often denoted:

$$-\beta^2+\alpha^2=-\mu\varepsilon\omega^2 \qquad 2\beta\alpha=\mu\sigma\omega \tag{10.4.242}$$

Hence:

$$\beta=\frac{\mu\sigma\omega}{2\alpha} \qquad -\left(\frac{\mu\sigma\omega}{2\alpha}\right)^2+\alpha^2=-\mu\varepsilon\omega^2 \tag{10.4.243}$$

Let us focus on the right equality, i.e.:

$$-\left(\frac{\mu\sigma\omega}{2\alpha}\right)^2+\alpha^2=-\mu\varepsilon\omega^2 \tag{10.4.244}$$

We rearrange:

$$-\left(\frac{\mu\sigma\omega}{2\alpha}\right)^2+\alpha^2+\mu\varepsilon\omega^2=0 \tag{10.4.245}$$

Let us multiply both sides by α^2 and rearrange to get a quadratic equation>:

$$\alpha^4+\mu\varepsilon\omega^2\alpha^2-\left(\frac{\mu\sigma\omega}{2}\right)^2=0 \tag{10.4.246}$$

We do a change of variable $\alpha^2=x$ and we have therefore a simple square polynomial:

$$x^2+\mu\varepsilon\omega^2 x-\left(\frac{\mu\sigma\omega}{2}\right)^2=0 \tag{10.4.247}$$

And the roots of the previous quadratic equation are immediate:

$$\alpha=\sqrt{\frac{-\mu\varepsilon\omega^2\pm\sqrt{\left(\mu\varepsilon\omega^2\right)^2+(\mu\sigma\omega)^2}}{2}} \tag{10.4.248}$$

Because we enforce that α is real and positive, and all of the parameters within the square root are positive, we need to choose the + sign:

$$\begin{aligned}
&\alpha=\sqrt{\frac{\sqrt{\left(\mu\varepsilon\omega^2\right)^2+(\mu\sigma\omega)^2}+\mu\varepsilon\omega^2}{2}}\\
&\rightarrow\alpha=\sqrt{\frac{\mu\varepsilon\omega^2}{2}}\sqrt{\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}-1}\\
&\rightarrow\alpha=\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}-1\right]^{1/2}
\end{aligned} \tag{10.4.249}$$

This is the imaginary part of k:

$$k:=\beta+\mathrm{i}\alpha=\beta+\mathrm{i}\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}-1\right]^{1/2} \tag{10.4.250}$$

Now remember that we have:

$$-\beta^2+\alpha^2=-\mu\varepsilon\omega^2 \tag{10.4.251}$$

Hence:

$$\begin{aligned}\beta=\sqrt{\mu\varepsilon\omega^2+\alpha^2}&=\sqrt{\mu\varepsilon\omega^2+\omega^2\frac{\varepsilon\mu}{2}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}-1\right]}\\&=\sqrt{\frac{\mu\varepsilon\omega^2}{2}+\omega^2\frac{\varepsilon\mu}{2}\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}}\\&=\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}\end{aligned} \tag{10.4.252}$$

As a check, if (insulator):

$$\sigma\rightarrow 0,\alpha\rightarrow 0,k\rightarrow\omega\sqrt{\frac{\varepsilon\mu}{2}}\sqrt{2}=\omega\sqrt{\varepsilon\mu}=\frac{\omega}{v} \tag{10.4.253}$$

and we are back to the linear medium!

For a perfect conductor:

$$\sigma\rightarrow+\infty,\alpha\rightarrow+\infty \tag{10.4.254}$$

and therefore there are no electromagnetic waves and $E,B=0$.

The skin depth is therefore given by:

$$\delta=\frac{1}{\alpha}=\frac{1}{\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}} \tag{10.4.255}$$

Let us remind the expression of the phase velocity (see section Mechanics page 3480):

$$v_\phi=\frac{\omega}{k}=\frac{\omega}{\Re(k)} \tag{10.4.256}$$

and of the group velocity (see section Mechanics page 3481):

$$v_g=\frac{\Delta\omega}{\Delta k}=\frac{1}{\mathrm{d}\Re(k)/\mathrm{d}\omega}=\left(\frac{\mathrm{d}\Re(k)}{\mathrm{d}\omega}\right)^{-1} \tag{10.4.257}$$

Therefore in our case:

$$v_\phi=\frac{\omega}{\Re(k)}=\frac{1}{\beta}=\frac{1}{\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}} \tag{10.4.258}$$

and:

$$v_g=\left(\frac{\mathrm{d}\Re(k)}{\mathrm{d}\omega}\right)^{-1}=\left(\frac{\mathrm{d}}{\mathrm{d}\omega}\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}\right) \tag{10.4.259}$$

So let's work out what the group speed v_g:

$$\begin{aligned}\frac{\mathrm{d}k}{\mathrm{d}\omega}&=\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}+\omega\sqrt{\frac{\varepsilon\mu}{2}}\frac{\mathrm{d}}{\mathrm{d}\omega}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}\\&=\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}+\omega\sqrt{\frac{\varepsilon\mu}{2}}\cdot\frac{\frac{1}{2}\cdot\frac{\cancel{1}}{\cancel{2}}\cdot\cancel{2}\cdot\left(\frac{\sigma}{\varepsilon}\right)^2\left(-\frac{1}{\omega^3}\right)}{\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}}\\&=\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}-\frac{1}{2}\sqrt{\frac{\varepsilon\mu}{2}}\cdot\frac{\left(\frac{\sigma}{\varepsilon\omega}\right)^2}{\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}}\\&=\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}\cdot\left\{1-\frac{1}{2}\frac{\left(\frac{\sigma}{\varepsilon\omega}\right)^2}{\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}}\right\}\end{aligned}\tag{10.4.260}$$

The group speed of an electromagnetic plane wave propagating in a conductor is (eeek!!!):

$$v_g(\omega)=\left[\frac{\mathrm{d}k(\omega)}{\mathrm{d}\omega}\right]^{-1}=\frac{1}{\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}}\cdot\frac{1}{\left\{1-\frac{1}{2}\frac{\left(\frac{\sigma}{\varepsilon\omega}\right)^2}{\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}}\right\}}\tag{10.4.261}$$

That can be rewritten:

$$v_g(\omega)=v_\phi\frac{1}{\left\{1-\frac{1}{2}\frac{\left(\frac{\sigma}{\varepsilon\omega}\right)^2}{\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}}\right\}}\tag{10.4.262}$$

Now let us focus on a good conductor that has for property:

$$\sigma\gg\varepsilon\omega\Leftrightarrow\frac{\sigma}{\varepsilon\omega}\gg 1\tag{10.4.263}$$

Then for a good conductor:

$$\beta=\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}+1\right]^{1/2}\cong\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}\right]^{1/2}\cong\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{\frac{\sigma}{\varepsilon\omega}}\right]^{1/2}=\omega\sqrt{\frac{\cancel{\varepsilon}\mu\sigma}{2\cancel{\varepsilon}\omega}}=\sqrt{\frac{\omega\mu\sigma}{2}}\tag{10.4.264}$$

and:

$$\alpha=\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}-1\right]^{1/2}\cong\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{1+\left(\frac{\sigma}{\varepsilon\omega}\right)^2}\right]^{1/2}\cong\omega\sqrt{\frac{\varepsilon\mu}{2}}\left[\sqrt{\frac{\sigma}{\varepsilon\omega}}\right]^{1/2}=\omega\sqrt{\frac{\cancel{\varepsilon}\mu\sigma}{2\cancel{\varepsilon}\omega}}=\sqrt{\frac{\omega\mu\sigma}{2}}\tag{10.4.265}$$

Therefore for a good conductor:

$$\beta\cong\alpha\cong\sqrt{\frac{\omega\mu\sigma}{2}}\tag{10.4.266}$$

Therefore still for a good conductor:

$$\delta=\frac{1}{\alpha}\simeq\sqrt{\frac{2}{\omega\mu\sigma}} \tag{10.4.267}$$

and also:

$$\lambda=\frac{2\pi}{\Re(k)}=\frac{2\pi}{\beta}\cong 2\pi\sqrt{\frac{2}{\omega\mu\sigma}} \tag{10.4.268}$$

The phase speed and group speed in a good conductor are respectively for the phase velocity:

$$v_\phi\cong\frac{\omega}{\Re(k)}=\frac{\omega}{\beta}\cong\frac{\omega}{\sqrt{\frac{\omega\mu\sigma}{2}}}=\sqrt{\frac{2\omega}{\mu\sigma}} \tag{10.4.269}$$

and for the group velocity:

$$v_g=\left[\frac{\mathrm{d}\Re(k)}{\mathrm{d}\omega}\right]^{-1}=\left[\frac{\mathrm{d}\beta}{\mathrm{d}\omega}\right]^{-1}\cong\left[\frac{\mathrm{d}}{\mathrm{d}\omega}\sqrt{\frac{\omega\mu\sigma}{2}}\right]^{-1}=\frac{2}{\sqrt{\frac{\omega\mu\sigma}{2}}}=\sqrt{\frac{8\omega}{\mu\sigma}}=2v_\phi(\omega) \tag{10.4.270}$$

So we the famous relation:

$$v_g\cong\sqrt{\frac{8\omega}{\mu\sigma}}=\sqrt{\frac{16\pi f}{\mu\sigma}}=2v_\phi(\omega) \tag{10.4.271}$$

For copper, with $\sigma=5.96\cdot 10^7\,[\mathrm{S}\cdot\mathrm{m}^{-1}]$ and $\mu\approx\mu_0=4\pi\cdot 10^{-7}\,[\mathrm{H}\cdot\mathrm{m}^{-1}]$, and for a plane wave with frequency $50\,[\mathrm{Hz}]$, the group velocity is roughly $5.79\,[\mathrm{m}\cdot\mathrm{s}^{-1}]$! This group velocity and corresponding phase velocity is obviously very slow for electromagnetic radiation!

Remark

Permittivity is typically associated with dielectric materials, however metals are described as having an effective permittivity, with real relative permittivity equal to one. In the high-frequency region, which extends from radio frequencies to the far infrared and terahertz region, the plasma frequency of the electron gas is much greater than the electromagnetic propagation frequency, so the refractive index n of a metal is very nearly a purely imaginary number. In the low frequency regime, the effective relative permittivity is also almost purely imaginary: It has a very large imaginary value related to the conductivity and a comparatively insignificant real-value.

Without doing the approximations we did above thanks to Maple™ and using the same values for f,μ,σ we can that changing the range value of ε_r from $1\cdot 10^{-50}$ to $1\cdot 10^{13}$ doesn't change the result (we still get $5.79\,[\mathrm{m}\cdot\mathrm{s}^{-1}]$). But when $\varepsilon_r>10^{13}$ the changes for start to be significant for v_g.

Notice that for copper the skin depth is therefore equal to:

$$\delta=\frac{1}{\Im(k)}=\frac{1}{\alpha}=\sqrt{\frac{2}{\omega\mu\sigma}}\sqrt{\frac{1}{\pi f\mu\sigma}}\cong 0.92\,[\mathrm{cm}] \tag{10.4.272}$$

We see something interesting here! The expression of the skin depth is exactly the same of that of the skin effect derived at page 4268. Are they they the two sides of the same coin???

Since $\vec{J} = \sigma\vec{E}$, the current density in the conductor and the electric field have the same profile. In particular, the characteristic depth for the current in the conductor is the same as the characteristic fall-off depth for the penetration of the wave; both are proportional to $e^{-z/\delta}$ (if the incident wave is in the positive z.

To clarify: the current and the electromagnetic field interact and sustain each other intimately. You cannot have the one without the other! Analysing the one also informs you about the other.

Instead of thinking of a transmission line as two wires with special behavior, the reader need to think of a transmission line as a guiding structure for electromagnetic waves. When we talk about currents and voltages and capacitance and inductance in a transmission line, that's a useful simplification for many cases. But to understand skin effect the reader should instead think about an electromagnetic wave that is guided by conductive structures. The currents and voltages that we measure on the transmission line are caused by the electromagnetic wave travelling along it, not the other way around.

So then, when an currents wave encounters a conductive material, what happens? The EM wave is reflected. It doesn't penetrate deeply into the conductor. But if the conductivity is not infinite, it does penetrate slightly. And up to the depth that it penetrates, it causes currents to flow in the conductor. That is the skin effect!

10.4.6 Semiconductors

The main defect of the Drude model seen above is to consider the electron as a classical particle. A set of such particles is obviously not subject to quantum distributions and therefore to an explicit relations of temperature.

Moreover, if we observe our Drude model, it is difficult to say anything about resistivity as a function of temperature.

In fact, we generally consider four dates at the source of the development of the semiconductor theory:

- In 11833 (holocene calendar), Michael Faraday reported the conductivity of a material that increases with temperature.
- In 11839 (holocene calendar), Antoine Becquerel discovers that under illumination an electrical tension appears at the junction of certain materials (and liquids). It is the photovoltaic effect, which will give birth much later (around 11950 according to holocene calendar) to the solar cells.
- In 11873 (holocene calendar), Willoughby Smith shows that the conductivity of certain substances increases when illuminated. This is photo-conductivity.
- Finally, in 11874 (holocene calendar), Karl Ferdinand Braun discovers the phenomenon of electrical straightening when a metallic tip is deposited on certain conductors, that is to say that the electric current passes in one direction when the electric potential applied to the point is positive but not when it is negative!

Although these discoveries were totally misunderstood and especially not recognized as the different expressions of the same physical phenomenon (semi-conductivity), practical applications were immediate and led to the second industrial revolution, that of microelectronics!

This type of difficulty (among many others...) largely disappears with the model of the free electron in a potential well, as imagined by Arnold Sommerfeld in 11928 according to holocene calendar (see section Wave Quantum Physics page 4796). In this model the electrons, subjected to the Pauli exclusion principle, follow the Fermi-Dirac energy distribution (see section Statistical Mechanics page 3571), whereas in the Drude model they followed the Maxwell-Boltzmann energy distribution.

There are two important results:

- Only a fraction of the electrons is likely to see its energy vary under the effect of an external action (temperature, electric field, etc.)
- Even at absolute zero, the kinetic energy of the electrons is not zero.

The Sommerfeld model provides a basis for the construction of more specific theories and is the basis of the field of "solid physics" according to some sources. It is therefore not a completed model dealing with a specific problem such as electrical conduction or thermoelectronic emission. This base is the energy distribution of the electrons, obtained by the product of two functions: the density of the states and the Fermi-Dirac distribution.

As the years go by, we will complete the developments that will follow to finally try to have the whole detailed approach. Until then, the reader will have to be patient or to go search the information in other sources on the Internet...

We will make abstraction of the concepts that are not absolutely necessary for the introduction of the model to present here only the essential which is sufficient for the engineer in his daily work.

To begin the mathematical part of the semiconductor study, we will consider a crystal subjected to a potential difference. A conduction electron of the crystal will therefore be subjected, on the one hand, to an internal force $\vec{F}_i$ resulting from the crystalline field and on the other hand to a force of external origin $\vec{F}_e$ resulting from the electric field applied to the crystal.

The model assumptions (hypothesis) of the model are:

H1. There is a high enough potential barrier on the metal surface that prevents electrons from leaving the material.

H2. Inside the material, electrons are subjected to constant potential!

H3. The electrons are independent (no interactions between them).

H4. The electrons obey the laws of Quantum Physics and Classical Mechanics.

H5. The electrons obey to the Maxwell's electrodynamics laws.

H6. The energy bands form a continuous spectrum of energy levels.

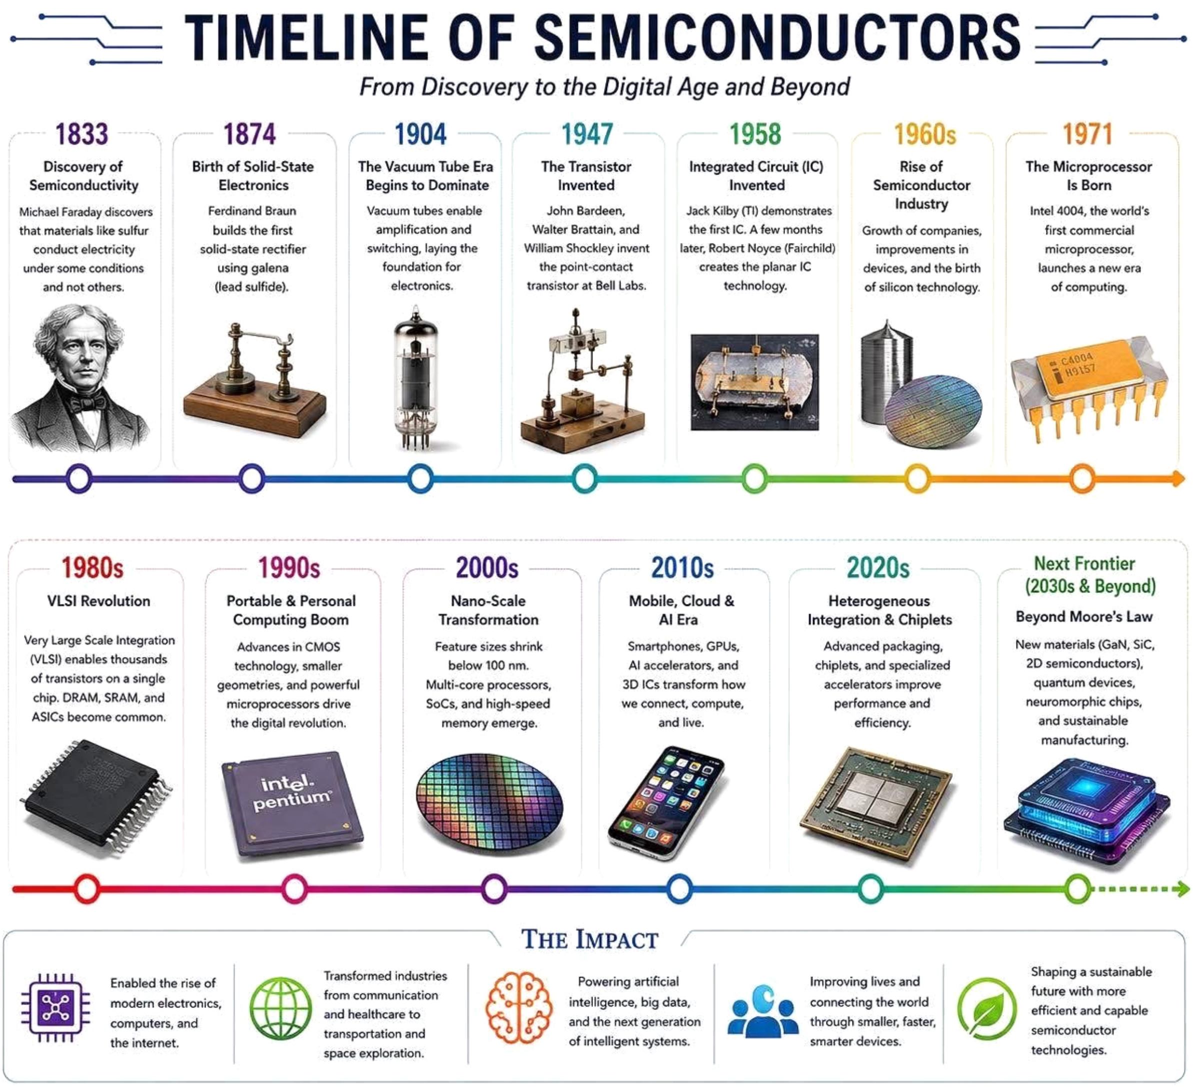
The first hypothesis is based on the following observation: electrons travelling in a metal do not cross, at room temperature at least, the surfaces limiting the sample.

The second hypothesis appears rather brutal. It banish from the model the notion of the "structure of matter". It will be replaced in the model of the energy bands by a periodic potential that accounts for the influence of the positively charged nuclei. This hypothesis reflects the fact that electrons are considered as free in the potential well defined by the sample.

The potential barrier has a finite width but infinite height, that is to say that the passage of the potential inside the material to the potential outside it is done on some inter-atomic distances. However, since the dimensions of the sample are in practice always very great with respect to an inter-atomic distance, the potential barrier can be considered as infinitely abrupt, which simplifies the calculations.

Remark

In order to simplify the calculations, we will assume that the electrons move in only one direction (that of the electric field), thus avoid to work with vectors.



TIMELINE OF SEMICONDUCTORS

From Discovery to the Digital Age and Beyond

1833 Discovery of Semiconductivity
Michael Faraday discovers that materials like sulfur conduct electricity under some conditions and not others.

1874 Birth of Solid-State Electronics
Ferdinand Braun builds the first solid-state rectifier using galena (lead sulfide).

1904 The Vacuum Tube Era Begins to Dominate
Vacuum tubes enable amplification and switching, laying the foundation for electronics.

1947 The Transistor Invented
John Bardeen, Walter Brattain, and William Shockley invent the point-contact transistor at Bell Labs.

1958 Integrated Circuit (IC) Invented
Jack Kilby (TI) demonstrates the first IC. A few months later, Robert Noyce (Fairchild) creates the planar IC technology.

1960s Rise of Semiconductor Industry
Growth of companies, improvements in devices, and the birth of silicon technology.

1971 The Microprocessor Is Born
Intel 4004, the world's first commercial microprocessor, launches a new era of computing.

1980s VLSI Revolution
Very Large Scale Integration (VLSI) enables thousands of transistors on a single chip. DRAM, SRAM, and ASICs become common.

1990s Portable & Personal Computing Boom
Advances in CMOS technology, smaller geometries, and powerful microprocessors drive the digital revolution.

2000s Nano-Scale Transformation
Feature sizes shrink below 100 nm. Multi-core processors, SoCs, and high-speed memory emerge.

2010s Mobile, Cloud & AI Era
Smartphones, GPUs, AI accelerators, and 3D ICs transform how we connect, compute, and live.

2020s Heterogeneous Integration & Chiplets
Advanced packaging, chiplets, and specialized accelerators improve performance and efficiency.

Next Frontier (2030s & Beyond) Beyond Moore's Law
New materials (GaN, SiC, 2D semiconductors), quantum devices, neuromorphic chips, and sustainable manufacturing.

THE IMPACT

Enabled the rise of modern electronics, computers, and the internet.

Transformed industries from communication and healthcare to transportation and space exploration.

Powering artificial intelligence, big data, and the next generation of intelligent systems.

Improving lives and connecting the world through smaller, faster, smarter devices.

Shaping a sustainable future with more efficient and capable semiconductor technologies.

The equation of the dynamics is then written naturally for this electron:

$$m_0\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}=\vec{F}_i+\vec{F}_e \qquad (10.4.273)$$

We then write (nothing prevents us to do so) that the electron in the crystal responds to the stress of the external force $\vec{F}_e$ as a quasi-particle of mass m_e in a vacuum:

$$m_0\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}=\vec{F}_i+\vec{F}_e=\vec{F}_i+m_e\frac{\mathrm{d}\vec{v}}{\mathrm{d}t} \qquad (10.4.274)$$

It is the study of the latter term which will interest us. For this purpose let us recall that in the detailed study of the propagation of the free electron in a vacuum, where we neglect the effects of its spin, we have shown that it must be described according to the Schrödinger equation by a wave packet (see section Wave Quantum Physics page 4786) centered on a state k_0, otherwise its energy would be infinite.

However, we can ask ourselves ... what leads us to consider it as free...? Well it is experience that shows that when we apply a certain threshold potential, a current begins to appear in the semiconductors.

We have proved (always in the context of the propagation of the free spin-free particle in the section of Wave Quantum Physics) that the wave packet can then be seen in its mathematical solution as a (free) plane wave moving at phase speed:

$$v_\varphi = \frac{\omega_0}{k_0} \tag{10.4.275}$$

which we will write for as following in order to simplify the notations of the next developments:

$$v = \frac{\omega}{k} \tag{10.4.276}$$

However, in the crystal lattice, the phase velocity can vary, depending on the location of the electron in the lattice due to the geometrical shape of the potential in the crystal. We must therefore use the instantaneous phase velocity:

$$\vec{v} = \frac{\mathrm{d}\omega}{\mathrm{d}\vec{k}} = \begin{pmatrix} \dfrac{\mathrm{d}\omega}{\mathrm{d}\vec{k}_x} \\ \dfrac{\mathrm{d}\omega}{\mathrm{d}\vec{k}_y} \\ \dfrac{\mathrm{d}\omega}{\mathrm{d}\vec{k}_z} \end{pmatrix} \tag{10.4.277}$$

Let us recall (see section Corpuscular Quantum Physics page 4627) that we also have in general the total energy given by:

$$E = h\nu = h\frac{\omega}{2\pi} = \hbar\omega \tag{10.4.278}$$

Therefore we get:

$$v = \frac{\mathrm{d}\omega}{\mathrm{d}\vec{k}} = \frac{1}{\hbar}\frac{\mathrm{d}E}{\mathrm{d}\vec{k}} \tag{10.4.279}$$

The term:

$$\frac{\mathrm{d}E}{\mathrm{d}\vec{k}} \tag{10.4.280}$$

is by no means simple in the case of a crystal (it is even a nightmare ...).

Obviously for a free particle (see section Wave Quantum Physics page 4788), let us recall that it is equal to:

$$\frac{\mathrm{d}E}{\mathrm{d}k} = \frac{\mathrm{d}}{\mathrm{d}k}\left(\frac{\hbar^2 k^2}{2m}\right) = \frac{\hbar^2 k}{m} \tag{10.4.281}$$

But for a particle in a potential field having a complex geometry, the energy E begins to have an expression dependent of k as a function of the zones which can become very complex (see the examples of the section Wave Quantum Physics). Hence the justification for the use of the derivative.

The acceleration in the classical sense of this electron is then given by:

$$\vec{a} = \frac{\mathrm{d}\vec{v}}{\mathrm{d}t} = \frac{1}{\hbar}\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\mathrm{d}E}{\mathrm{d}\vec{k}}\right) = \frac{1}{\hbar}\frac{\mathrm{d}}{\mathrm{d}\vec{k}}\frac{\mathrm{d}E}{\mathrm{d}t} \tag{10.4.282}$$

We also have (see section Classical Mechanics page 3293):

$$\mathrm{d}E=\vec{F}\circ\mathrm{d}\vec{x}=\vec{F}\circ\vec{v}\mathrm{d}t \tag{10.4.283}$$

Therefore:

$$\frac{\mathrm{d}E}{\mathrm{d}t}=\vec{F}\circ\vec{v} \tag{10.4.284}$$

Hence:

$$\vec{a}=\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}=\frac{1}{\hbar}\frac{\mathrm{d}}{\mathrm{d}\vec{k}}\frac{\mathrm{d}E}{\mathrm{d}t}=\frac{1}{\hbar}\frac{\mathrm{d}}{\mathrm{d}\vec{k}}\left(\vec{F}\circ\vec{v}\right)=\frac{1}{\hbar}\frac{\mathrm{d}}{\mathrm{d}\vec{k}}\left(\vec{F}\circ\frac{1}{\hbar}\frac{\mathrm{d}E}{\mathrm{d}\vec{k}}\right) \tag{10.4.285}$$

The derivative of $\vec{F}$ with respect to $\vec{k}$ in the preceding relation will be cancelled because the force is derived from the potential applied to the semiconductor only and not from the wave vector of the electron itself! We then have:

$$\vec{a}=\vec{F}\frac{1}{\hbar^2}\frac{\mathrm{d}^2E}{\mathrm{d}\vec{k}^2} \tag{10.4.286}$$

Since here E is only the total energy coming from the externally submitted potential, then the force $\vec{F}$ is the external force $\vec{F}_e$ generated by the application of this same potential. We then have:

$$\vec{F}_e=m_e\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}=m_e\cdot\vec{a} \tag{10.4.287}$$

and:

$$\vec{F}_e=\frac{1}{\dfrac{1}{\hbar^2}\dfrac{\mathrm{d}^2E}{\mathrm{d}k^2}}\vec{a} \tag{10.4.288}$$

It then comes by equalization:

$$m_e=\frac{\hbar^2}{\dfrac{\mathrm{d}^2E}{\mathrm{d}k^2}} \tag{10.4.289}$$

Since the energy of the electron can have a complicated mathematical form according to the practical applications cases presented in the section of Wave Quantum Physics, let us express $E(\vec{k})$ in the form of a limited Taylor development (see section Sequences and Series page 1703) of a function of three variables at the second order by dropping the terms of interactions and by not taking the terms of first degree:

$$\begin{aligned}E(\vec{k})&=E(k_x,k_y,k_z)\\&\cong E(k_{x0},k_{y0},k_{z0})+\frac{1}{2!}\frac{\partial^2E}{\partial k_x^2}(k_x-k_{x0})^2+\frac{1}{2!}\frac{\partial^2E}{\partial k_y^2}(k_y-k_{y0})^2+\frac{1}{2!}\frac{\partial^2E}{\partial k_z^2}(k_z-k_{z0})^2\end{aligned} \tag{10.4.290}$$

In fact, this rough but still acceptable approximation in many practical cases is due to the fact that experience shows that the energy surfaces as a function of k approximate a parabolic shape in certain semiconductor crystals.

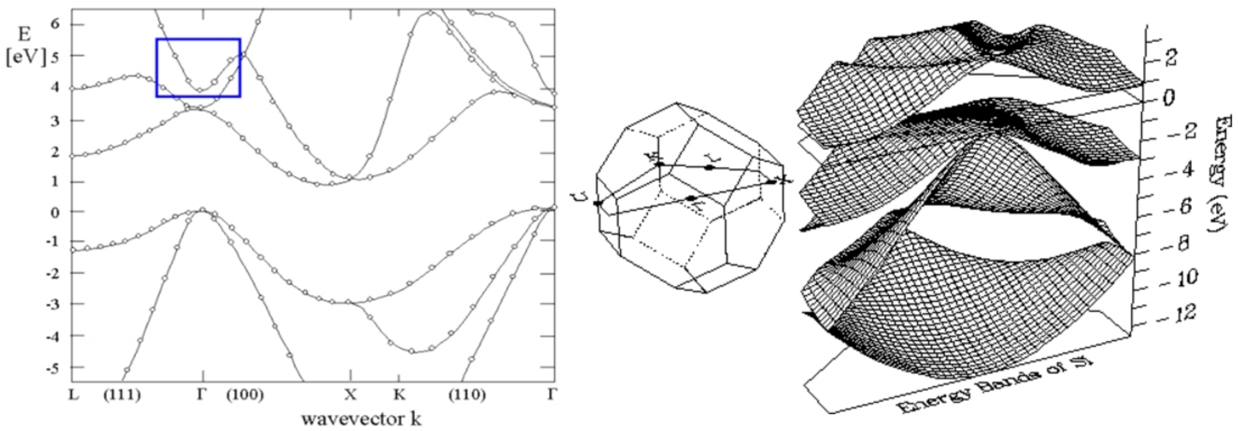


Figure 10.101: Band structure of Silicium following different plane in the crystal. The blue rectangle shows a region of one of the conduction bands which may be described by a parabola approximately

In the conductors, the approximation of the preceding relation is taken only at the first term.

Another way of seeing it is that for a free electron, for recall, in one dimension, the dispersion curve (see section Wave Quantum Physics page 4785):

$$E(k)=\frac{\hbar^2}{2m}k^2 \tag{10.4.291}$$

which is indeed a parabola as a function of k. Indeed, if we take our Taylor development in one dimension it remains:

$$E(k)\cong E(k_0)+\frac{1}{2!}\frac{\partial^2 E}{\partial k^2}(k-k_0)^2 \tag{10.4.292}$$

and as we determined before that:

$$m_e=\frac{\hbar^2}{\dfrac{\mathrm{d}^2E}{dk^2}} \tag{10.4.293}$$

It comes:

$$E(k)\cong E(k_0)+\frac{1}{2!}\frac{\partial^2 E}{\partial k^2}(k-k_0)^2=\frac{1}{2!}\frac{\hbar^2}{m_e}(k-k_0)^2 \tag{10.4.294}$$

If the electron is free, the dispersion curve imposes us to have (without the presence of a potential):

$$E(k_0)=0 \tag{10.4.295}$$

which is then considered as the "energy of the minimum" E_{min}. It then remains:

$$E(k)=\frac{\hbar^2}{2m_e}(k_x-k_{x0})^2 \tag{10.4.296}$$

and by taking $k_{x0}=0$ we fall back on the dispersion curve of a free particle (which therefore justifies the fact of having to choose $E(k_0)=0$ for a free electron):

$$E(k)=\frac{\hbar^2}{2m_e}k_x^2 \tag{10.4.297}$$

This shows that the approximation is not too false ... and justifies the fact that in some textbooks the previous relation (Taylor series) describes a so-named "quasi-free particle".

But let us come back to:

$$E(k)=E(k_0)+\frac{\hbar^2}{2m_e}(k-k_0)^2 \qquad (10.4.298)$$

And since the wave packet is centered around k_0, let us normalize it as being equal to 0 (which is equivalent to centering the wave vector values). We then have:

$$E(k)=E(k_0)+\frac{\hbar^2}{2m_e}k^2=E_0+\frac{\hbar^2}{2m_e}k^2 \qquad (10.4.299)$$

What is interesting with these developments is that we started from a free electron in the form of a wave packet and thanks to the Taylor development we find ourselves with an extremely simple expression of the energy of a quasi-free electron.

It emerges that for a quasi-free electron, without interactions and without taking into account the effects of spin we have:

$$k\cong\sqrt{(E-E_0)\frac{2m_e}{\hbar}} \qquad (10.4.300)$$

We then notice a very sympathetic thing! This is that our quasi-free electron has a wave number which resembles in all points tot particle stuck in a potential well with rectilinear walls (see the proof in the section of Wave Quantum Physics).

We now wish to calculate the density of states (in extenso of electrons) in the volume given by the corresponding rectangular well, by means of the expression of k (not having directly that of E as being too complex).

We have proved in the section of Wave Quantum Physics that for the potential well with rectangular barriers that:

$$k=n\frac{\pi}{L} \qquad (10.4.301)$$

if we imposed an integer half wavelength. If we impose an integer wavelength ("Born-von Karman conditions" so that after a translation of the periodic lattice of the crystal we fall back on the same properties) so that the solution is physically acceptable, then we have:

$$k=n\frac{2\pi}{L} \qquad (10.4.302)$$

Which obviously implies two times fewer states.

By extension, for space, we then have in the three-dimensional case:

$$k_x=n_x\frac{2\pi}{L_x},k_y=n_y\frac{2\pi}{L_y},k_z=n_z\frac{2\pi}{L_z} \qquad (10.4.303)$$

with:

$$E_{n_x,n_y,n_z}=\frac{\pi^2\hbar^2}{2mL^2}\left(n_x^2+n_y^2+n_z^2\right)=E_0\left({n_x}^2+{n_y}^2+{n_z}^2\right) \qquad (10.4.304)$$

and where $n_{x,y,z}=1,2,3,\ldots$.

The result is very similar to that of the one-dimensional infinite rectangular potential well but now we have special boundary conditions in the purpose to have a correspondence with the experiment and three main quantum numbers instead of just one. Moreover, each combination of these three numbers corresponds to a different wave function (state). Moreover, these numbers are independent (no condition imposed).

✍**Example:**

Consider a solid metal cube of edge length 2 [cm]. We want to know the value of the lowest energy level for an electron within the metal and what is the spacing between this level and the next energy level!

The lowest energy level corresponds to the quantum numbers $n_x=n_y=n_z=1$. From the above relation, the energy of this level is:

$$E_{1,1,1}=\frac{\pi h^2}{2m_eL^2}(1^2+1^2+1^2)\cong\frac{3\pi^2(1.05\cdot 10^{-34})^2}{2(9.11\cdot 10^{-31})(2\cdot 10^{-2})^2}\cong 4.48\cdot 10^{-34}\,[\text{J}] \qquad (10.4.305)$$

The next-higher energy level is reached by increasing any one of the three quantum numbers by 1. Hence, there are actually three quantum states with the same energy. Suppose we increase n_x by 1. Then the energy becomes:

$$E_{2,1,1}=\frac{\pi^2h^2}{2m_eL^2}(2^2+1^2+1^2)\cong\frac{6\pi^2(1.05\cdot 10^{-34})^2}{2(9.11\cdot 10^{-31})(2\cdot 10^{-2})^2}\cong 8.96\cdot 10^{-34}\,[\text{J}] \qquad (10.4.306)$$

The energy spacing between the lowest energy state and the next-highest energy state is therefore:

$$E_{2,1,1}-E_{1,1,1}=2.8\cdot 10^{-15}\,[\text{eV}] \qquad (10.4.307)$$

his is a very small energy difference. Compare this value to the average kinetic energy of a particle, as the product kT is in comparison $1,000$ times greater than the previously calculated energy spacing.

We then have for the first level where all n are unitary:

$$k_xk_yk_z=\frac{(2\pi)^3}{L_xL_yL_z} \qquad (10.4.308)$$

If we accept to simplify that the well has edges of equal length (cubic crystal lattice semiconductor), we then have:

$$k_xk_yk_z=\frac{(2\pi)^3}{L^3}=\left(\frac{2\pi}{L}\right)^3 \qquad (10.4.309)$$

Let us represent the space k for such a cubic lattice and for different multiples of n_x, n_y, n_z:

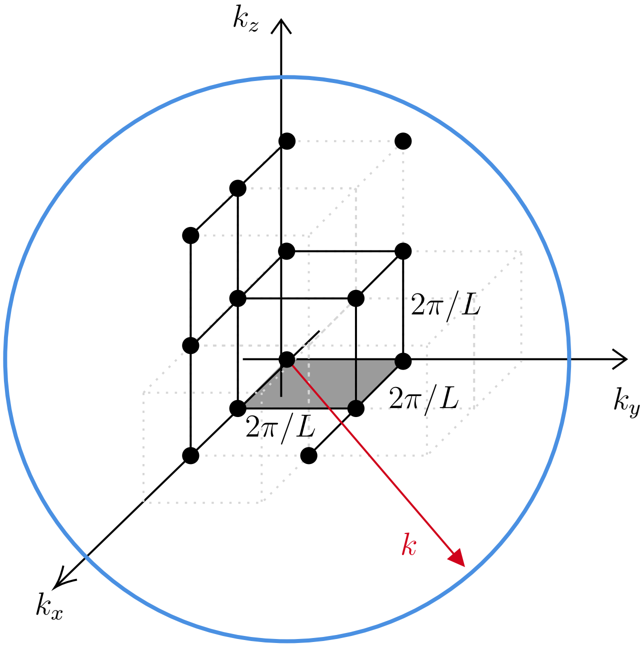

Figure 10.102: k-space for a cubic crystal lattice

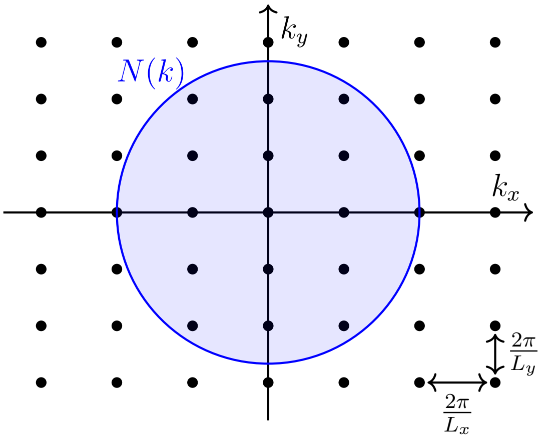
Or in two dimensions:



Therefore, all quantized states can take only values space from $2\pi/L$ in the space of k, which means that by elementary volume there is only one possible wave vector and therefore only one associated state. Indeed, the reader can draw a picture over the figure above if he wants and he will see (!) but do not rely on the big blackheads that are there only to show the ends of the elementary volumes and which do not all correspond to possible states!

Remark

The sphere of radius k containing the levels with one electron is sometimes referred to as the "Fermi sphere". The radius value is then denoted k_F and named the "Fermi wave vector". The surface of the Fermi sphere, which separates the occupied levels from those which are not occupied as we shall see later, is named the "Fermi surface".

Thus, in a spherical volume with radius k of the k-space. We have a precise number (upper limit) of elementary volumes (states), remembering that $V = L^3$, given by:

$$\boxed{N(k) = \frac{\frac{4}{3}\pi k^3}{k_x k_y k_z} = \frac{\frac{4}{3}\pi k^3}{(2\pi/L)^3} = \frac{k^3}{6\pi^2}V} \tag{10.4.310}$$

where in literature it is customary (tradition) to retain only the form of the second equality in the developments. This relation has been a useful to us for recall in the section of Thermodynamics to determine the Debye-Einstein model of the constant-volume (isochoric) thermal capacity of crystalline solids (see page 3622)!

The density of modes in a volume V will then be given by (relation used in the section of Thermodynamics to express the calorific capacity at constant volume of solids):

$$D(\omega) = \frac{\mathrm{d}N}{\mathrm{d}k} = \frac{\mathrm{d}k}{\mathrm{d}\omega} = \frac{Vk^2}{2\pi^2}\frac{\mathrm{d}k}{\mathrm{d}\omega} \tag{10.4.311}$$

In facts, due to the presence of potential bonds between the atoms of the crystal, the sphere is not perfect and has like giant pockmarks/photholes on what is otherwise a smooth surface:

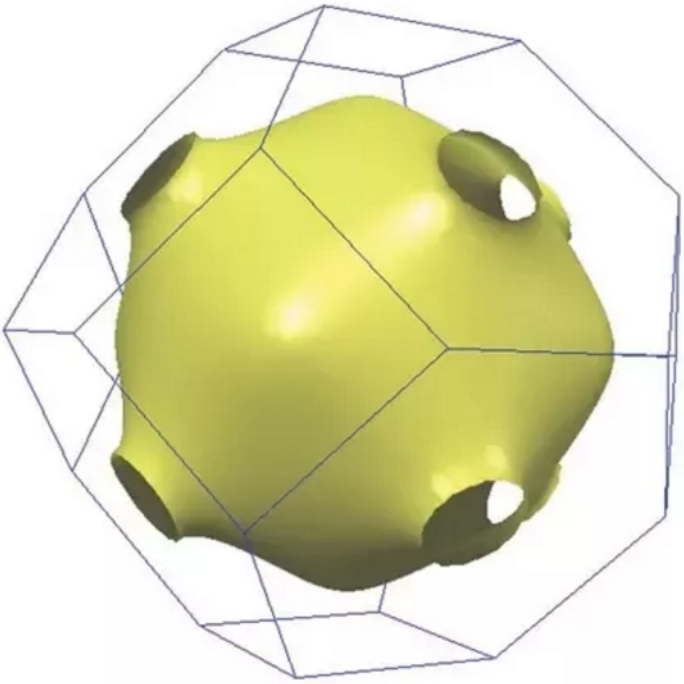


Figure 10.103: **Fermi surface of copper**

or for real, here is a (supposed) Fermi surface and electron momentum density of Copper in the reduced zone schema measured with 2D Angular Correlation of Electron Positron Annihilation Radiation method ("supposed" as I was not able to find the original article with the picture):

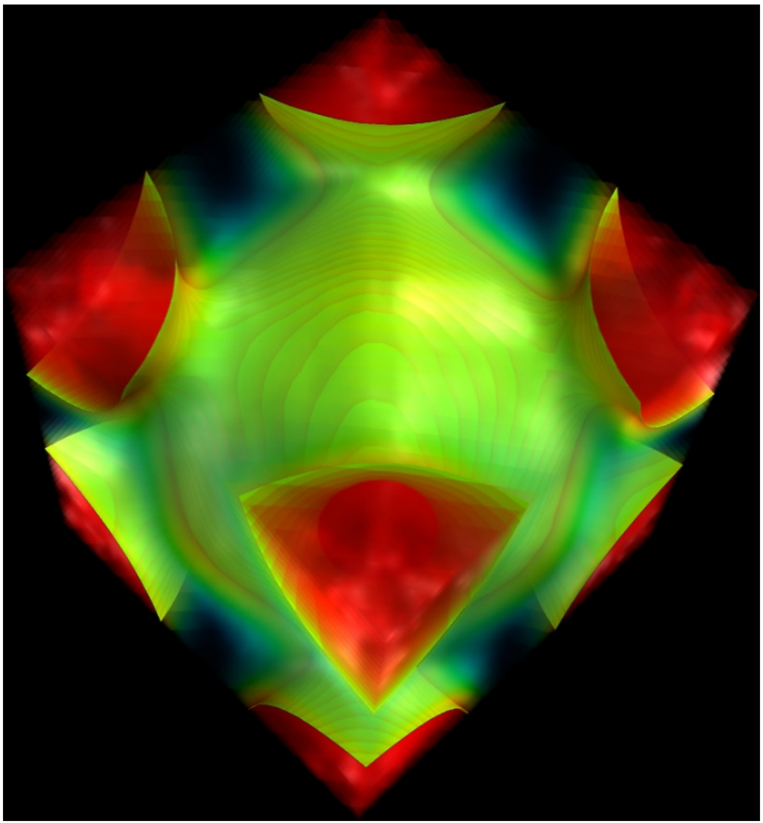

Figure 10.104: **Fermi surface of copper with 2D ACAR method (source: Wikipedia)**

Now considering the spin (yes indeed why not do it...?!) we multiply by 2 since there are two spin states possible by state for the electron (remembering that $V=L^3$):

$$N(k)=2\cdot\frac{4}{3}\frac{\pi k^3}{(2\pi)^3}L^3=\frac{k^3}{3\pi^2}V \tag{10.4.312}$$

(relation that we will see again in the section of Nuclear Physics chapter during our study of the liquid drop nucleus model at page 5141) and by injecting in it:

$$k\cong\sqrt{(E-E_0)\frac{2m_e}{\hbar^2}} \tag{10.4.313}$$

we then have:

$$\begin{aligned}N(E)&\cong 2\cdot\frac{\frac{4}{3}\pi}{(2\pi)^3}\left((E-E_0)\frac{2m_e}{\hbar^2}\right)^{3/2}L^3=\frac{\frac{4}{3}}{(2\pi)^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}(E-E_0)^{3/2}L^3\\&=\frac{\frac{4}{3}}{(2\pi)^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}(E-E_0)^{3/2}\cdot V\end{aligned} \tag{10.4.314}$$

The volume density of (quasi-free) states will be obtained by deriving this last relation by the volume:

$$\rho(E)=\frac{\mathrm{d}N(E)}{\mathrm{d}V}=\frac{\frac{4}{3}}{(2\pi)^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}(E-E_0)^{3/2} \tag{10.4.315}$$

And if we want the density of (quasi-)free states (of vibrations) per unit of energy and volume, we will have to derive also with respect to the energy:

$$\frac{\mathrm{d}\rho(E)}{\mathrm{d}E}\cong\frac{\frac{4}{3}}{(2\pi)^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\frac{\mathrm{d}}{\mathrm{d}E}(E-E_0)^{3/2}=\frac{\frac{4}{3}}{(2\pi)^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\frac{3}{2}(E-E_0)^{1/2} \tag{10.4.316}$$

which gives:

$$\boxed{D(E)\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}(E-E_0)^{1/2}} \tag{10.4.317}$$

This result does not depend on the volume, it is unchanged when the latter tends towards infinity! So it is valid for any point of the semiconductor crystal if this one is perfect and without bonds between atoms...

What we also find sometimes in the following (somewhat unfortunate ...) forms in some textbooks:

$$\begin{aligned}D(E)&\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\sqrt{E}\\D(E)&\cong\frac{4}{h^3\sqrt{\pi}}(2\pi m_e)^{3/2}(E-E_0)^{1/2}\end{aligned} \tag{10.4.318}$$

and there are also those who take into account the spin into account only much more later ... which gives a form identical to that of the previous three relations but divided by a factor 2.and there are also those who take into account the spin into account only much more later ... which gives a form identical to that of the previous three relations but divided by a factor 2.

The difference $E-E_0$ as we will see further below is denoted E_F, and for obvious reasons related to Statistical Mechanics that we will see further below named the "Fermi Energy". Therefore notice that we have using the previous results:

$$N(E)\cong\frac{4/3}{(2\pi)^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}(E-E_0)^{3/2}V=\frac{1}{3\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}E_F^{3/2}V \tag{10.4.319}$$

After rearranging we get immediately:

$$\begin{aligned}E_F&=\frac{\hbar^2}{2m_e}\left(\frac{N}{V}\right)^{2/3}(3\pi^2)^{2/3}=\frac{h^2}{8\pi^2m_e}\left(\frac{3N}{V}\right)^{2/3}\pi^{4/3}=h^28m_e\left(\frac{3N}{V}\right)^{2/3}\pi^{-2/3}\\&=h^28m_e\left(\frac{3N}{\pi V}\right)^{2/3}\end{aligned} \tag{10.4.320}$$

Therefore:

$$\boxed{E_F=\frac{h^2}{8m_e}\left(\frac{3N}{\pi V}\right)^{2/3}} \tag{10.4.321}$$

Fermi energies for selected materials are listed in the following table:

Element	Conduction band electron density	Free-Electron Model Fermi Energy
Al	$18.1\cdot10^{28}$ [m^{-3}]	11.7 [eV]
Ba	$3.15\cdot10^{28}$ [m^{-3}]	3.64 [eV]
Cu	$8.47\cdot10^{28}$ [m^{-3}]	7.00 [eV]
Au	$5.90\cdot10^{28}$ [m^{-3}]	5.53 [eV]
Fe	$17.0\cdot10^{28}$ [m^{-3}]	11.1 [eV]
Ag	$5.86\cdot10^{28}$ [m^{-3}]	5.49 [eV]

Table 10.7: **Fermi energy for some materials**

We can obviously associate the Fermi temperature (see section Statistical Mechanics page 3576) with the Fermi Energy as $E=kT$. Therefore:

$$T_F=\frac{E_F}{k}=\frac{h^2}{8m_ek}\left(\frac{3N}{\pi V}\right)^{2/3} \quad (10.4.322)$$

✍**Example:**

The Fermi temperature associated to the Fermi energy of silver is:

$$T_F\cong\frac{8.8\cdot 10^{-19}}{1.38\cdot 10^{-23}}\cong 6.4\cdot 10^4\,[\text{K}] \quad (10.4.323)$$

which is much higher than room temperature and also the typical melting point ($\sim 10^3$ [K]) of a metal.

10.4.6.1 Non-degenerated statistic density of negative electric charge carriers

In short, however this relation has an issue (one more...)! Indeed, we have seen in the section of Statistical Mechanics in our study of Quantum Statistics that in a system where even the energy spectrum is considered continuous it is impossible not to take into account the degeneration of the different levels of energy. We have then demonstrated that for a population of fermions, at a given energy (or temperature) the percentage of degenerate levels occupied is given by the Fermi-Dirac function:

$$f_{\text{FD}}(E,T,\mu)=\frac{1}{\exp\left(\dfrac{E-\mu}{kT}\right)+1} \quad (10.4.324)$$

and that function therefore returns a value between 0 and 1.

This function therefore gives for a fixed temperature T the probability that an electron occupies a state of energy E.

Hence our relation $D(E)$ overestimates the real density value of (quasi-)free occupied states for a given energy (or temperature). In order to obtain a better approximation, we logically write the volumetric density of (quasi-free) states per unit of energy by:

$$D(E)\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}(E-E_0)^{1/2}f_{\text{FD}}(E,T,\mu)=\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}(E-E_0)^{1/2}\cdot\frac{1}{\exp\left(\dfrac{E-\mu}{kT}\right)+1} \quad (10.4.325)$$

However, in practice, we will try to calculate the volume density of (quasi-free) states in a spectrum (interval) of energy. It then comes with the correction added previously:

$$\frac{\mathrm{d}\rho(E)}{\mathrm{d}E}\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\frac{(E-E_0)^{1/2}}{\exp\left(\dfrac{E-\mu}{kT}\right)+1} \quad (10.4.326)$$

Thus:

$$\mathrm{d}\rho(E)\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\frac{(E-E_0)^{1/2}}{\exp\left(\dfrac{E-\mu}{kT}\right)+1}\mathrm{d}E \tag{10.4.327}$$

It then immediately follows that the volumetric density of (quasi-free) states at a given temperature (normal temperature conditions for civilian applications) taking into account all possible states (continuous levels) of energy is then given by:

$$\rho(E)\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\int\limits_{E_0}^{+\infty}\frac{(E-E_0)^{1/2}}{\exp\left(\dfrac{E-\mu}{kT}\right)+1}\mathrm{d}E \tag{10.4.328}$$

Take E_0 as a lower boundary avoids us, as we shall see explicitly a further below, to find ourselves with a negative root ... which would be very a priori troublesome!

Moreover, we can, without any appreciable error, postpone the limit of the integral to the infinity because $f_{\text{FD}}\rightarrow 0$ when E is large.

Unfortunately, this (improper) integral is generally not analytically soluble. We will have to use approximations.

We will start by making the assumption that we are in the classical regime of electron gas. That is, we have:

$$\exp\left(\frac{E-\mu}{kT}\right)\gg 1 \tag{10.4.329}$$

which implies:

$$E-\mu\gg kT \tag{10.4.330}$$

Therefore, we also have the approximation:

$$\frac{1}{\exp\left(\dfrac{E-\mu}{kT}\right)+1}\cong\frac{1}{\exp\left(\dfrac{E-\mu}{kT}\right)+1}=\exp\left(-\frac{E-\mu}{kT}\right) \tag{10.4.331}$$

In other words, the energy E must be much higher than the chemical potential μ (assimilated often unfortunately to my knowledge wrongly in the literature on semiconductors to the Fermi level E_F). Physicists then note this energy E_C to distinguish it and name it "minimal energy of the conduction band" (which corresponds to the minimum energy of a quasi-free electron to satisfy this condition).

Therefore, we also change the notation for the charge density:

$$\rho(E)\longrightarrow\rho_C(E) \tag{10.4.332}$$

Remark

Unfortunately, as mentioned in the previous paragraph (!) in many quality textbooks on semiconductors, the chemical potential μ, which is a purely thermodynamic notion implying a hypothesis of interactions, is replaced by the concept of Fermi energy E_F and however this is not the same thing! The two energies coincide only in the case where the temperature T is equal to zero!

So we must consider the term "Fermi level" as being nothing but a synonym for "chemical potential" in the context of semiconductors.

We then have:

$$\begin{aligned}\rho_C(E) &\cong \frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\int\limits_{E_C}^{+\infty}(E-E_C)^{1/2}\exp\left(-\frac{E-\mu}{kT}\right)\mathrm{d}E\\ &=\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\int\limits_{E_C}^{+\infty}(E-E_C)^{1/2}f_{\text{MB}}\mathrm{d}E\\ &=\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\exp\left(\frac{\mu}{kT}\right)\int\limits_{E_C}^{+\infty}(E-E_C)^{1/2}\left(-\frac{E}{kT}\right)\mathrm{d}E\end{aligned} \tag{10.4.333}$$

where f_{MB} is the Maxwell-Boltzmann distribution (see section Statistical Mechanics page 3554) given for recall by:

$$f_{\text{MB}}(E,T,\mu)=\exp\left(-\frac{E-\mu}{kT}\right) \tag{10.4.334}$$

and thus corresponds well to a non-quantum behaviour (i.e. a non-degenerate electron gas!) because when:

$$E-\mu\gg kT \tag{10.4.335}$$

we have:

$$f_{\text{MB}}(E,T,\mu)\ll 1 \tag{10.4.336}$$

and therefore the energy states of are far from being all occupied by electrons (there is therefore no degeneration).

We are therefore well in a situation where Classical Physics predominates over Quantum Physics. This is why in this approximation (of Maxwell-Boltzmann type) we say that we are dealing with a "non-degenerate semiconductor" because the electrons are not all stacked into the lowest available levels.

To continue, we make a change of variable by putting:

$$x=\frac{E-E_C}{kT} \tag{10.4.337}$$

hence:

$$\mathrm{d}x=\frac{1}{kT}\mathrm{d}E \quad \text{and} \quad E=x\cdot kT+E_C \tag{10.4.338}$$

Therefore it comes:

$$\begin{aligned}\int\limits_{E_C}^{+\infty}\sqrt{E-E_C}\left(-\frac{E}{kT}\right)\mathrm{d}E&=\sqrt{kT}\int\limits_0^{+\infty}x^{1/2}\exp\left(-\frac{x\cdot kT+E_C}{kT}\right)\mathrm{d}xkT\\&=(kT)^{3/2}\exp\left(-\frac{E_C}{kT}\right)\int\limits_0^{+\infty}x^{1/2}e^{-x}\mathrm{d}x\end{aligned} \tag{10.4.339}$$

We do an integration by parts:

$$\int\limits_0^{+\infty}x^{1/2}e^{-x}\mathrm{d}x=-\left[x^{1/2}e^{-x}\right]_0^{+\infty}+\frac{1}{2}\int\limits_0^{+\infty}\frac{e^{-x}}{\sqrt{x}}\mathrm{d}x=\frac{1}{2}\int\limits_0^{+\infty}\frac{e^{-x}}{\sqrt{x}}\mathrm{d}x \tag{10.4.340}$$

We then make a change of variable by putting:

$$u=\sqrt{x}\Rightarrow\frac{\mathrm{d}u}{\mathrm{d}x}=\frac{1}{2\sqrt{x}}\Rightarrow\mathrm{d}x=2\sqrt{x}\mathrm{d}u=2u\mathrm{d}u \tag{10.4.341}$$

which gives:

$$\frac{1}{2}\int\limits_0^{+\infty}\frac{e^{-x}}{\sqrt{x}}\mathrm{d}x=\frac{1}{2}\int\limits_0^{+\infty}\frac{e^{-u^2}}{u}2u\mathrm{d}u=\int\limits_0^{+\infty}e^{-u^2}\mathrm{d}u \tag{10.4.342}$$

We have already calculated this integral in the Statistics section. It comes:

$$\int\limits_0^{+\infty}x^{1/2}e^{-x}\mathrm{d}x=\int\limits_0^{+\infty}e^{-u^2}\mathrm{d}u=\frac{\sqrt{\pi}}{2} \tag{10.4.343}$$

We then have finally:

$$\begin{aligned}\rho_C(E)&\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\exp\left(\frac{\mu}{kT}\right)(kT)^{3/2}\exp\left(-\frac{E_C}{kT}\right)\frac{\sqrt{\pi}}{2}\\&=\frac{1}{2\pi^2}\left(\frac{2m_ekT}{\hbar^2}\right)^{3/2}\exp\left(\frac{\mu-E_C}{kT}\right)\frac{\sqrt{\pi}}{2}=\frac{1}{2^2\pi^{3/2}}\left(\frac{2m_ekT}{\hbar^2}\right)^{3/2}\exp\left(\frac{\mu-E_C}{kT}\right)\\&=2\left(\frac{m_ekT}{2\pi\hbar^2}\right)^{3/2}\exp\left(\frac{\mu-E_C}{kT}\right)\end{aligned} \tag{10.4.344}$$

Where, for recall, m_e is the mass of the quasi-particle (and not the mass of the electron for recall!). So after integration everything happens as if all the electrons were concentrated on the level of energy E_C with a number of available places corresponding to:

$$2\left(\frac{m_ekT}{2\pi\hbar^2}\right)^{3/2} \tag{10.4.345}$$

The relation $\rho_C(E)$ is traditionally written (and in a somewhat unfortunate way ... because it is not easy to remember that it is a density):

$$N_n = N_{n,T}\exp\left(\frac{\mu - E_C}{kT}\right) \tag{10.4.346}$$

or also:

$$\boxed{N_n = N_C\exp\left(\frac{\mu - E_C}{kT}\right)} \tag{10.4.347}$$

where we have approximately at ambient temperature the following values of (quasi-)free states for Silicium:

$$N_C \cong 2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2} \cong 2.7\cdot 10^{19}\ \left[\mathrm{cm}^{-3}\right] \tag{10.4.348}$$

and for the Germanium:

$$N_C \cong 2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2} \cong 1\cdot 10^{19}\ \left[\mathrm{cm}^{-3}\right] \tag{10.4.349}$$

while there is a density of about $4.5\cdot 10^{22}$ atoms by cubic centimetres and about 10^{24} electron by cubic centimetre for these two elements.

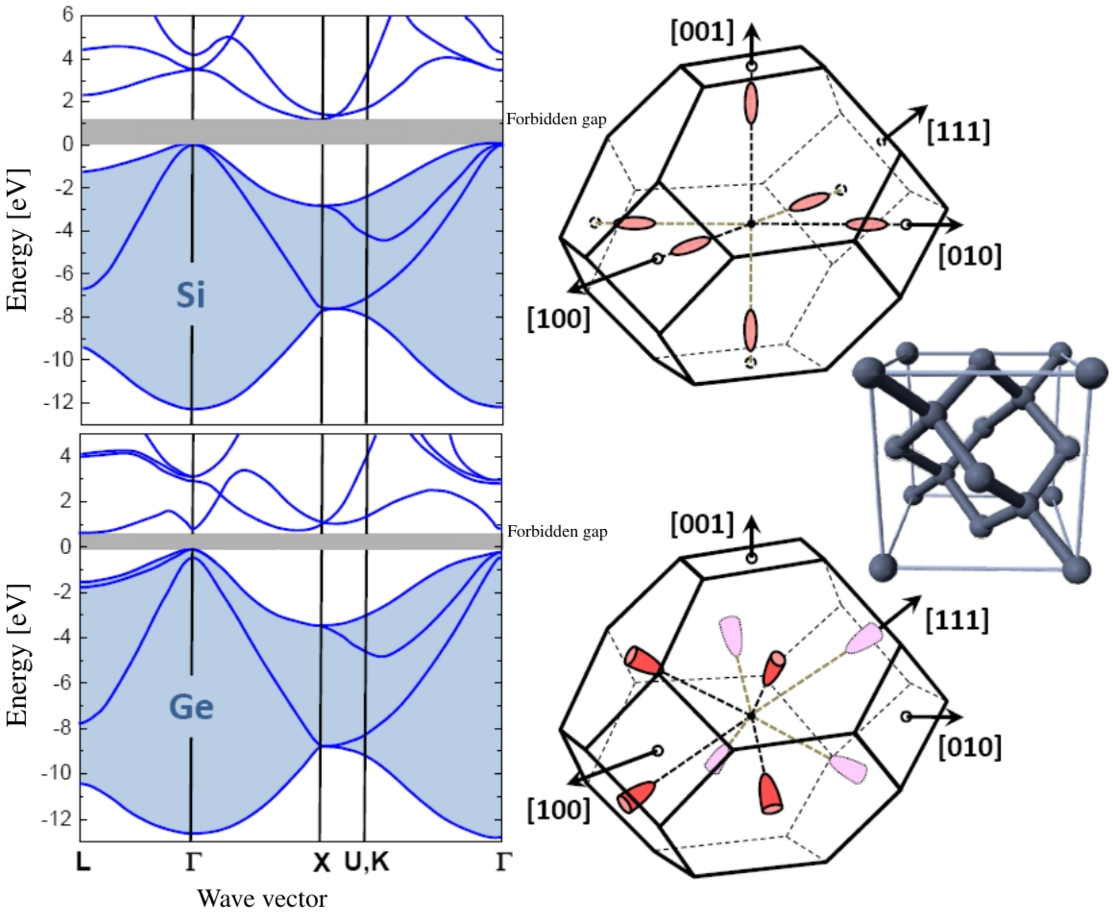

Figure 10.105: Silicium vs Germanium band and crystal structure (source: ?)

This means that there is thus a ratio of: $10^{19}/10^{24}=10^{-5}$ between the total electron density and the number of quasi-free electrons.

We also notice that this theoretical model does not take into account the electronic structure (atomic number) of the studied material.

Thus, we see that the variations of quasi-free electron densities as a function of temperature (in the temperature validity range ...) are essentially of increasing or decreasing exponential type.

From the density of the free electrons (caution! it must be remembered that these are only the quasi-free electrons that are wandering in our mathematical equations so far...) in the semi-conductor crystal, we can deduce the Fermi energy level (more rigorously it is the chemical potential!):

$$N_n=N_C\exp\left(\frac{\mu-E_C}{kT}\right)\Rightarrow\frac{N_n}{N_C}=\exp\left(\frac{\mu-E_C}{kT}\right)\Rightarrow\ln\left(\frac{N_n}{N_C}\right)=\frac{\mu-E_C}{kT}\qquad(10.4.350)$$

hence:

$$\mu=E_C+kT\ln\left(\frac{N_n}{N_C}\right)\qquad(10.4.351)$$

and since $N_{n,T}\geq N_n$ we always have because of the logarithm which is negative, the energy of Fermi (more rigorously it is the chemical potential!) which is less than or equal to the energy of the quasi-free electrons:

$$\mu\leq E_C\qquad(10.4.352)$$

or in other words, (quasi-)free electrons have an energy higher than the Fermi energy (chemical potential...), which is in line with the non-degenerate gas approximation made earlier above. This gives a condition of major importance for the negative carriers to be the generators of the conduction in the material.

Thus, when we place ourselves at a temperature different from absolute zero, the electronic states are not all degenerate: there is spreading of occupied states in the neighbourhood of what constitutes by definition the Fermi energy level (see sections of Statistical Mechanics page 3576 and Wave Quantum Physics page 4805), effect that is as increase as the temperature is high.

10.4.6.2 Non-degenerated statistic density of positive electric charge carriers

First of all, we must know that in the present state of our knowledge, "holes" do not emerge from equations, but are an empirical construction that makes it possible to match theory and experience (positive charges of the Hall effect for example). It is therefore an artifice to make a simple theory of a question that seems rigorously nowadays not manageable by Quantum Physics.

Personally, I consider the holes in the same way as the Lagrange points in astronomy: Even if there are no bodies at these points of Lagrange this does not avoid a satellite from orbiting around them (possibility that we have not proved in the section of Astronomy) as if there was a mass even if the orbit is quasi-stable! Moreover, experiments would have shown in the early

12000s (holocene calendar) that Lagrange points appear at the level of the atom under certain ideal and simplified conditions!

That said, it must be remembered that a hole is not a missing electron! It is an idiocy (in my opinion ...) that we see in some specialized works.

At the risk of being repeated a little often, let us recall that for a fixed temperature T the probability that an electron occupies a state of energy E is given by:

$$f_{\text{FD}}(E,T,\mu)=\frac{1}{\exp\left(\dfrac{E-\mu}{kT}\right)+1} \tag{10.4.353}$$

What bring us in order to get a better approximation, we logically had written the volume density of occupied states per unit of energy:

$$D(E)\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}(E-E_0)^{1/2}\cdot\frac{1}{\exp\left(\dfrac{E-\mu}{kT}\right)+1} \tag{10.4.354}$$

This finally led to the following relation of the volumetric density of negative charge states where the presence of a mass in the relation indicates that the occupied states are by quasi-particles such as:

$$N_n=2\left(\frac{m_ekT}{2\pi\hbar^2}\right)^{3/2}\exp\left(\frac{\mu-E_C}{kT}\right) \tag{10.4.355}$$

But what about the probability that an electron does not occupy for a fixed temperature T a state of energy E and trivially given by the difference:

$$f_p(E,T,\mu)=1-f_n(E,T,\mu)=1-f_{\text{FD}}(E,T,\mu) \tag{10.4.356}$$

where the n in index is there to indicate that the distribution concerns the "negative" carriers (distribution given as we have rightly proved earlier by the Maxwell-Boltzmann distribution which follows from an approximation of the Fermi-Dirac law).

Well! We shall see that the equations lead us to the possibility to associate also to these unoccupied states a density of states with a given effective mass. We shall also see later that it will be possible to associate to these unoccupied states a positive and equal electric charge to that of the electron, hence the p in index in the preceding relation and signifying "positive".

We therefore have for these positive carriers:

$$\begin{aligned}f_p(E,T,\mu)&=1-\frac{1}{\exp\left(\dfrac{E-\mu}{kT}\right)+1}=\frac{\exp\left(\dfrac{E-\mu}{kT}\right)+1}{\exp\left(\dfrac{E-\mu}{kT}\right)+1}-\frac{1}{\exp\left(\dfrac{E-\mu}{kT}\right)+1}\\&=\frac{\exp\left(\dfrac{E-\mu}{kT}\right)}{\exp\left(\dfrac{E-\mu}{kT}\right)+1}=\frac{\exp\left(\dfrac{E-\mu}{kT}\right)}{\exp\left(\dfrac{E-\mu}{kT}\right)+1}\frac{\exp\left(\dfrac{\mu-E}{kT}\right)}{\exp\left(\dfrac{\mu-E}{kT}\right)}=\frac{1}{\exp\left(\dfrac{\mu-E}{kT}\right)+1}\end{aligned} \tag{10.4.357}$$

let us now make an approximation similar to that used for the negative carriers, that is to say:

$$f_p(E,T,\mu)\ll 1 \tag{10.4.358}$$

to impose a semi-classical regime and therefore the states of energy are by far not all occupied by the holes (there is therefore no degeneration).

This restriction requires:

$$\exp\left(\frac{\mu-E}{kT}\right)\gg 1 \tag{10.4.359}$$

Either written in the same way as for negative carriers:

$$\exp\left(-\frac{E-\mu}{kT}\right)\gg 1 \tag{10.4.360}$$

Unlike negative carriers, this imposes:

$$E-\mu\ll kT \tag{10.4.361}$$

in other words the energy must be much lower than the Fermi level (chemical potential). Physicists then write this energy E_V to distinguish it and name it "maximum energy of the valence band" (which corresponds to the maximum energy of a quasi-free hole to satisfy this condition).

Remark

The reader may observe that the conditions mentioned earlier above also impose that E is either very small in absolute value or negative. Which gives us already a track for the integration terminals to come...

We then have:

$$f_p(E,T,\mu)=\frac{1}{\exp\left(\dfrac{\mu-E}{kT}\right)+1}\cong\frac{1}{\exp\left(\dfrac{\mu-E}{kT}\right)}=\exp\left(-\frac{\mu-E}{kT}\right) \tag{10.4.362}$$

Therefore, we also have the approximation:

$$f_p(E,T,\mu)\cong\exp\left(-\frac{\mu-E}{kT}\right) \tag{10.4.363}$$

We are therefore well in a situation where classical physics predominates over quantum physics. This is why in this approximation we say that we are dealing with a "non-degenerate semiconductor" because the holes are not crammed into the highest levels available.

We have then:

$$\begin{aligned}\rho_V(E)&\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\int\limits_{-\infty}^{E_V}(E_V-E)^{1/2}\exp\left(-\frac{\mu-E}{kT}\right)\mathrm{d}E\\&=\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\exp\left(\frac{-\mu}{kT}\right)\int\limits_{-\infty}^{E_V}(E_V-E)^{1/2}\exp\left(\frac{E}{kT}\right)\mathrm{d}E\end{aligned} \tag{10.4.364}$$

where the reader will have observed that the integration terminals have been chosen according to the remark we had just made earlier and that the terms in the square root have been swapped so as not to have any negative value.

To continue, we make a change of variable by putting:

$$x=\frac{E_V-E}{kT} \tag{10.4.365}$$

hence:

$$\mathrm{d}x=-\frac{1}{kT}\mathrm{d}E \qquad \text{and} \qquad E=-x\cdot kT+E_V \tag{10.4.366}$$

Therefore it comes:

$$\begin{aligned}\int_{-\infty}^{E_V}\sqrt{E_V-E}\exp\left(\frac{E}{kT}\right)\mathrm{d}E&=-\sqrt{kT}\int_{+\infty}^{0}x^{1/2}\exp\left(\frac{-x\cdot kT+E_V}{kT}\right)\mathrm{d}xkT\\&=-(kT)^{3/2}\exp\left(\frac{E_V}{kT}\right)\int_{+\infty}^{0}x^{1/2}e^{-x}\mathrm{d}x\end{aligned} \tag{10.4.367}$$

We do an integration by parts:

$$\int_{+\infty}^{0}x^{1/2}e^{-x}\mathrm{d}x=-\left[x^{1/2}e^{-x}\right]\Big|_{+\infty}^{0}+\frac{1}{2}\int_{+\infty}^{0}\frac{e^{-x}}{\sqrt{x}}\mathrm{d}x=\frac{1}{2}\int_{+\infty}^{0}\frac{e^{-x}}{\sqrt{x}}\mathrm{d}x \tag{10.4.368}$$

we then make a change of variable by putting:

$$u=\sqrt{x}\Rightarrow\frac{\mathrm{d}u}{\mathrm{d}x}=\frac{1}{2\sqrt{x}}\Rightarrow\mathrm{d}x=2\sqrt{x}\mathrm{d}u=2u\mathrm{d}u \tag{10.4.369}$$

which gives:

$$\frac{1}{2}\int_{+\infty}^{0}\frac{e^{-x}}{\sqrt{x}}\mathrm{d}x=\frac{1}{2}\int_{+\infty}^{0}\frac{e^{-u^2}}{u}2u\mathrm{d}u=\int_{+\infty}^{0}e^{-u^2}\mathrm{d}u \tag{10.4.370}$$

We have already calculated this integral in the section Statistics. It comes (since the function is even we use the property demonstrated in the section of Differential and Integral Calculus):

$$\int_{+\infty}^{0}x^{1/2}e^{-x}\mathrm{d}x=-\int_{0}^{+\infty}e^{-u^2}\mathrm{d}u=-\frac{\sqrt{\pi}}{2} \tag{10.4.371}$$

We then have finally:

$$\begin{aligned}\rho_V(E)&\cong\frac{1}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\exp\left(-\frac{\mu}{kT}\right)(kT)^{3/2}\exp\left(\frac{E_V}{kT}\right)\frac{\sqrt{\pi}}{2}\\&=\frac{1}{2\pi^2}\left(\frac{2m_ekT}{\hbar^2}\right)^{3/2}\exp\left(\frac{E_V-\mu}{kT}\right)\frac{\sqrt{\pi}}{2}=\frac{1}{2^2\pi^{3/2}}\left(\frac{2m_ekT}{\hbar^2}\right)^{3/2}\exp\left(\frac{E_V-\mu}{kT}\right)\\&=2\left(\frac{m_ekT}{2\pi\hbar^2}\right)^{3/2}\exp\left(\frac{E_V-\mu}{kT}\right)\end{aligned} \tag{10.4.372}$$

Where, for recall, m_e is the mass of the quasi-particle (and not the mass of the hole for recall!). So after integration everything happens as if all the holes were concentrated on the level of energy E_V with a number of available places corresponding to:

$$2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2} \tag{10.4.373}$$

What we write traditionally (and in a somewhat unfortunate way ... because it is not easy to remember that it is a density):

$$N_p = N_{p,T}\exp\left(\frac{E_V-\mu}{kT}\right) \tag{10.4.374}$$

or:

$$\boxed{N_p = N_V\exp\left(\frac{E_V-\mu}{kT}\right)} \tag{10.4.375}$$

where we have approximately at ambient temperature the following values of (quasi-)free states for Silicon:

$$N_V = 2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2} \cong 1.1\cdot 10^{19}\;\left[\text{cm}^{-3}\right] \tag{10.4.376}$$

and for Germanium:

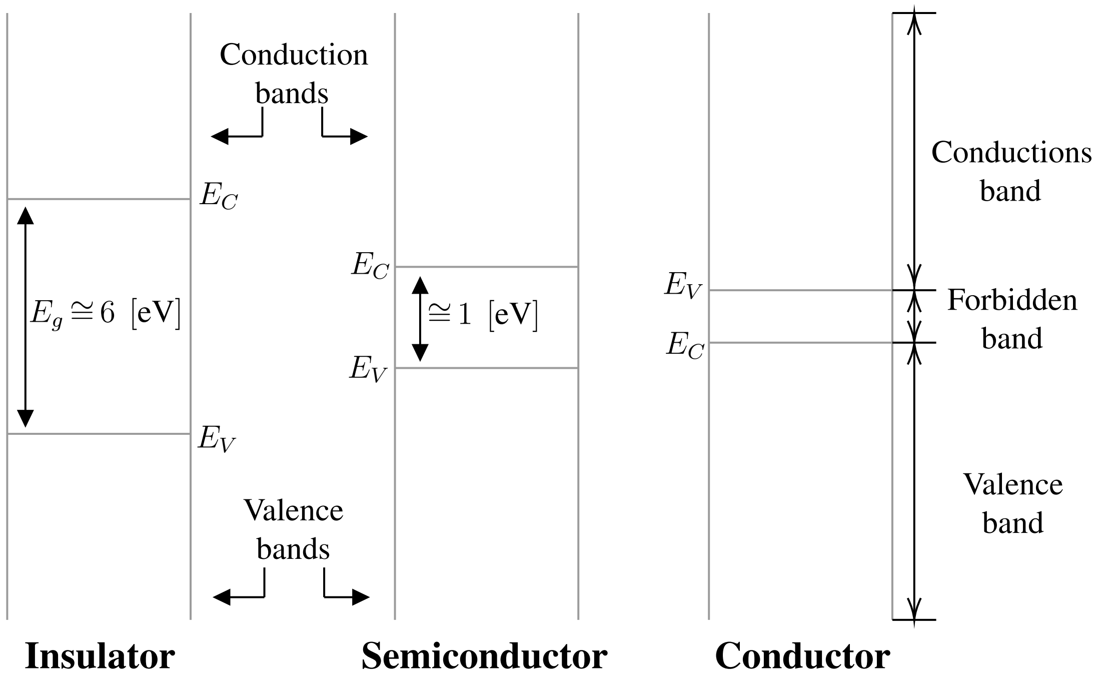
$$N_V = 2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2} \cong 0.5\cdot 10^{19}\;\left[\text{cm}^{-3}\right] \tag{10.4.377}$$

10.4.6.3 Energy bands (conduction band, band gap, valence band)

The previous developments for negative and positive carriers have shown us that, in the approximation of a non-degenerate fermion gas, the energy of the negative carriers must be well above the Fermi level (chemical potential) and positive carrier energy well below.

It is therefore as if there was a forbidden energy interval or neither electrons nor holes have the right to be located! This energy interval is traditionally referred to as "forbidden energy band" or simply "band gap" and abbreviated B.G. The forbidden energy interval is often named simple "gap" and is denoted E_g.

Let us see this in a rough schematic form, taking care that this scheme is somewhat misleading because it gives the impression that the conduction or valence band occupies an entire block (furthermore "flat"...), whereas in reality the valence band is constituted by the last layer completely filled, the band of permitted energy which follows being named "conduction band".



Conduction bands
E_C
$E_g \cong 6$ [eV]
E_V
E_C
$\cong 1$ [eV]
E_V
Valence bands
E_V
E_C
Conductions band
Forbidden band
Valence band
Insulator
Semiconductor
Conductor

Figure 10.106: **Representation of band structures in different materials**

Moreover, knowing that molecular chemistry makes it possible to demonstrate that structures are composed of multiple bands (as a function of the first and second quantum number), the following rigorous definitions are obtained:

D1. The "conducting band" (denoted sometimes "CB") of a solid structure is the lowest energy partially occupied or empty band (other bands are above in energy terms but will only fill at high temperatures And exist only by a theoretical description when they are empty).

D2. The "valence band" (denoted sometimes "BV") of a solid structure is the band of highest energy that is saturated, that is to say where all the states of which are occupied (knowing that there may be below the valence band other multiple bands in energy terms and all saturated).

We also have the traditional schematic association of the conduction and valence bands with the Fermi-Dirac function (which as already mentioned in all rigour should be the chemical potential at non-zero temperature!) represented in simplified form by:

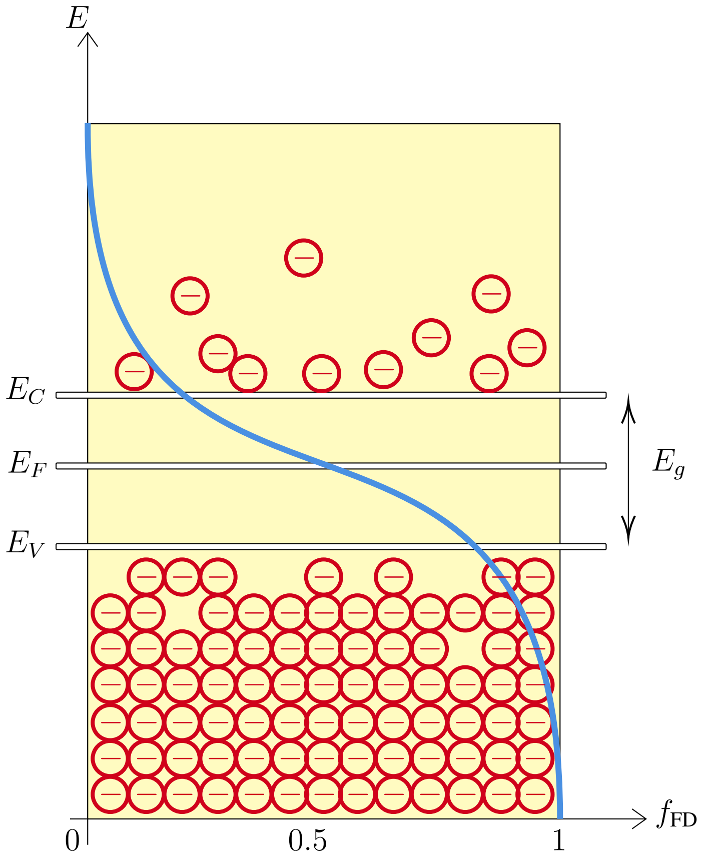


Figure 10.107: **Association of band structure with Fermi-Dirac function**

But in fact this representation, which we find almost everywhere in certain textbooks, is relatively erroneous ... since by making a semi-classical approximation by the Maxwell-Boltzmann distribution there is no longer question of rigorously representing the distribution in the form of a Fermi-Dirac distribution as the attentive reader will have noticed! This shows that we must always be useful with figures since the traditional representation of f_{FD} in the semi-classical model would indicate that there would be occupied states in the forbidden band, whereas if we represented the Maxwell-Boltzmann distribution we see two distinct functions, above and below the forbidden band!

And it must be remembered (!!!) that the above figure (even if it is quite false) represents conceptually a non-degenerate semiconductor following semi-classical approximations that we have made in our developments using the model of a non-degenerate gas (Maxwell-Boltzmann approximation) and that theoretically imposed:

$$E_C \gg \mu \gg E_V \qquad (10.4.378)$$

that many authors write (again it's unfortunate but it is so...):

$$E_C \gg E_F \gg E_V \qquad (10.4.379)$$

So there is another possible definition of the non-degenerate semiconductor: this is where the Fermi level (the chemical potential!) lies in the forbidden band and this case corresponds to how the majority of the microelectronic components work.

Remark

Let us recall (see section Statistical Mechanics page 3554) that the Maxwell-Boltzmann statistic was constructed on the assumption of the absence of interaction between the particles involved. Moreover, this statistic is constructed in the framework of Classical Mechanics and therefore applies only when the quantum effects are negligible, for example at high enough temperatures!

Here are some experimental values for common semiconductors:

E_g [eV]	300 [K]	0 [K]
C	5.47	5.51
Ge	0.66	0.75
Si	1.12	1.16
GeAs	1.43	1.53

Table 10.8: **Values of a few semiconductors gaps**

and visually and in 3D here is another figure representing de various idealized bands:

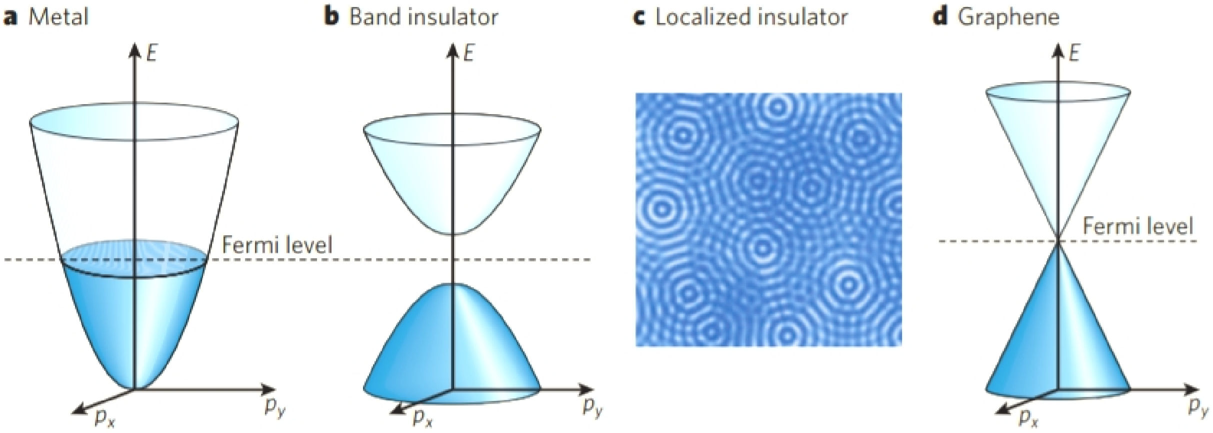

Figure 10.108: **Metal-insulator transitions (source: Carbon conductor corrupted, authors: Michael S. Fuhrer and Shaffique Adam)**

We understand then on the basis of these figures why the diamond, with a quasi-identical crystalline and atomic structure, is insulating while the silicon becomes conductive!

What is interesting for researchers is to combine materials in order to play with the width of the equation according to the needs!

Moreover, we can also conclude hastily ... that what differentiates insulators and semiconductors is the width of their forbidden band.

It should also be noted that the energy required for an electron to pass from the valence band to the conduction band can be supplied by radiation. In the case of light absorption, the energy equation of a photon may be sufficient for this as long as:

$$h\nu \geq E_g \tag{10.4.380}$$

At low temperatures, such a process is capable of making the material conductive (low-temperature space telescope technology). This property is named "photo-conductivity".

Finally, let us recall the two relations obtained above:

$$\begin{aligned}\bar{n}=\rho_C(E)=2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2}\exp\left(\frac{\mu-E_C}{kT}\right)\\ \bar{p}=\rho_V(E)=2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2}\exp\left(\frac{E_V-\mu}{kT}\right)\end{aligned} \tag{10.4.381}$$

The product of these two densities possesses a very interesting property. We can observe that it is independent of the position of the Fermi level and named "intrinsic density":

$$\begin{aligned}\bar{n}\cdot\bar{p}&=2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2}\exp\left(\frac{\mu-E_C}{kT}\right)\cdot 2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2}\exp\left(\frac{E_V-\mu}{kT}\right)\\ &=\left[2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2}\right]^2\exp\left(\frac{E_V-E_C}{kT}\right)=N^2\exp\left(\frac{E_V-E_C}{kT}\right)=N^2\exp\left(\frac{E_g}{kT}\right)\end{aligned} \tag{10.4.382}$$

For example, some values of the square root of the intrinsic density at 300 [K] are given in the table below:

Material	$\bar{n}\bar{p}$
Ge	$2.5\cdot 10^{13}$ [cm^{-3}]
Si	$1.6\cdot 10^{10}$ [cm^{-3}]
GaAs	$1.1\cdot 10^{7}$ [cm^{-3}]

Table 10.9: **Some square root intrinsic density values**

We also notice that the critical density is strongly temperature dependent. These values of densities are obviously idealized, in reality these values are much lower due to imperfections (residual impurities, defects in crystallization, etc.) which locally disrupt the periodicity of the potential and, therefore, introduce energy levels which can be accessible to electrons. In contrast to the levels corresponding to the pure material, we will speak of "extrinsic levels".

10.4.6.4 Ohm's law of Semiconductors

We have proved in the framework of the Drude model that the conductivity was given by:

$$\sigma=\frac{nq^2\tau}{m} \tag{10.4.383}$$

where n is for recall the density of carriers in the material. We have also proved that the current is inversely proportional to the conductivity according to the relation:

$$U=RI=\left(\frac{1}{\sigma\dfrac{S}{L}}\right)I \tag{10.4.384}$$

In the framework of the developments made above we have seen that the density n of the carriers was given respectively by the following relations for a constant potential (model hypothesis):

$$N_n=2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2}\exp\left(\frac{\mu-E_C}{kT}\right)\qquad\text{and}\qquad N_p=2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2}\exp\left(\frac{E_V-\mu}{kT}\right) \tag{10.4.385}$$

where the relative masses m_e of the quasi-particle (negative carrier or positive carrier) are not necessarily equal! Thus, we have the resistance which can be approximated by a relation of the form:

$$\boxed{R=A\exp\left(\frac{B}{T}\right)} \tag{10.4.386}$$

and we easily verify this dependence by graphically representing:

$$\ln(R)=\ln(A)+\frac{B}{T} \tag{10.4.387}$$

that is $\ln(R)$ as a function of $1/T$ (the resistance therefore depends only on the theoretical temperature at constant voltage).

The real complexity lies in the fact that many terms are dependent on temperature (Fermi level, mean free travel time, etc.) and the applied potential, which means that in reality the curves obtained are by no means according to the theory....!

A numerical application shows that the carrier densities N_n and N_p therefore increase very quickly already from the ambient temperature! What is consistent with the experience with non-degenerate semiconductors because we will then have the conductivity which increases just as strongly which implies a rapid decrease in resistance!

The high sensitivity of the conductivity of certain solids to temperature variations is the cause of many applications, both for conductive metals and semiconductors. This is what we name "thermistors".

Finally, let us notice that in the case of Silicium, we have $E_g=1.12$ [eV] whereas the kinetic energy due to the thermal agitation (see section Continuum Mechanics page 3897) is given at ambient temperature by:

$$E_{c,\text{th}}=\frac{3kT}{2}=\frac{1}{2}m_e v_{th}^2\cong 0.037\ [\text{eV}] \tag{10.4.388}$$

But, we have already seen that only the electrons whose energy was close to that of the Fermi level could participate in the conduction. Their kinetic energy then given by:

$$E_{c,F}=\frac{1}{2}m_e v_F^2\cong 1.12\,[\text{eV}] \tag{10.4.389}$$

where v_F is the "Fermi velocity" (velocity of electron-wave in a conductor).

By equalizing the last two relations:

$$\frac{1}{2}m_e v_F^2=\frac{1}{2}m_e v_{\text{th}}^2\cong 0.037\,[\text{eV}] \tag{10.4.390}$$

There is therefore a ratio of a factor of 30 between the two energies, either by taking the square root, a ratio of 5 between the velocities. Therefore we have:

$$v_F \gg v_{\text{th}} \tag{10.4.391}$$

But we have already seen, in our study of the Drude model, that the thermal velocity led us to a superior average distance of one order of magnitude (factor 10) of the inter-atomic distances. And here we have a factor 5 more !!!! Thus more than 50 inter-atomic distances! The mean free path of an electron of conduction is therefore much greater than that which we had determined from the classical Drude model. Thus, the mean free path does not seem to be due to collisions with the ions of the network but it is due to the network's imperfections: structural defects, foreign atoms ...

A perfect (pure) semiconductor, without imperfections, as we have theoretically treated it so far, is named an "intrinsic semiconductor": it therefore has no impurity and its electrical behaviour depends only on the Structure of the material. This behaviour corresponds to a perfect semiconductor, that is to say without structural defects or chemical impurities. A real semiconductor is never perfectly intrinsic, but can sometimes be as close as pure mono-crystalline silicon.

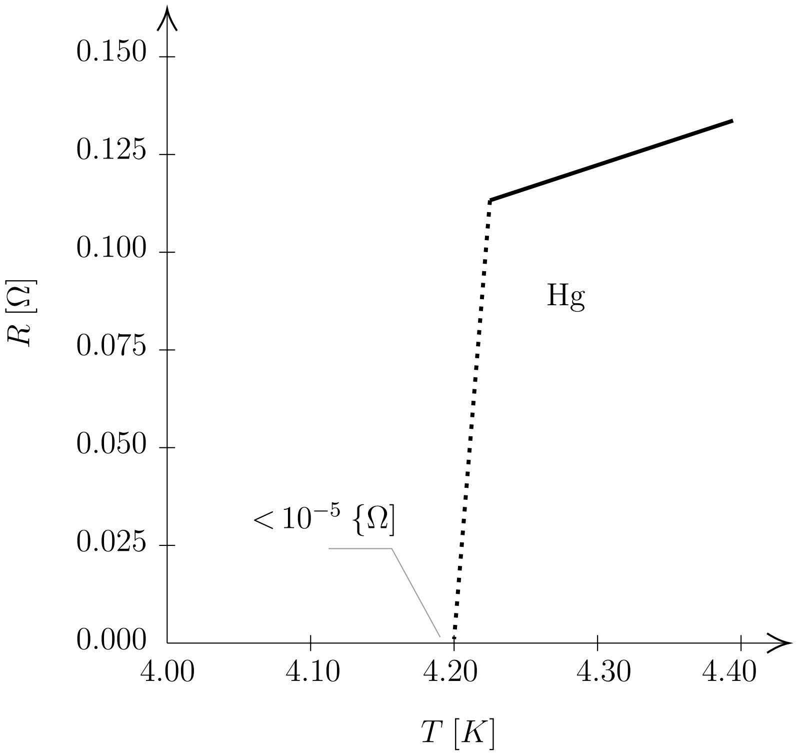
In an intrinsic semiconductor, the charge carriers are generated only by thermal excitation. The number of electrons in the conduction band is then equal to the number of holes in the valence band as shown by our theoretical model.

It must be realized that these semiconductors actually do not, or very little, conduct the current, except if we carry them at high temperature.

10.4.7 Superconductivity

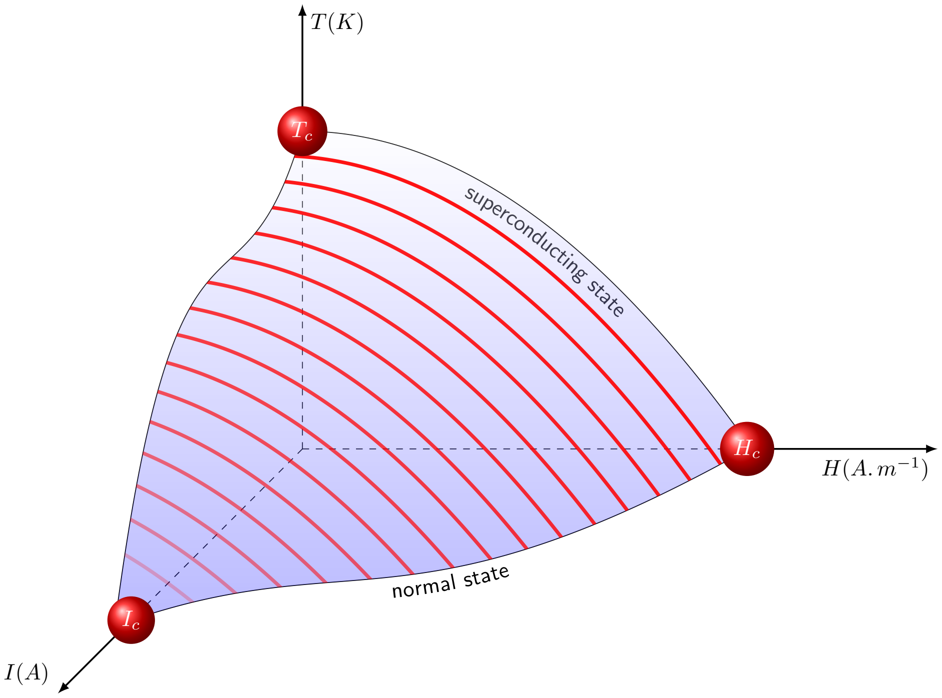
"Superconductivity" is a phenomenon of exactly zero electrical resistance and expulsion of magnetic flux fields occurring in certain materials, named "superconductors", when cooled below a characteristic critical temperature. It was discovered by Dutch physicist Heike Kamerlingh Onnes on April 8, 11911 (holocene calendar), in Leiden (he get the Nobel Prize for this discovery on with the element Mercury Hg).

Like ferromagnetism and atomic spectral lines, superconductivity is a quantum mechanical phenomenon. It is characterized by the Meissner effect, the complete ejection of magnetic field lines from the interior of the superconductor as it transitions into the superconducting state. The occurrence of the Meissner effect indicates that superconductivity cannot be understood simply as the idealization of perfect conductivity in classical physics.



Superconductors are also able to maintain a current with no applied voltage whatsoever, a property exploited in superconducting electromagnets such as those found in MRI machines. Experiments have demonstrated that currents in superconducting coils can persist for years without any measurable degradation. Experimental evidence points to a current lifetime of at least 100,000 years. Theoretical estimates for the lifetime of a persistent current can exceed the estimated lifetime of the universe, depending on the wire geometry and the temperature.

In reality the superconductivity depend of different variables as illustrated below:



10.4.7.1 Meissner effect (second London's equation)

The "Meissner effect" is the expulsion of a magnetic field from a superconductor during its transition to the superconducting state. The German physicists Walther Meissner and Robert Ochsenfeld discovered this phenomenon in 11933 (holocene calendar) by measuring the magnetic field distribution outside superconducting tin and lead samples. The samples, in the presence of an applied magnetic field, were cooled below their superconducting transition temperature. Below the transition temperature the samples cancelled nearly all interior magnetic fields. They detected this effect only indirectly because the magnetic flux is conserved by a superconductor: when the interior field decreases, the exterior field increases. The experiment demonstrated for the first time that superconductors were more than just perfect conductors and provided a uniquely defining property of the superconductor state.

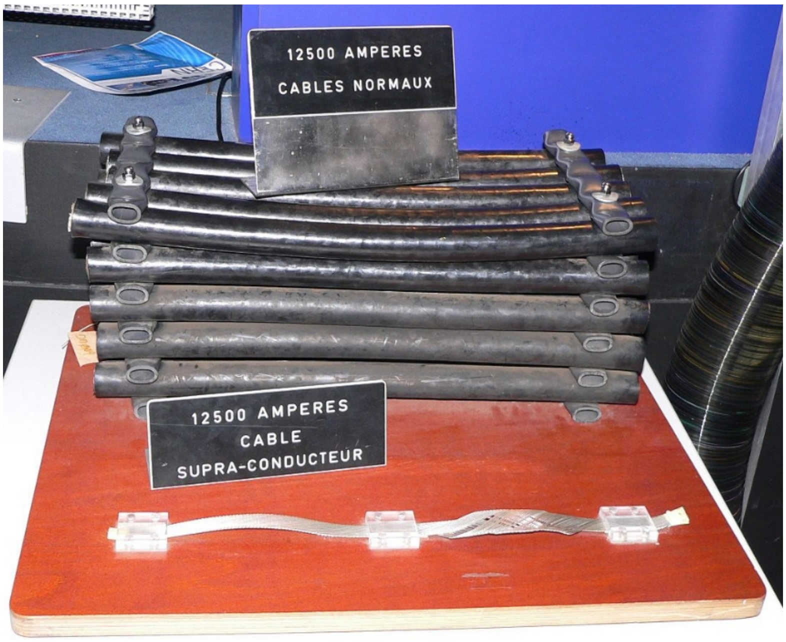


Figure 10.109: **Electric cables for accelerators at CERN (source: Wikipedia)**

A superconductor with little or no magnetic field within it is said to be in the "Meissner state". The Meissner state breaks down when the applied magnetic field is too large. Superconductors can be divided into two classes according to how this breakdown occurs:

- In "Type I superconductors", superconductivity (perfect diamagnetism behaviour) is abruptly destroyed when the strength of the applied field rises above a critical value H_c. Depending on the geometry of the sample, one may obtain an intermediate state consisting of a baroque pattern of regions of normal material carrying a magnetic field mixed with regions of superconducting material containing no field.

- In "Type II superconductors", raising the applied field past a critical value H_{c1} leads to a mixed state (also known as the "vortex state") in which an increasing amount of magnetic flux penetrates the material, but there remains no resistance to the flow of electric current as long as the current is not too large. At a second critical field strength H_{c2}, superconductivity is destroyed. The mixed state is actually caused by vortices in the electronic superfluid, sometimes named "fluxons" because the flux carried by these vortices is quantized. Most pure elemental superconductors, except niobium and carbon nanotubes, are Type I, while almost all impure and compound superconductors are Type II.

We will now determine London's second equation. It relate the external magnetic field applied on a sample to the value of this same magnetic field inside the sample.

We consider for this purpose that in the superconductor phase, the electric charge carrier of mass m, of electric charge q, of density ρ, animated of a speed v such that their kinetic energy is written:

$$E_c = \iiint_V \frac{1}{2} m\vec{v}^2 \rho \circ \mathrm{d}^3\vec{r} \qquad (10.4.392)$$

where the integral is obviously extended to the whole sample volume of the superconductor.

We have proved earlier that we also:

$$\vec{j}=\rho q\vec{v} \tag{10.4.393}$$

and in static regime, it is linked to the magnetic field $\vec{B}$ by the four Maxwell equation and if the conductor is perfect it has no capacity and we can omit the second term such that it remain:

$$\vec{\nabla}\times\vec{B}=\mu\vec{j} \tag{10.4.394}$$

Combining these relations we have:

$$\begin{aligned}E_c&=\iiint_V \frac{1}{2}m\vec{v}^2\rho\circ\mathrm{d}\vec{V}=\iiint_V \frac{1}{2}m\left(\frac{\vec{j}}{\rho q}\right)^2\rho\circ\mathrm{d}\vec{V}=\iiint_V \frac{1}{2}m\left(\frac{\vec{\nabla}\times\vec{B}}{\mu\rho q}\right)^2\rho\circ\mathrm{d}^3\vec{r}\\&=\frac{m}{2\mu^2\rho q^2}\iiint_V(\vec{\nabla}\times\vec{B})^2\circ\mathrm{d}\vec{V}=\frac{1}{2\mu}\left(\frac{m}{\mu\rho q^2}\right)\iiint_V(\vec{\nabla}\times\vec{B})^2\mathrm{d}V\\&=\frac{1}{2\mu}\left(\sqrt{\frac{m}{\mu\rho q^2}}\right)^2\iiint_V(\vec{\nabla}\times\vec{B})^2\circ\mathrm{d}\vec{V}\end{aligned} \tag{10.4.395}$$

It is important at this step to notice that we assume that in the superconductor that since $\vec{v}\neq 0$ there is like as permanent current! So if we observe the Meissner effect it means that implicitly that there is something like a current inside the superconductor sample and this without that we need to provide any external potential (voltage)!

The term in parenthesis has the dimension of a length and is named "London penetration depth" and denoted λ_L such that the latter equality is written:

$$E_c=\frac{1}{2\mu}\lambda_L^2\iiint_V\vec{\nabla}\times\vec{B}\circ\mathrm{d}\vec{V} \tag{10.4.396}$$

Furthermore, we have prove in the section of Electrodynamics that the energy density of a monochromatic wave was given by:

$$u_B=\frac{1}{2\mu}\hat{B}^2 \tag{10.4.397}$$

Therefore we assume that to the external magnetic field energy is given by:

$$E_B=\iiint_V\frac{1}{2\mu}\vec{B}^2\circ\mathrm{d}\vec{V} \tag{10.4.398}$$

The total energy is the written:

$$E_{\text{tot}}=\frac{1}{2\mu}\iiint_V\left(\vec{B}^2+\lambda_L^2(\vec{\nabla}\times\vec{B})^2\right)\circ\mathrm{d}\vec{V} \tag{10.4.399}$$

The total energy should be, by the Maupertuis principle, minimal for the real magnetic field profile that we will denote $B^*(\vec{r})$ and that we are looking for.

The variational δE_{tot} is then equal to zero if the profile $B(r)$ departs only in an infinitesimal way from the real profile from a quantity $\delta B(\vec{r})$. Therefore:

$$\begin{aligned}\delta E_{\text{tot}}&=\frac{1}{2\mu}\iiint_V\left(2\vec{B}\delta\vec{B}+2\lambda_L^2(\vec{\nabla}\times\vec{B})\delta(\vec{\nabla}\times\vec{B})\right)\circ\mathrm{d}\vec{V}=\frac{1}{\mu}\iiint_V\left(\vec{B}\delta\vec{B}+\lambda_L^2(\vec{\nabla}\times\vec{B})\delta(\vec{\nabla}\times\vec{B})\right)\circ\mathrm{d}\vec{V}\\&=\frac{1}{\mu}\iiint_V\left(\vec{B}\delta\vec{B}+\lambda_L^2(\vec{\nabla}\times\vec{B})(\vec{\nabla}\times\delta\vec{B})\right)\circ\mathrm{d}\vec{V}=\frac{1}{\mu}\iiint_V\left(\vec{B}\delta\vec{B}+\lambda_L^2\mathrm{rot}(\vec{B})\mathrm{rot}(\delta\vec{B})\right)\circ\mathrm{d}\vec{V}\end{aligned} \tag{10.4.400}$$

But we have introduced in the section of vector Calculus the following identity:

$$\vec{\nabla}(\vec{x}\times\vec{y})=\vec{y}\cdot(\text{rot}(\vec{x}))-\vec{x}\cdot(\text{rot}(\vec{y})) \tag{10.4.401}$$

Therefore with $\vec{x}=\text{rot}(\vec{B})$ and $\vec{y}=\delta\vec{B}$ we have:

$$\vec{\nabla}(\text{rot}(\vec{B})\times\delta\vec{B})=\delta\vec{B}\cdot(\text{rot}(\text{rot}(\vec{B})))-\text{rot}(\vec{B})\cdot(\text{rot}(\delta\vec{B})) \tag{10.4.402}$$

Therefore:

$$\text{rot}(\vec{B})\cdot(\text{rot}(\delta\vec{B}))=\delta\vec{B}\cdot(\text{rot}(\text{rot}(\vec{B})))-\vec{\nabla}(\text{rot}(\vec{B})\times\delta\vec{B}) \tag{10.4.403}$$

Therefore our variational can be written:

$$\begin{aligned}\delta E_{\text{tot}}&=\frac{1}{\mu}\iiint_V\left(\vec{B}\delta\vec{B}+\lambda_L^2\text{rot}(\vec{B})\text{rot}(\delta\vec{B})\right)\circ\text{d}\vec{V}\\&=\frac{1}{\mu}\iiint_V\left[\vec{B}\delta\vec{B}+\lambda_L^2\left(\delta\vec{B}\cdot(\text{rot}(\text{rot}(\vec{B})))-\vec{\nabla}(\text{rot}(\vec{B})\times\delta\vec{B})\right)\right]\circ\text{d}\vec{V}\\&=\frac{1}{\mu}\left\{\iiint_V\left[\vec{B}+\lambda_L^2\text{rot}(\text{rot}(\vec{B}))\right]\cdot\delta\vec{B}\circ\text{d}\vec{V}-\lambda_L^2\iiint_V\vec{\nabla}(\text{rot}(\vec{B})\times\delta\vec{B})\circ\text{d}\vec{V}\right\}\end{aligned} \tag{10.4.404}$$

Now let us recall the Ostrogradsky theorem proved in the section of Vector Calculus:

$$\iiint_V(\vec{\nabla}\circ\vec{f})\text{d}V=\iiint_V\vec{\nabla}(\vec{f})\circ\text{d}\vec{V}=\oiint_S\vec{f}\circ\text{d}\vec{S} \tag{10.4.405}$$

Therefore:

$$\begin{aligned}\delta E_{\text{tot}}&=\frac{1}{\mu}\left\{\iiint_V\left[\vec{B}+\lambda_L^2\text{rot}(\text{rot}(\vec{B}))\right]\cdot\delta\vec{B}\circ\text{d}\vec{V}-\lambda_L^2\iiint_V\vec{\nabla}(\text{rot}(\vec{B})\times\delta\vec{B})\circ\text{d}\vec{V}\right\}\\&=\frac{1}{\mu}\left\{\iiint_V\left[\vec{B}+\lambda_L^2\text{rot}(\text{rot}(\vec{B}))\right]\cdot\delta\vec{B}\circ\text{d}\vec{V}-\lambda_L^2\oiint_S(\text{rot}(\vec{B})\times\delta\vec{B})\circ\text{d}\vec{S}\right\}\end{aligned} \tag{10.4.406}$$

The surface integral is always zero since, by hypothesis, $\vec{B}$ is fixed on the sample boundary ($\delta\vec{B}(r_{\text{surface}})=0$), therefore it remains:

$$\delta E_{\text{tot}}=\frac{1}{\mu}\iiint_V\left[\vec{B}+\lambda_L^2\text{rot}(\text{rot}(\vec{B}))\right]\cdot\delta\vec{B}\circ\text{d}\vec{V} \tag{10.4.407}$$

The real $B^*(\vec{r})$ we are looking for is such that:

$$\delta E_{\text{tot}}=\frac{1}{\mu}\iiint_V\left[B^*(\vec{r})+\lambda_L^2\text{rot}(\text{rot}(B^*(\vec{r})))\right]\cdot\delta B^*(\vec{r})\circ\text{d}\vec{V}=0 \tag{10.4.408}$$

Therefore we can try the trivial solution:

$$B^*(\vec{r})+\lambda_L^2\text{rot}(\text{rot}(B^*(\vec{r})))=\vec{0} \tag{10.4.409}$$

But we have seen in the section of Vector Calculus that:

$$\text{rot}(\text{rot}(\vec{f}))=\overrightarrow{\text{grad}}(\text{div}(\vec{f}))-\Delta\vec{f} \tag{10.4.410}$$

Therefore (don't forget that the divergence of the magnetic field is always equal to zero!):

$$\text{rot}(\text{rot}(B^*(\vec{r}))) = \overrightarrow{\text{grad}}(\text{div}(B^*(\vec{r}))) - \Delta B^*(\vec{r}) = -\Delta B^*(\vec{r}) \tag{10.4.411}$$

Therefore:

$$B^*(\vec{r}) - \lambda_L^2 \Delta B^*(\vec{r}) = \vec{0} \tag{10.4.412}$$

Hence:

$$\Delta B^*(\vec{r}) - \frac{1}{\lambda_L^2} B^*(\vec{r}) = \vec{0} \tag{10.4.413}$$

Now it must be notice that we cannot have B_x that of x if the sample is put in a magnetic field that is static and uniform otherwise we would not have $\text{div}(B^*(\vec{r})) = 0$. And as we need $\text{rot}(B^*(\vec{r})) = \mu\vec{j}$ then as simple solution is to suppose that each component B_i depends only on a coordinate that is perpendicular to itself. Therefore we will choose B_z as depending on x such that the latter differential equation will be written for this component:

$$\frac{\partial^2 B_z(x)}{\partial x^2} - \frac{1}{\lambda_L^2} B_z(x) = 0 \tag{10.4.414}$$

A special simple solution is obviously:

$$\boxed{B_z(x) = B_0 e^{-x/\lambda_L}} \tag{10.4.415}$$

This relation is knows as the "second London's equation". The fact that the magnetic field decrease exponential inside the material is interpreted (...) in many textbooks and by many physicists as the fact the superconductor rejects the magnetic field since in laboratories we have the following observation:

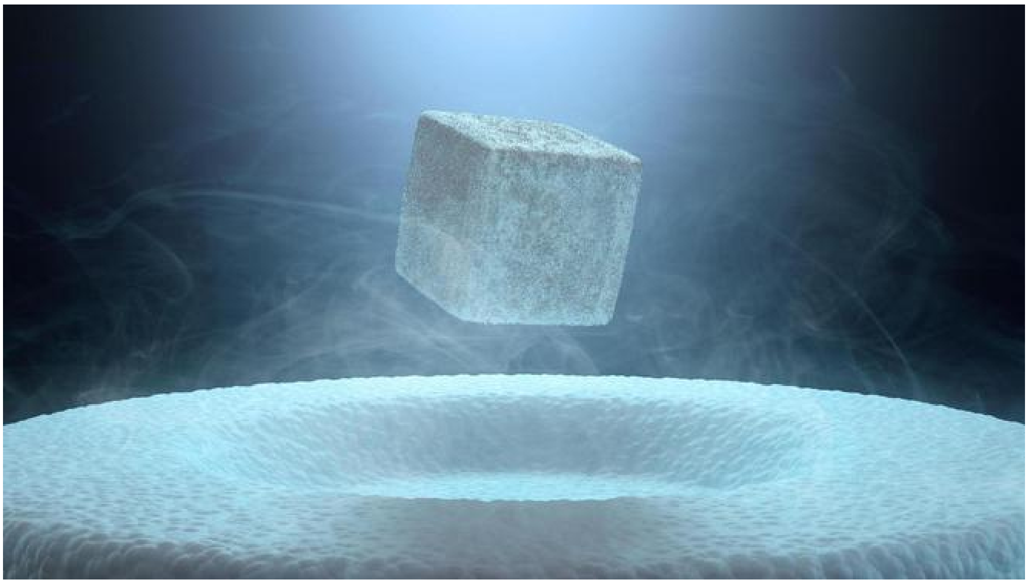

Figure 10.110: **Observation of a superconductor in levitation in magnetic field due to Meissner effect**

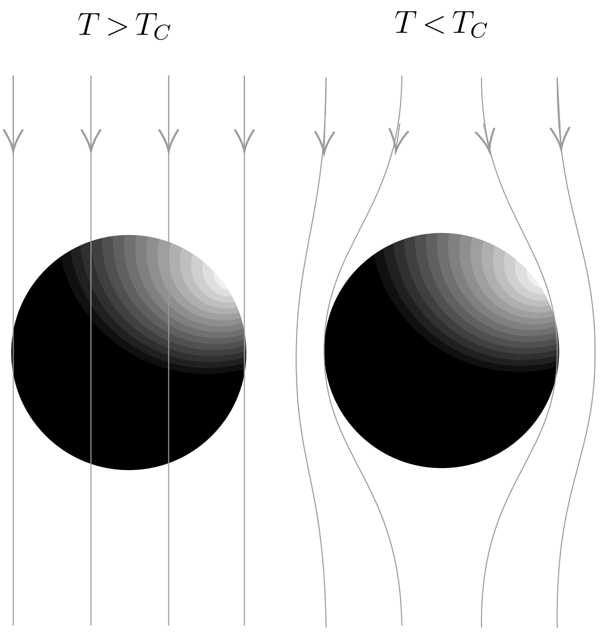
This bring us to the following well known misleading figure below that we can see on many Internet sites and in many textbooks:



The derivation above proposed by Pierre-Gilles de Gennes for undergraduate class that don't use Quantum Physics is however a coincidence (as there exists many others in physics)! Obviously we see that this derivation of the London equation is very not appropriate. In this derivation the fact that the metal is in superconducting state is not used at all for example... Therefore, if this derivation is correct, any metal should show the Meissner effect.

10.5. Optics (ray optics)

OPTICS is the study of the fraction of radiant energy sensitive to the retina, that is to say the "light" or said more generally: the "electromagnetic waves" (see section Electrodynamics page 4138) and over a wide frequency band which is not limited (depending on the case studies) to visible light!

We chose in this textbook to split the study of "geometrical optics" or simply "optics" into three parts: the photometry (see below), geometrical optics (this section) and wave optics (next section).

Definitions (#10.5.481):

D1. "Photometry" is responsible for the study of some of the variables definitions of energy properties of electromagnetic waves with respect to the visual sensitivity.

D2. "Geometrical optics" is responsible for the study that describes the propagation of light in transparent media without involving the nature of light. This is a part of physics has the advantage not to require complicated mathematical tools, but a lot of good geometrical sense...

D3. "Wave optics" is responsible for the study where the luminous phenomena are interpreted taking into account of the nature of light. This is considered as an electromagnetic wave of a given wavelength defining its color (subjective concept as we will discussed below). This use much more complicate tools as Fourier transforms and Green theorem for example.

In some experiments, however, we must consider light as a corpuscular phenomenon (see section Wave Quantum Physics). We assume then that it is formed by particles, "photons" whose energy is proportional to the light frequency according to the Planck's law (not the Planck's law of thermodynamics ... the other one!).

For consistency reasons, as we have already mentioned, we have chosen to put photometry in the section of Geometric Optics (here so...).

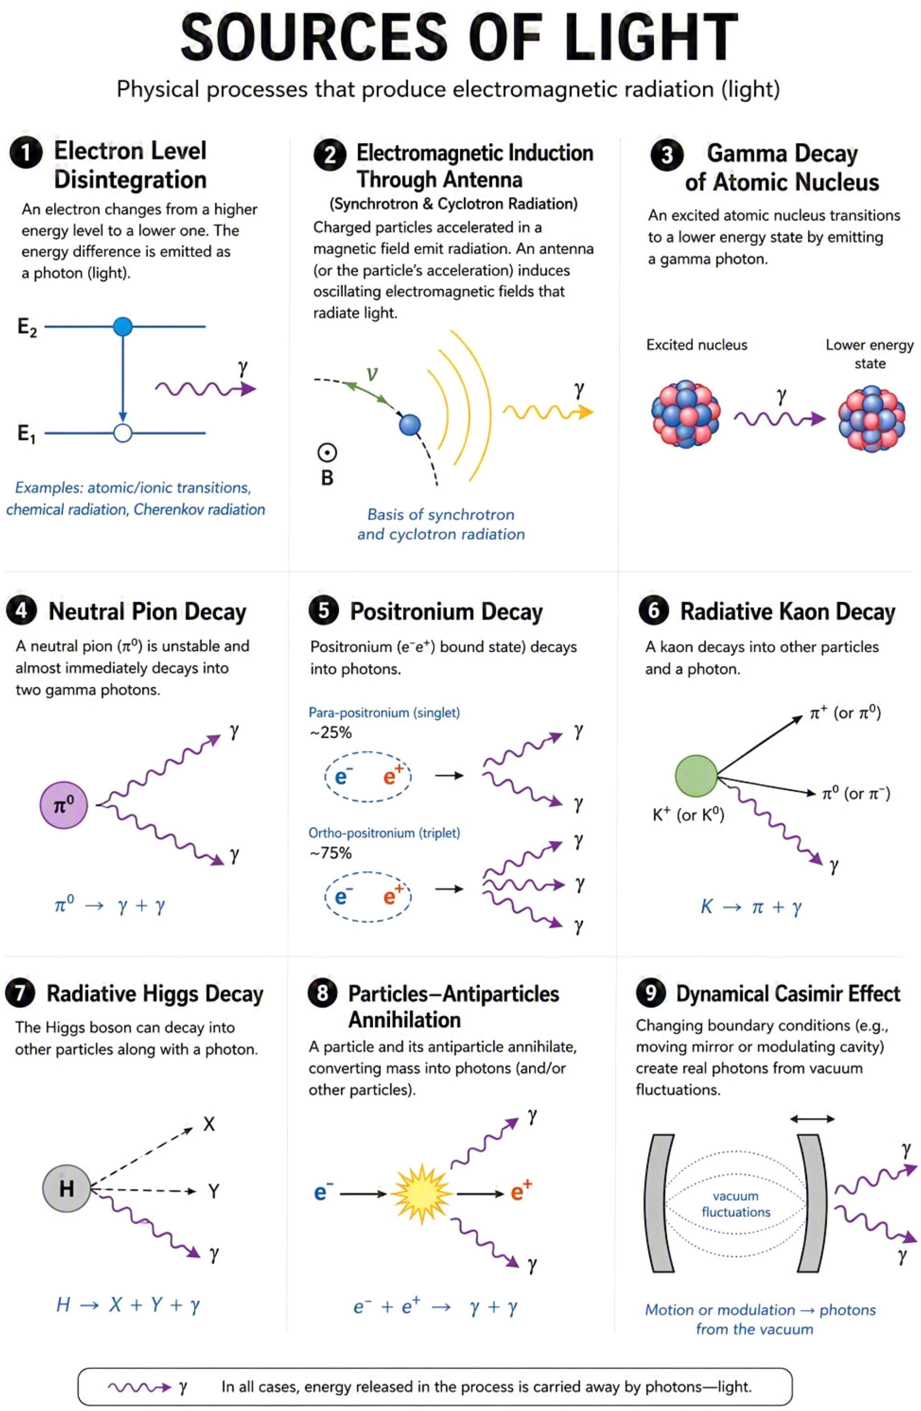
Before we start studying the mathematics of geometrical optics, it seemed good to us clarify some blurred areas of optics that are rarely clearly defined or not even treated at all in most physics books. Thus, we will first present what is a source of light or an absence of light and then how colors are seen and treated by humans (and most similar animals).

Remark

It would be pretentious to claim to do with this section as well and also complete as the *Optics* textbook of Eugene Hecht that is a priori unrivalled in content and quality to this date. It is therefore strongly recommended to refer to it if the reader wants to drive full information about Optics ([239])!

10.5.1 Sources and Shadows

Experience teaches us that in a homogeneous and transparent medium light travels in a straight line (at least in a flat space) and that the latter always comes from "light sources".



SOURCES OF LIGHT

Physical processes that produce electromagnetic radiation (light)

1 Electron Level Disintegration

An electron changes from a higher energy level to a lower one. The energy difference is emitted as a photon (light).

Examples: atomic/ionic transitions, chemical radiation, Cherenkov radiation

2 Electromagnetic Induction Through Antenna

(Synchrotron & Cyclotron Radiation)

Charged particles accelerated in a magnetic field emit radiation. An antenna (or the particle's acceleration) induces oscillating electromagnetic fields that radiate light.

Basis of synchrotron and cyclotron radiation

3 Gamma Decay of Atomic Nucleus

An excited atomic nucleus transitions to a lower energy state by emitting a gamma photon.

Excited nucleus
γ
Lower energy state

4 Neutral Pion Decay

A neutral pion (π^0) is unstable and almost immediately decays into two gamma photons.

π^0
γ
γ

$\pi^0 \rightarrow \gamma + \gamma$

5 Positronium Decay

Positronium (e^-e^+) bound state) decays into photons.

Para-positronium (singlet)
~25%
e^- e^+
γ
γ
Ortho-positronium (triplet)
~75%
e^- e^+
γ
γ
γ

6 Radiative Kaon Decay

A kaon decays into other particles and a photon.

π^+ (or π^0)
π^0 (or π^-)
K^+ (or K^0)
γ

$K \rightarrow \pi + \gamma$

7 Radiative Higgs Decay

The Higgs boson can decay into other particles along with a photon.

$H \rightarrow X + Y + \gamma$

8 Particles–Antiparticles Annihilation

A particle and its antiparticle annihilate, converting mass into photons (and/or other particles).

e^-
e^+
γ
γ

$e^- + e^+ \rightarrow \gamma + \gamma$

9 Dynamical Casimir Effect

Changing boundary conditions (e.g., moving mirror or modulating cavity) create real photons from vacuum fluctuations.

vacuum fluctuations
γ
γ

Motion or modulation → photons from the vacuum

γ In all cases, energy released in the process is carried away by photons—light.

Some objects are illuminated by themselves (Sun, Flames, etc.). Some other objects are not generally visible in the dark in the visible bandwidth (when there is absolutely no source of light) but if they are illuminated they send back all or part of light in some or all directions and therefore behave like light sources but with less intensity as the original one.

Definitions (#10.5.482):

D1. A "punctual source" is a unique "bright spot".

D2. An "extended source" is a set being a sum of punctual sources.

D3. A "light ray" is any straight line (or "geodesic"...) that light will follow.

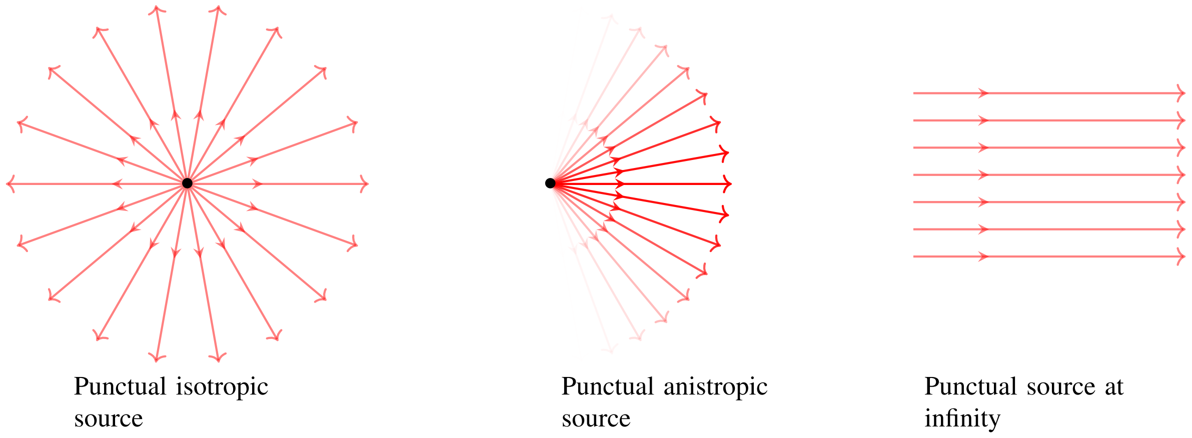
D4. A "reversible light ray" is a light ray that will follow the exactly same path backwards if we reverse its direction of propagation.

D5. A "light beam" is a set of light rays.

D6. A "ray diagram" is used to determine the image location, size, orientation and type of image formed by objects when place at a given location from a mirror or lens. They proved useful information about object-image relations and focal-geometry properties.

D7. An "apparent diameter" is the angle, usually small, under which we see one of the dimensions of an object (angle in radians as seen in the section of Trigonometry).

Light passes through empty space (assumed as because we will see during study of quantum field theory that there are not such things as "empty space") without undergoing alteration (on small distance at least...). Thus is how Sunlight, before reaching the limit of the Earth's atmosphere, travel through huge empty spaces without undergoing major transformations.



Punctual isotropic source
Punctual anistropic source
Punctual source at infinity

Figure 10.111: **Various types of light punctual sources (author: Jimmy Roussel)**

On Earth, between a luminous object and the seeing eye of the object, the light passes through a certain thickness of air. The object remains visible in other gases, or through a sheet of glass, mica, cellophane ..., or even through a layer of water, alcohol, glycerine ... such bodies are "transparent media" (even if they alter the quality of the image).

Most bodies do not let light pass through. Placed between the eye and a luminous object, they suppress the vision of the object: then we say that they are "opaque bodies".

In fact, no substance is perfectly transparent and propagation in a transparent medium is always accompanied by a weakening. This phenomenon of absorption depends on the nature of the medium and increases with the thickness of material traversed. Thus the water, even very pure, is opaque at a thickness of a few hundred meters. Also the deep seabed never receive sunlight.

Sometimes some bodies, named "translucent bodies", let light filter without allowing the eye to identify the object that emits light. These are frosted glass, striped glass, thin porcelain, oiled paper...

In a dark space, the eye located outside the path of light, sees this path thanks to fine solid particles (dust, tobacco smoke, fog, etc.) suspended in the air. These illuminated particles scatter the light they receive, becoming as many bright spots which materialize the volume traversed by the light. The familiar observation shows that these light volumes still seem limited by straight lines of light.

We can therefore apply the theorem of Thales to some light phenomena. So imagine the following experiment:

We create quite small dimensions light sources that we can consider as point sources (i.e. bright spots).

Consider S is such a point source of light. Consider the volume that the source S illuminates through an aperture in a diaphragm located in the path of the light at a distance d. If we denote by AB the circular diameter of the opening diaphragm K and that we cut the light path by a screen E, parallel to K and at a distance D from the source, we would observe that the irradiated region is limited by a disc of diameter $A'B'$.

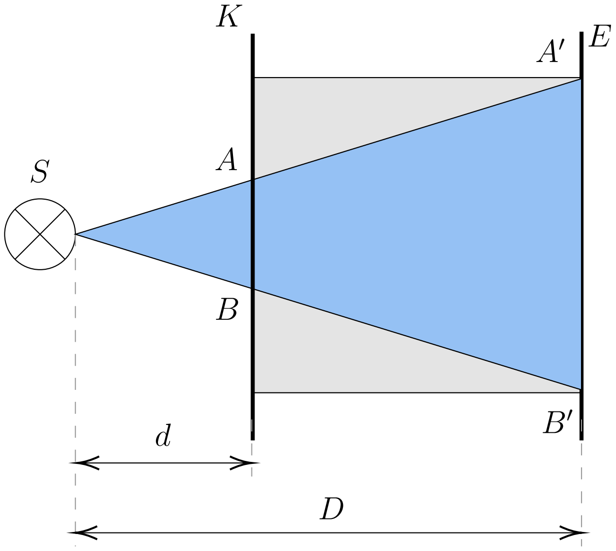


Figure 10.112: Application of Thales' theorem on punctual sources

If we can measure the diameters AB and $A'B'$ of the two discs and their distances d and D to the source, we would find that they satisfy the Thales' theorem and therefore that:

$$\frac{A'B'}{AB}=\frac{D}{d} \tag{10.5.1}$$

It is also proof that the light volume is effectively limited by straight lines issues from S and leaning on the edge of the aperture.

These observational facts and basic experience suggest the following hypothesis:

In a homogeneous transparent medium (remember that a medium is homogeneous when all is infinitesimal volumes have the same physical properties) light coming from a light spot propagates along straight lines from this point. These lines are named as we already know "light rays".

If we return to the previous above figure, all the light rays contained in the cone defined by the source S and the diaphragm K is also as we already know a "light beam".

Definitions (#10.5.483):

D1. Light travelling here from S we say then that the ray "diverges" or that the beam is a "divergent beam" (at the opposite of the LASER for those that know what is a LASER).

D2. When a point source is at infinity (as is almost a star in the night sky for example), the rays that come from it are considered as parallel and the beams that they form are named "parallel beam" or "cylindrical beams".

D3. Thanks to a convergent lens (magnifying glass for example), we will see that it is possible to change the direction of rays from a punctual source and make the concentrate on a point S'. Such a set of rays then constitutes a "convergent beam".

A very narrow light beam takes the name of "light pen". For example, the rays from a light spot on the eye always form a very slender pencil of light, because the distance from the observed eye is necessarily large compared to the diameter of the pupil.

If we return to our experience with the diaphragm: If we decrease the opening of the diaphragm that will limit a light beam to a light pen, we observe (when the diameter is reduced to less than a few tenths of a millimetre) that the trace of the brush on a screen E, rather than diminish, expands (!) and this is an evidence that the light reaches now points outside of the cone $SA'B'$.

It is as if the very small aperture AB itself became a punctual source: we say that the light is "diffracted". We will return later to this property of light because it is a fairly elaborate mathematical study (see section Wave Optics page 4492) and therefore complex to handle but still very very interesting (having huge implications because related to quantum physics!).

Now consider a punctual source of light. Between the source and a screen E, let us interpose an opaque body of any shape. Under the assumption of rectilinear propagation, we observe a "shadow cone" limited by the rays that are based on the outline of the interposed body.

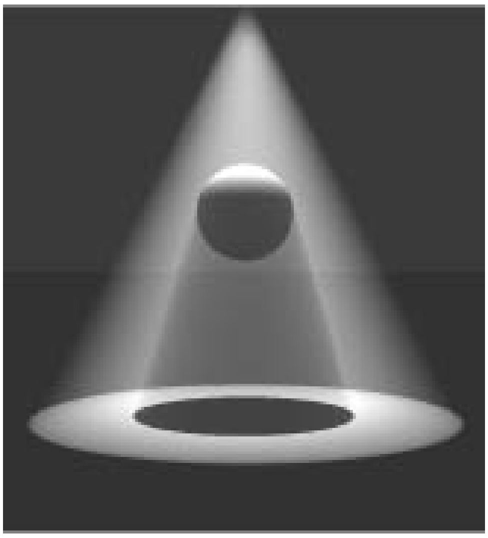

Figure 10.113: Shadow cone with proper shadow example

Definitions (#10.5.484):

D1. The non-illuminated region of an opaque body is the "proper shadow" or "umbra".

D2. The non-illuminated region of an opaque body that matches the screen is the "projected shadow".

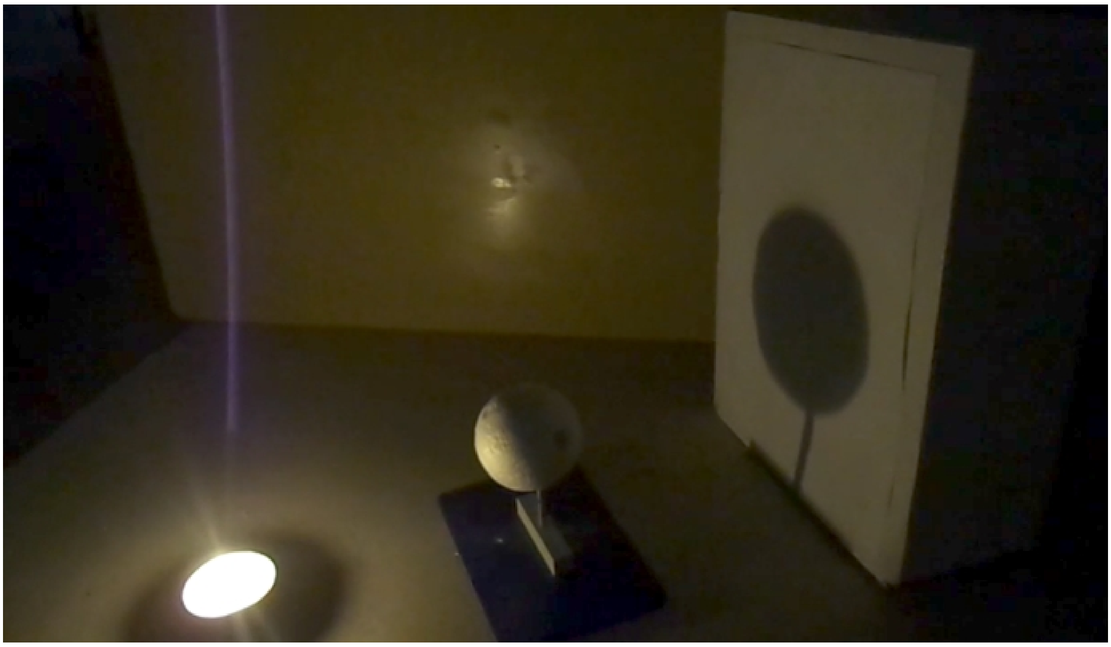

Figure 10.114: Shadow of a ball with a point like source of light

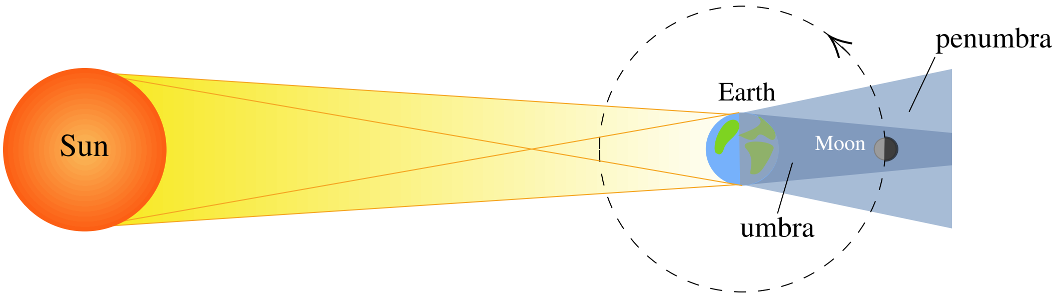
If the light source is extended, the proper shadow and projected shadow have no longer clearly defined contours. Their edges are surrounded by an intermediate area which is named the "penumbra". A well known example is given by the figure below (obviously not to scale[11]...!):



penumbra
Earth
Sun
Moon
umbra

Figure 10.115: Shadow cone with penumbra example

Below we can see an experimental configuration with an extended source of light to see the penumbra of a ball:

4
umbra < 3/4" (~1.9 cm)
penumbra < 3/4" (~1.9 cm)

Figure 10.116: Penumbra and umbra of a ball with an extended like source of light (credit: L. Hedberg City College New-York Planetarium)

Definition (#10.5.485): As the "shadow" (whatever the type of shadow, "proper shadow/umbra" or "projected shadow") is an area defined by the light that surrounds it, then obviously it is quite common to say that «*the shadow is refracted*» or that «*the shadow is reflected*» when in reality it is the light surrounding the shadow that is reflected or refracted.

---

[11] Don't forget that the Sun has actually a diameter of approximately 109 times that of the Earth and that the angular size of the Sun is of 0.53° (or 32 arcminutes). Hence even if in the figure above - that is not to scale for reminder... - the light rays seem significantly not parallel, in reality there are almost parallel!!

As we can see in the photo below, the mirrors seems to reflect the various shadows of the surrounding room when in reality it is the light surrounding that shadows that is reflected!:

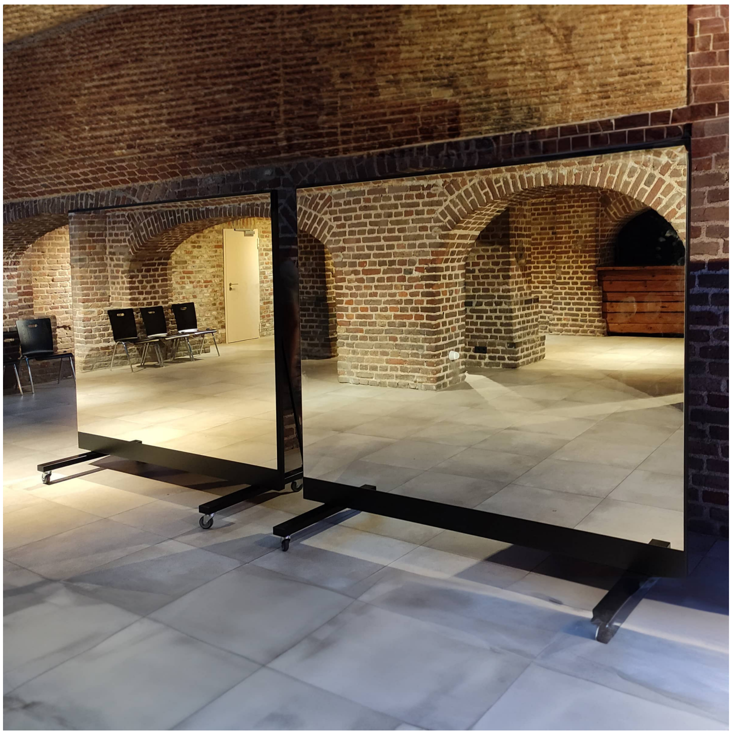

Figure 10.117: **Reflection of shadows (light surrounding shadows) by mirrors**

And here below an example of the shadow of a pen that is refracted by a recipient of glass with water:

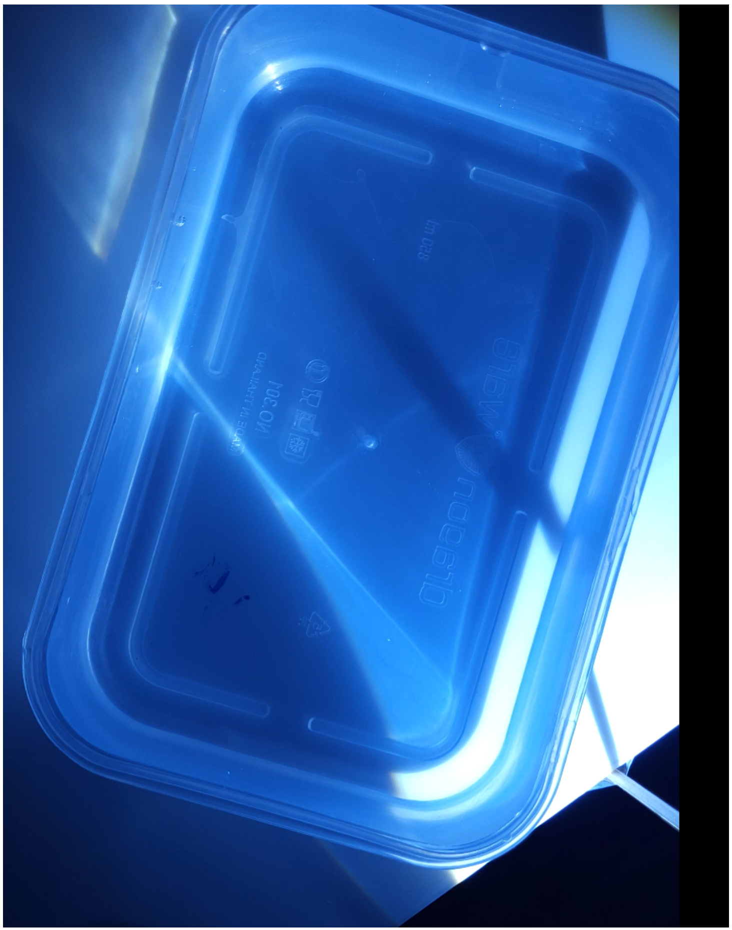

Figure 10.118: **Refraction of shadows (light surrounding shadows) by mirrors**

We may even define also a third type of shadow!

Definition (#10.5.486): A "caustic shadow" is an optical phenomenon where light, after being reflected or refracted by a curved or transparent surface (like glass or water), creates intricate patterns of brightness and shadow on another surface by interference.

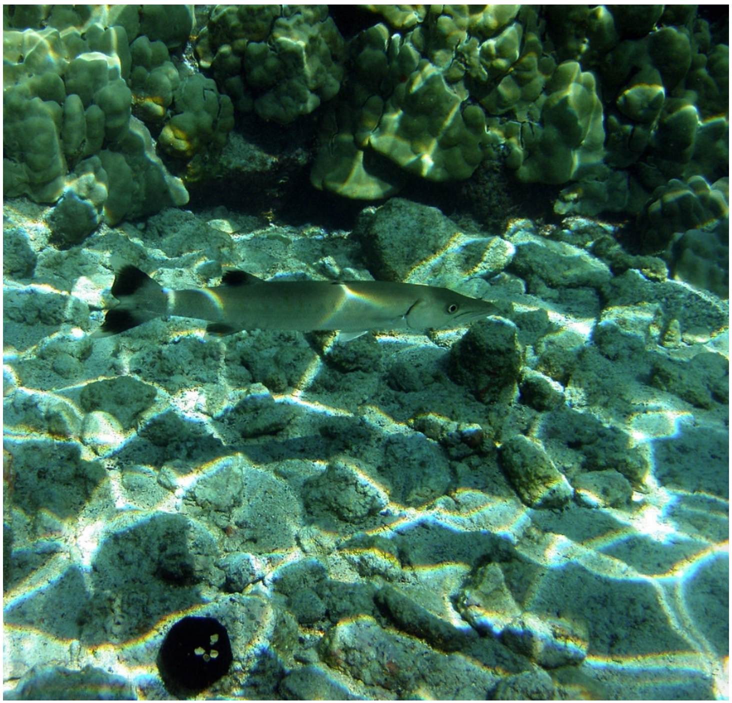

Figure 10.119: **Caustic on water surface**

To close this topic on shadows, let us mention the "magnetic shadow effect" that refers to a perceptual illusion where overlapping, blurry shadows (bokeh) in out-of-focus images appear to attract and merge, creating "blisters". For example, the sequence below from show such an effect:

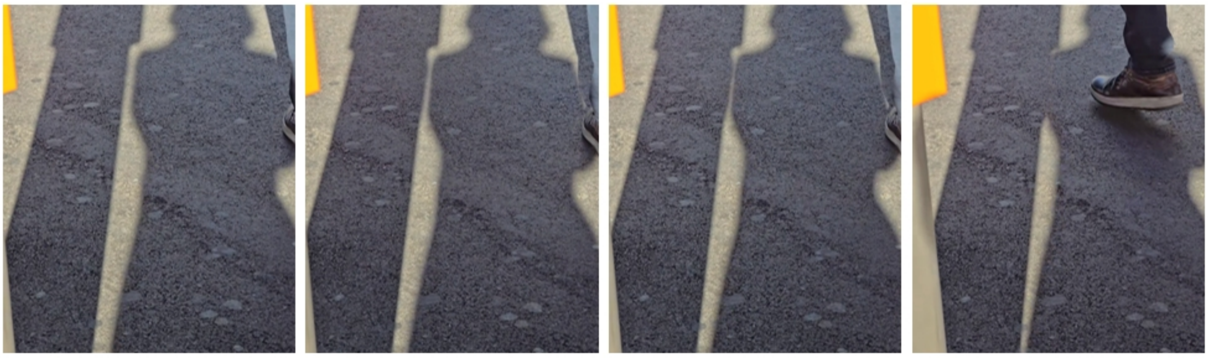

Figure 10.120: **Magnetic shadow effect**

The shadow the reader can see above is the really dark part (umbra). Imagine various lights behind you (the Sun rays). The part that blocks most rays is the darkest. Other parts block some rays but not all, so they are only slightly dark (penumbra). When slightly dark parts intersect, they get darker, like the figure below

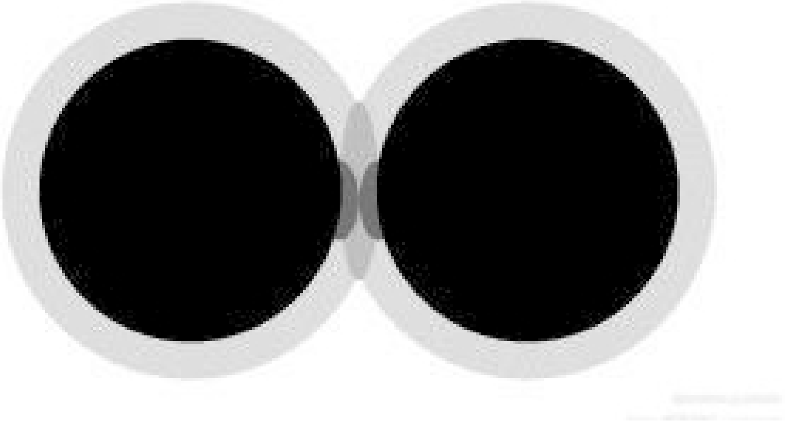

Figure 10.121: **Magnetic shadow effect explained**

By the way... Shadow patterns are sometimes difficult for the human brain to grasp (particularly for the brains of an unfortunate yet significant segment of the population that fails spatial cognitive tests like the quite famous one made by Ramful, A., Lowrie, T., and Logan, T.):

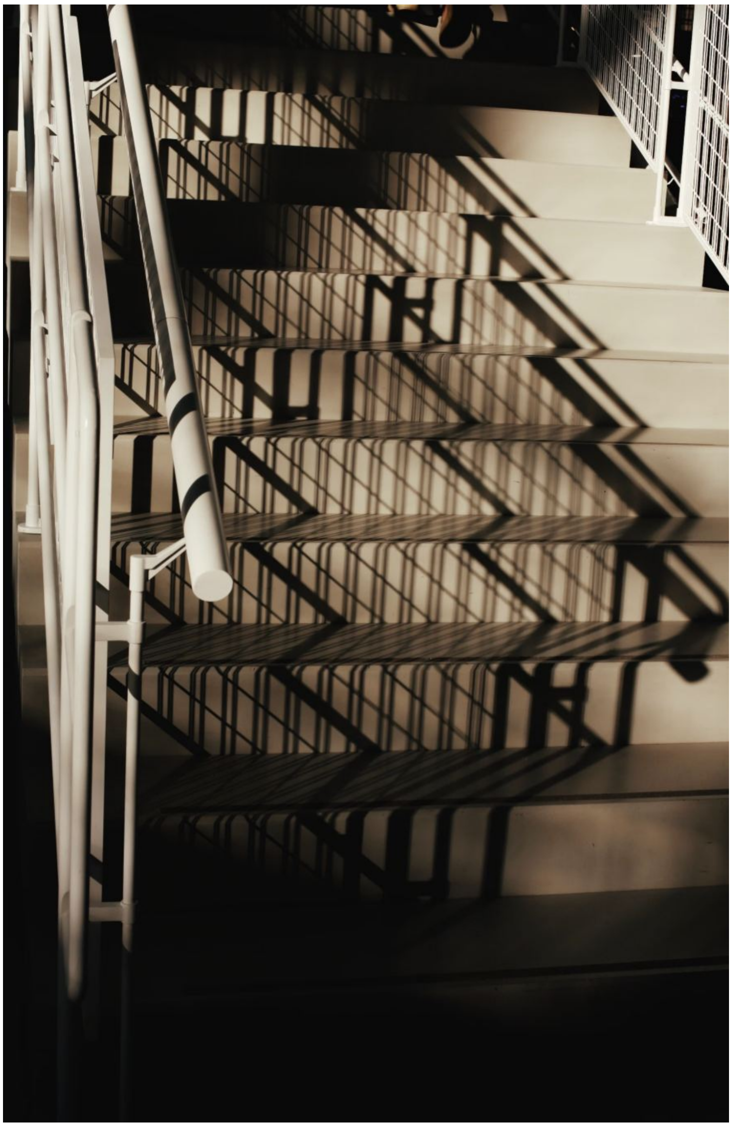

Figure 10.122: **Stairs with sunlight (photograph: Sofia Guzeva)**

10.5.2 Colors

Definitions (#10.5.487):

D1. We name "color" the perception of light excitation following neurophotochemical reaction process in the eye following of one or more light wave frequencies with one or more given amplitudes. This term is generally used to identify a frank or pure color, such as the primary and secondary colors of Itten, that is to say the yellow, the red (magenta), the blue, the orange, the purple and the green (therefore obviously "black" isn't a color as it correspond to the absence of radiation nor "white" as it sum of all colors of the visible spectrum!).

D2. We name "hue" the three primary colours (red, blue, and yellow) as well as the three secondary colours (orange, green, and purple). These colours are pure, meaning that white or black have not been mixed in with them.

D3. We name "tint" that is lighter than a pure hue, this is achieved by adding white. However, the term "tint" can also refer to a mixture of two colors. For example, turquoise is a shade resulting from the mixture of blue and green.

D4. We name "tone" a color to which white or black has been added (i.e. grey). Depending on how much white or black is added, a lighter or darker tone results. When you add white, you get a gradient tone, while when you add black, you get a broken tone.

D5. We name "shade" the result we get when just black is added to a pure hue. This makes the original colour darker. In a technical sense, black and white are not colors as we have already mention it, they're shades!

It is important never to confuse "color" that is a perceptive concept (it is not a physical property!!!) and "wavelength" that is a physical concept. Thus, the human eye is most often unable to distinguish a theoretical yellow monochromatic (single wavelength) of a corresponding composition of green and red. This illusion will display yellow on our computer screens, and more generally any color.

By the fact that the sensitive part of the retina of the human eye is made up of elements named "cones" each sensitive to a small bandwidth of wavelength corresponding respectively[12] to Red (via the erythrolabe molecule sensible to wavelength $\sim 700\,[\text{nm}]$ and denoted by the letter L) , Green (via the chlorolabe molecule sensible to wavelength $\sim 545\,[\text{nm}]$ and denoted by the letter M) and Blue (via the molecule cyanolabe sensible to wavelength $\sim 440\,[\text{nm}]$ and denoted by the letter S):

---

[12] According to some rare studies at this day (year 12019 according to holocene calendar), it seems that a few humans are able to see in some very special conditions (impulse LASER) low infra-red around $\sim 1000\,[\text{nm}]$

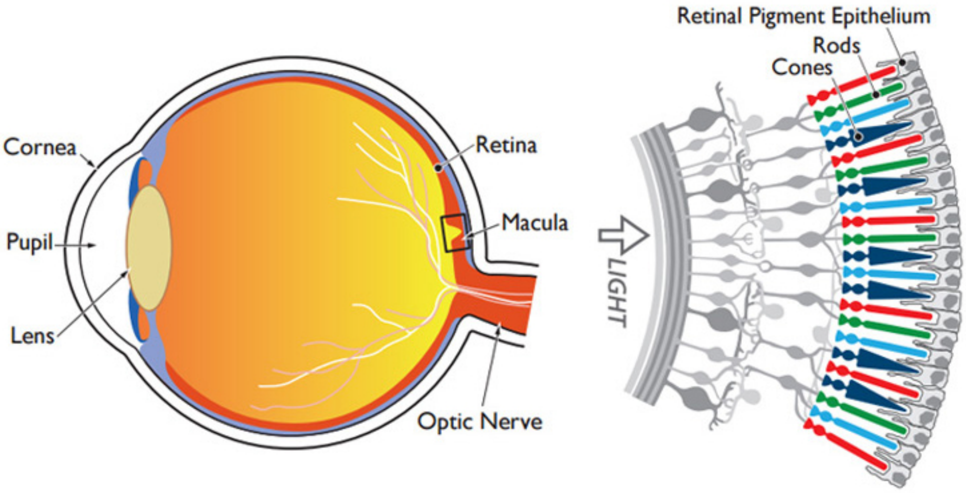

Figure 10.123: **Naive eye structure summary**

We can generate any color by adding these three basic colors named "additive primary colors" (or "additive primary colors"). This is named the "additive synthesis of colors".

Remark

Some scientists think (without proof and without being able to reproduce this fact) that the sensitivity to each of theses colors comes from: for the Red for the time where evolution was in water and animals were looking in infra-red, for the Green at the time where animals were on Earth with a luxurious and dense vegetation and finally for the Blue because of the blue sky!

In what follows, we will denote the red by (R), the green by (G), the blue by (B), the white by (W) and the black by (N):

Color	Wavelength interval	Frequency interval
red	$\sim 625-740$ [nm]	$\sim 480-405$ [THz]
orange	$\sim 590-625$ [nm]	$\sim 510-480$ [THz]
yellow	$\sim 565-590$ [nm]	$\sim 530-510$ [THz]
green	$\sim 500-565$ [nm]	$\sim 600-530$ [THz]
cyan	$\sim 485-500$ [nm]	$\sim 620-600$ [THz]
blue	$\sim 440-485$ [nm]	$\sim 680-620$ [THz]
violet	$\sim 380-440$ [nm]	$\sim 790-680$ [THz]

Table 10.10: **Visible spectrum summary**

As suggested by a unique scientific paper on a very small sample of people grouped as females/males (see [4]) there is a relatively small (of the order of a few percent only!) but clear and statistically significant, difference between males and females in the hue sensations elicited by almost the entire color spectrum. Generally, males required a slightly longer wavelength (a shift of 3 to 10 nanometres) to experience the same hue as did females. Furthermore there is a difference in pupil diameter between individuals that can sometimes double between to individuals of the same age (a smaller diameter means that less light enters the eye, so scotopic vision may be prevalent) that's why when people go chase the northern lights (or southern lights) there are sometimes important differences in the perception of the phenomena (see [593]).

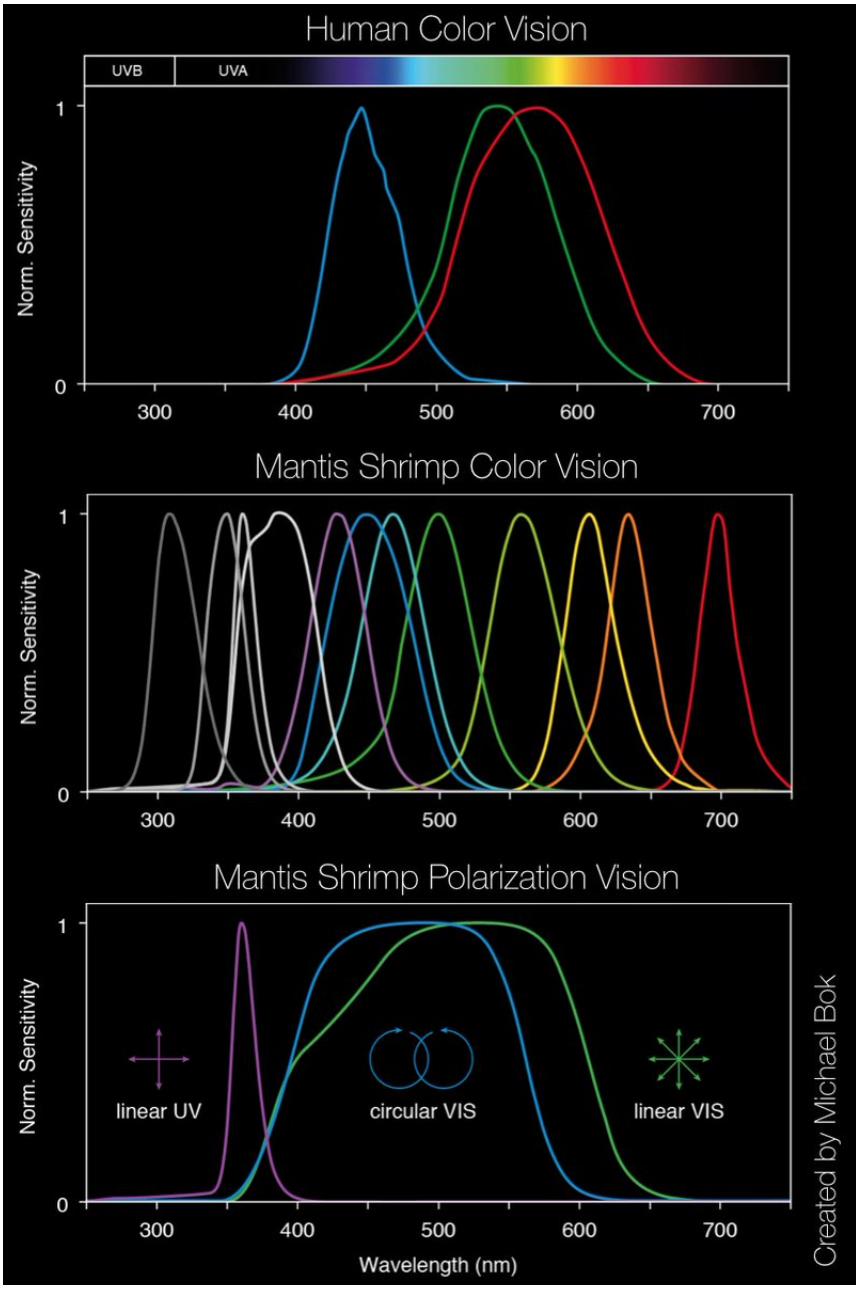
The entire rainbow of radiation observable to the human eye only makes up a tiny portion of the electromagnetic spectrum – about 0.0035%.

However, if you want to calculate the percentage represented by visible light at a given temperature of a black body, you can therefore use Planck's law (see section Statistical Mechanics page 3719):

$$p_{\text{vis.}}=\frac{2\pi\frac{h}{c^2}\int_{405\cdot 10^{12}}^{790\cdot 10^{12}}\frac{\nu^3}{e^{\frac{h\nu}{kT}}-1}\,\mathrm{d}\nu}{2\pi\frac{h}{c^2}\int_{0}^{+\infty}\frac{\nu^3}{e^{\frac{h\nu}{kT}}-1}\,\mathrm{d}\nu}=\frac{2\pi\frac{h}{c^2}\int_{405\cdot 10^{12}}^{790\cdot 10^{12}}\frac{\nu^3}{e^{\frac{h\nu}{kT}}-1}\,\mathrm{d}\nu}{\frac{2\pi^5k^4}{15c^2h^3}T^4}\cong\frac{2\pi\frac{h}{c^2}\int_{405\cdot 10^{12}}^{790\cdot 10^{12}}\frac{\nu^3}{e^{\frac{h\nu}{kT}}-1}\,\mathrm{d}\nu}{0.5188\cdot 10^{8}} \tag{10.5.2}$$

and for a temperature of $T=5,500$ [K] this ratio (computed with Maple™ 4.00b) is equal to 42.1% and for room temperature ($T=293.15$ [K]) it is equal to $0.752\cdot 10^{-22}\%$...

It's interesting to compare the human color vision with that of another animal like the mantis shrimp:



The French Association for Standardization (AFNOR) has defined in the 120th century (holocene calendar) the visual trivariance principle as follows: « *A radiation of any color can be produced visually identically by algebraic mixture, in a uniquely defined proportions, of luminous beam of three rays that can be arbitrarily selected, provided that none of them can be reproduced by a combination of the other two*».

Clearly when we see the frequencies of the visible spectrum it will not be tomorrow with the known material of this early 121st century (holocene calendar) that we are going to build antennas or parabola able to transmit at such frequencies! Already $120\;[\text{GHz}]$ is a challenge by the year 12010 (holocene calendar) then $500\;[\text{THz}]$ will not be for tomorrow...

The reader should know that until the years 11800 (holocene calendar) it was not known if the colors were limited or not those visible to the human eye. It was with the advent of thermometers with mercury that were sufficiently sensitive and specific that the astronomer Herschel placed one in front of a light spectrum and found that moving it from a color strip to the other, from violet to red, the temperature raised. To his surprise, it continued to rise when he accidentally let the thermometer to one or two centimetres beyond the red light visible bandwidth. Herschel detected invisible light to the human eye, described later as being infra-red radiation.

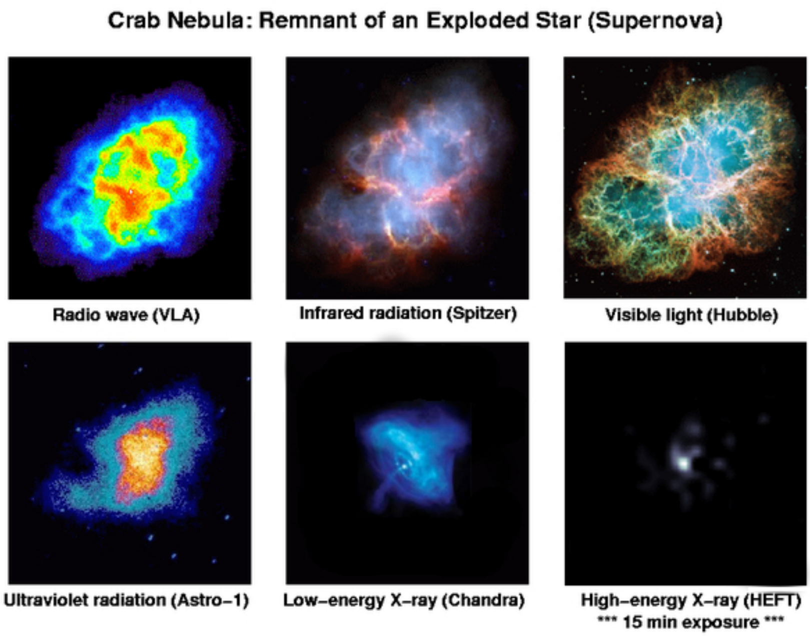
Remark

Experimental measurements of the early 121st century (holocene calendar) provide us strong evidence that hydrogen bonds ionization ranges between $1000\,[\text{kJ}\cdot\text{mol}^{-1}]$ to $2000\,[\text{kJ}\cdot\text{mol}^{-1}]$ (i.e. 10 [eV] to 20 [keV]) and hydrogen bonds energy ranges between $6\,[\text{kJ}\cdot\text{mol}^{-1}]$ to $1000\,[\text{kJ}\cdot\text{mol}^{-1}]$ (i.e. 0.06 [eV] to 10 [keV]). Keep in mind that to ionize or break such bonds, photons must have at least the same energy (the energy of multiple photons can't be summed easily as it is quantum physics under the hood). For the 0.06 [eV] ionization bond we need then photons with a frequency of at least 1 [THz]...

A magistral and pedagogical example of what can be seen in the various spectra is the Crab Nebula that is a supernova remnant resulting from the explosion of a historical supernova (SN 1054) observed by several Chinese astronomers of the dynasty Song from July 1054 to April 1056:



Crab Nebula: Remnant of an Exploded Star (Supernova)
Radio wave (VLA)

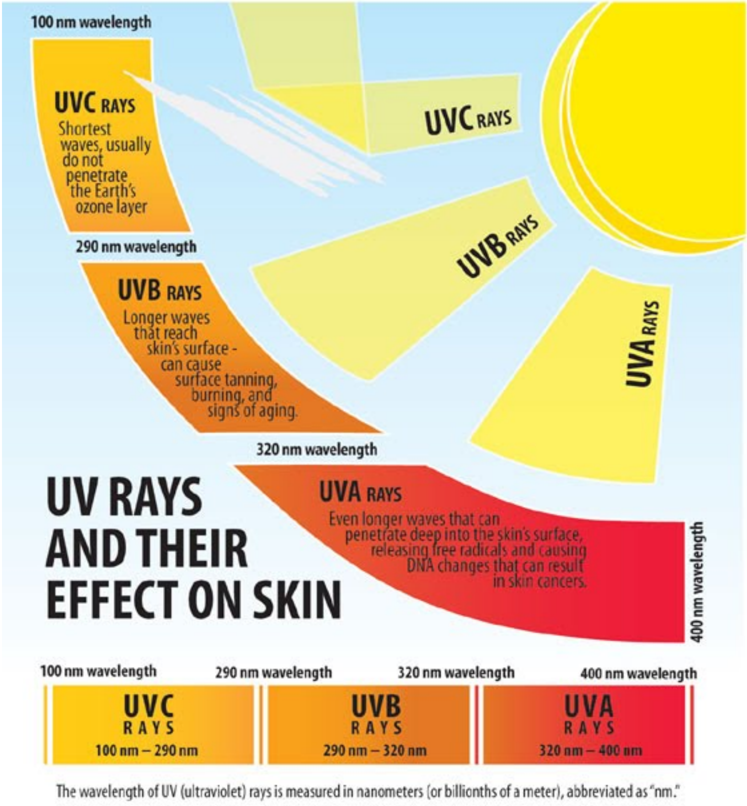
X-ray
Gamma

Figure 10.127: **Earth viewed under different wavelengths**

Also for health prevention reasons, let us inform that Ultraviolet[13] is commonly separated in three well known groups (UVC in space is a killer factor...):



100 nm wavelength
UVC RAYS
Shortest waves, usually do not penetrate the Earth's ozone layer
290 nm wavelength
UVB RAYS
Longer waves that reach skin's surface - can cause surface tanning, burning, and signs of aging.
320 nm wavelength
UVA RAYS
Even longer waves that can penetrate deep into the skin's surface, releasing free radicals and causing DNA changes that can result in skin cancers.
400 nm wavelength
UVC RAYS
UVB RAYS
UVA RAYS
UV RAYS AND THEIR EFFECT ON SKIN
100 nm wavelength
290 nm wavelength
320 nm wavelength
400 nm wavelength
UVC RAYS 100 nm – 290 nm
UVB RAYS 290 nm – 320 nm
UVA RAYS 320 nm – 400 nm
The wavelength of UV (ultraviolet) rays is measured in nanometers (or billionths of a meter), abbreviated as "nm."

Figure 10.128: **Various types of Ultraviolet rays**

And also let us give the following figure that is quite instructive (representing the state of knowledge and Earth's atmosphere of the early 121st century):

---

[13] The penetration depth of ultraviolet radiation in various materials depends on factors like wavelength and material type. In polymers the UV penetration depth is about 0.025 [mm], for glass the penetration depth may approach 0.5 [mm], for skin the UV penetration is about 2 [mm].

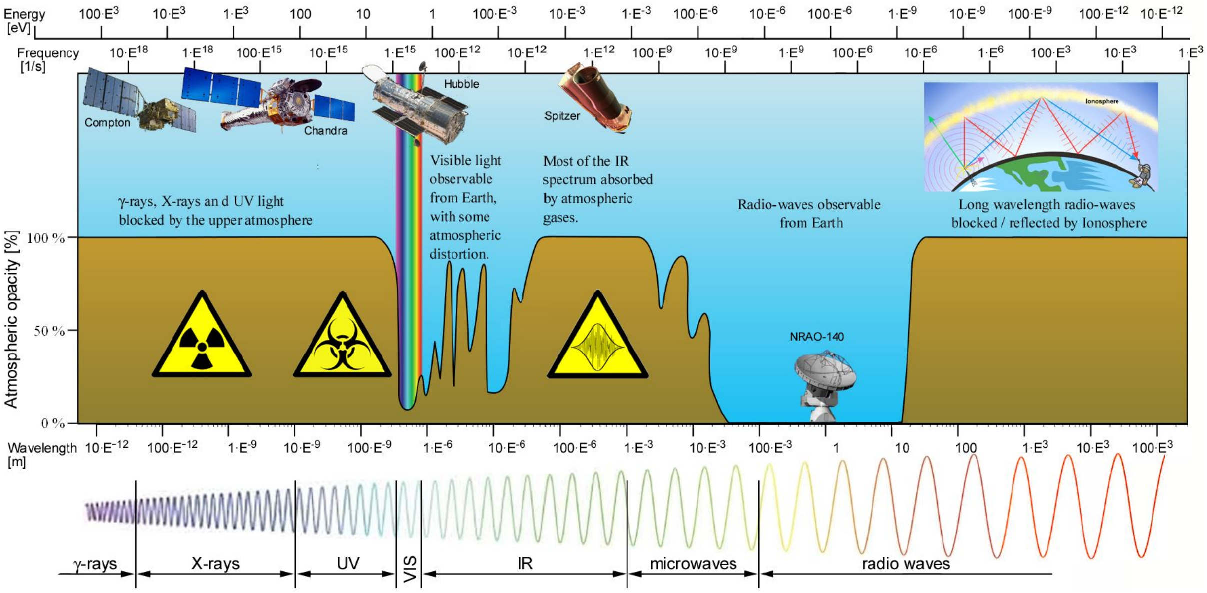


Figure 10.129: **Electromagnetic spectrum energy and atmosphere absorption (source: [177])**

Pointing three light beams (R, G and B) in the same place, we can get (in fact it would be more rigorous to say "perceived" because this is specific only to certain trichromats mammals): white light. We say then that white (W) (in the human sense) is the sum of the three additive primary colors (remember that white is rigorously the sum of all the colors of the spectrum - so that white is made of a continuous light spectrum). All imaginable colors are obtained by varying the intensity of each of the three beams. Black is obtained when we do send no light at all.

For example, if we add (in the theoretical sense: with infinitely small and transparent colors component ...) just red (R) and green (G), we get the yellow (Y), if we add the red and blue we get the magenta (M), if we add green (G) and blue (B), we get the Cyan (C). So we can sum this up by the following equations:

$$\begin{aligned} RG&=R+G=Y\\ RB&=R+B=M\\ GB&=G+B=C \end{aligned} \tag{10.5.3}$$

These three colors (YMC) obtained by adding two additive primary colors are named "secondary additive colors". The notion that blue and yellow form green is only a perception in our eyes!!! If the reader shine blue and yellow light on a chromograph it will show blue and yellow independently. In fact light doesn't interfere with light in our regular experience set at the opposite of sound. And this because as our eye only measure three things at the opposite of ears that measure every sound on the spectrum we can hear (as it do a indirectly a Fourier Transform).

Diagram of additive synthesis:

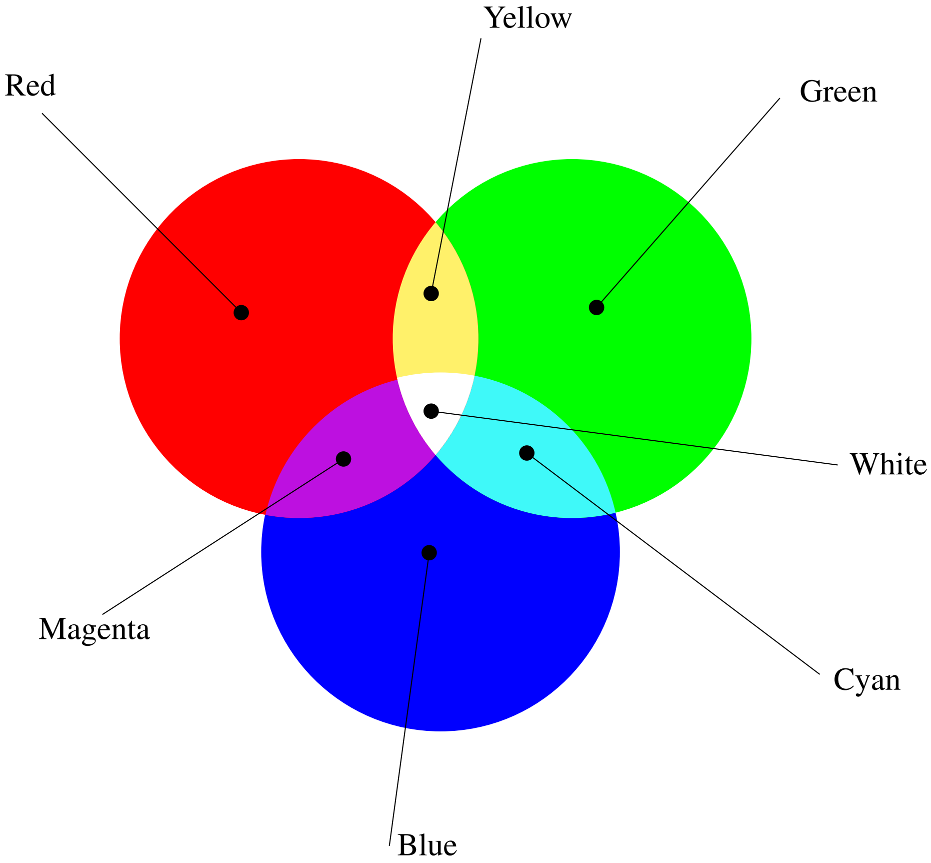

Figure 10.130: **Additive synthesis (RGB)**

The existence of these three types of pigments in our photoreceptor cones serves as physiological basis to the "trichromatic model" or of "visual trivariance".

Definition (#10.5.488): A color is named "complementary color" of another if they give white[14] when you add them. For example, yellow (Y) is the complementary color of blue (B):

$$Y+B=(R+G)+B=W \tag{10.5.4}$$

Remark

These chromatic concepts are quite useful or even important to understand as quantum chromodynamics use a special quantum number named the "color" to describe the state of quark. And the reasons that this quantum number is named "color" and that subject of study is named "quantum chromodynamics" is because it behaves similarly as the RGB system!!!

In contrast to additive synthesis, there are the "subtractive colors": it is that we are talking about when we take away the color to a base color. This is for example the case of the ink or of color filters (in the sense that there is a base support where color must be treated).

---

[14] Keep in mind that strictly speaking, white nor black are colors. White is the sum of all colors (electromagnetic waves radiation) from all the visible spectrum and black is the absence of colors (the absence of electromagnetic waves in the visible spectrum)

To understand what this is, let us put a red filter on a projector. The projected light will be red. We note that the filter has removed color to white light: W became R but as $W = RGB$, this means that the red color filter removed the GB to the white light of the overhead projector. With the same reasoning, we understand that a G filter subtracts the colors RB and B filter subtracts RG.

If we overlay two filters of different primary colors: for example, R and G filter filters, we will not get anything at all, that is, to say N. Indeed, the R filter let pass only red light and G filter subtracts this color and nothing remains. This leaves no more color, i.e. N.

We notice that filters R, G and B fail to synthesize different colors by subtraction as we get the black (N) as soon as we superimpose two different. What is very annoying when the concerned support is paper and the purpose is to print something colourful.

It is therefore more useful to use the yellow, magenta and cyan filters (Y, M and C) that is to say secondary additive colors. Indeed, a filter Y let pass yellow, that is to say RG. It therefore subtracts only the blue B to the original white W light. By the same principle, a magenta M filter subtracts green G and a filter cyan C subtracts red R.

We note therefore that the superposition of two filters of these secondary colors gives a new color to an existing support. We can synthesize any color by varying the intensity of each of the three filters Y, M and C that we overlay (on the projector or paper for example). We name these three colors "basic subtractive colors".

Scheme for subtractive synthesis:

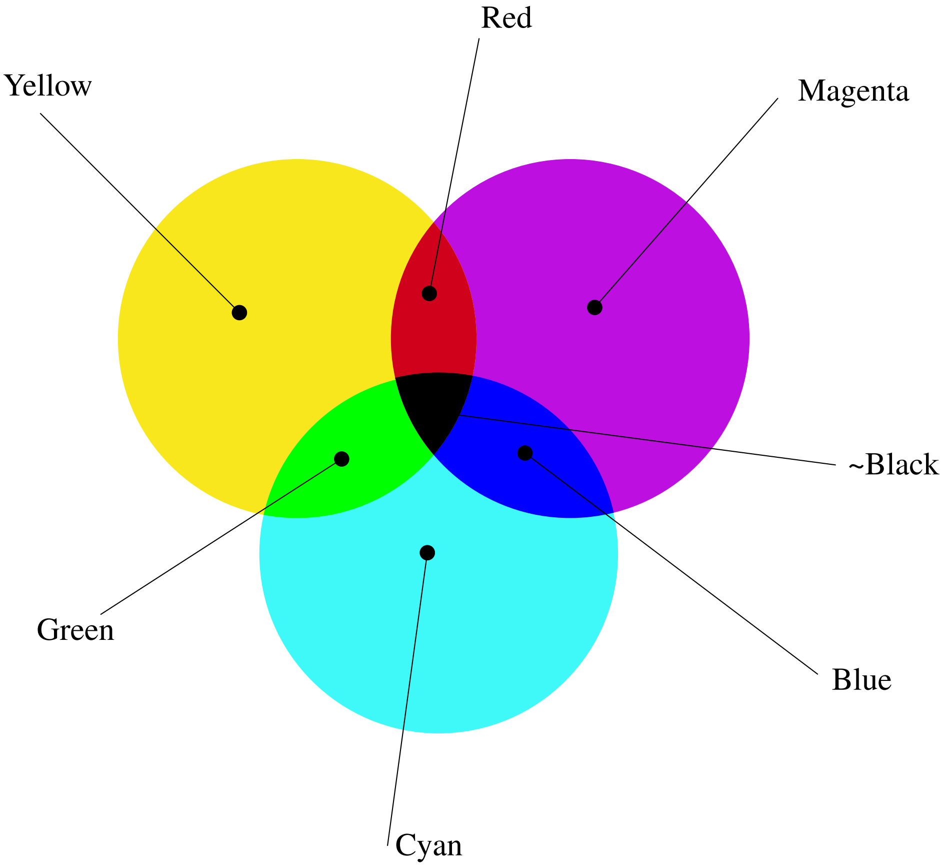

Figure 10.131: **Subtractive synthesis (CMYK)**

In reality we do not get a perfect black N this is why printers have a black color ink.

✍**Examples:**

E1. A television or computer screen works on the principle of additive color mixing. Indeed, looking at the screen through a magnifying glass, one can realize that it is filled with small groups (pixels) of three phosphors (bright area when excited by electricity) R, G and B. These phosphors are so close that when they light up together, they seem to get confused (at least on screen have a good "definition": pixels per inch) and most human therefore only sees the additive synthesis of the three phosphors. For example, on a television screen entirely red, only red phosphors glow. By cons, if the screen turns yellow, this means that green phosphors glow along with the red one.

E2. At the opposite to television or computer screens, we find the printing processes that operate in subtractive synthesis. Indeed, the sheet is white and you have to remove from it to get the color we are looking for. The technique is the same as that of filter: inks contain pigments which filter certain colors. Using Y, M and C inks we can get all colors of the visible spectrum. However, the pigments are not perfect and black N is very difficult to obtain (ink and color overload rather dark brown). So we use black as a fourth color. This system is named "quadrichromy printing". It is used for example in most color printers and in rotary newspapers.

It is interesting now to focus on the phenomena that overlap the two concepts (if we can say ...).

Thus, a system that projects color following a RGB concepts by additive or subtractive system itself may be illuminated by an equivalent system. This results in an effect overlay.

So when we talk about the color of objects, we normally refer to the appearance they have when they are illuminated with white light!

✍**Example:**

A red R tomato, absorbs some of the white light W (GB part) and distributes the rest (red R) back around. That is why it appears Red R to us when under white light. A yellow lemon, appears yellow to us because it absorbs the Blue B color distributes the rest around ($RG=R+G=Y$) .... But what about a tomato lit by a blue light? What looks like a yellow lemon if we illuminate it by red light?

We can answer by reasoning as follows: as tomato absorbs GB and therefore intrinsically Blue (B), there remains nothing. It then appears black N. For the lemon, as it absorbs the blue B and diffuses back $R+V=Y$ light so if we only illuminate it with red R it will only diffuse the red and therefore appear will appear Red R to us.

Because of how additive and subtractive light interference work, shadows aren't always black as illustrated below:

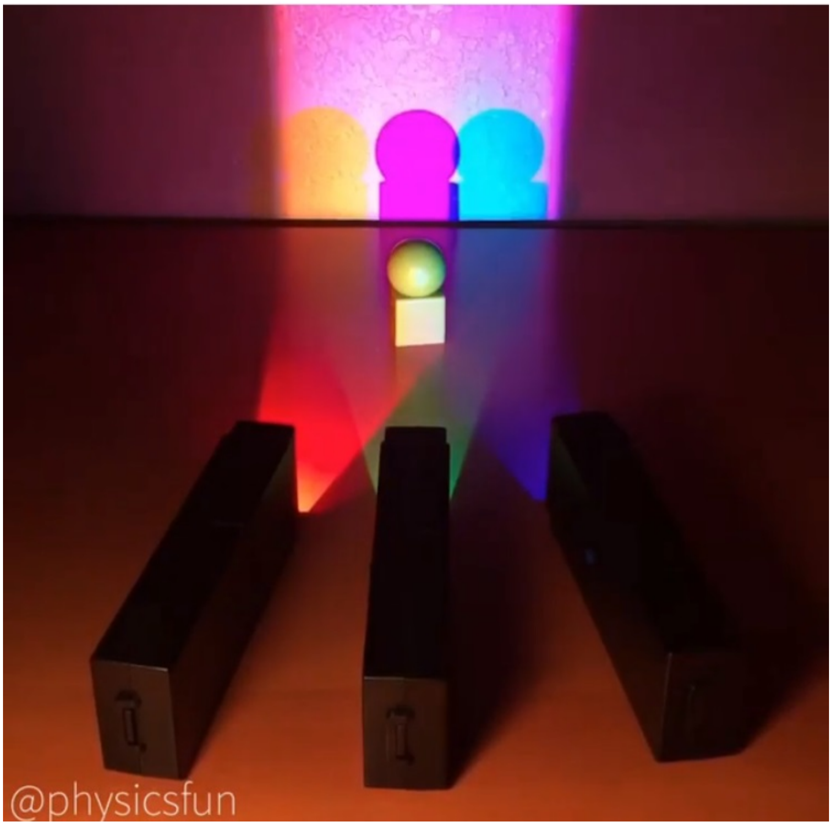

Figure 10.132: **Additive and Subtractive experiment (source: physicsfun instagram)**

10.5.3 Radiometry/Photometry

Material are capable of emitting, transmitting and / or absorb electromagnetic energy. Several factors characterize the radiation such as its spectral range, intensity, direction, and some intrinsic properties to the material. Photometry proposes to seek the magnitudes that are specific to the material and the laws governing them.

We recognize two types of photometry: "energetic photometry" and "visual photometry". In what follows, we will stick mainly to energetic photometry which generally relate to the energy carried by electromagnetic radiation, whatever its wavelength.

Beforehand, we have to specify the conditions under which we will define the new variables/quantities. We will assume the following assumptions:

H1. The radiation propagates in a transparent medium for all intensities, wavelength and polarization.

H2. The propagation takes place along the solid angles (see section Trigonometry page 2549). We therefore omit the radiation (approximation) in parallel rays.

H3. The elementary surfaces $\mathrm{d}S$ that are study are sufficiently small so that the radiation of their points are identical but not too small to avoid phenomena such as diffraction.

10.5.3.1 Energy flow

Definition (#10.5.489): The "energy flow" or "radiant flow" of a radiation source is the power it radiates. The flow equation is measured in Watts [W] (or joules per second $[\mathrm{J}\cdot\mathrm{s}^{-1}]$), and it follows therefore that for a source that radiates energy (not necessarily constant), we have:

$$\Phi=\frac{\mathrm{dE}_r(t)}{\mathrm{d}t} \tag{10.5.5}$$

In some professional fields the energy flow is expressed in photometric units as the "Lumen" denoted [lm] or in photonic units as a number of photons per second: $[\mathrm{s}^{-1}]$. This is why, when buying lamps or displays in some stores, the units are not the same from one brand to another... (ISO norms are not respected...!).

10.5.3.1.1 Beer–Lambert law

The "Beer–Lambert law", also known as "Beer's law", the "Lambert–Beer law", or the "Beer–Lambert–Bouguer law" relates the attenuation of light to the properties of the material through which the light is travelling. The law is commonly applied to chemical analysis measurements and used in understanding attenuation in physical optics, for photons, neutrons or rarefied gases.

If the absorption and diffusion of a medium can be considered proportional to the thickness $\mathrm{d}z$ of the crossing matters, the energy flow variation can be written:

$$\mathrm{d}\Phi=-\mu\Phi_0\mathrm{d}z \tag{10.5.6}$$

in this expression Φ_0 is the incident energy flow and $\mu\,[\mathrm{m}^{-1}]$ is the "linear attenuation coefficient", which is a function of the radiation frequency depending of the material the radiation pass through.

So we have a simple differential equation (see section Differential and Integral Calculus page 1609):

$$\boxed{\frac{\mathrm{d}\Phi}{\Phi_0}=-\mu\mathrm{d}z \Rightarrow \Phi(z)=\Phi_0 e^{-\mu z}} \tag{10.5.7}$$

which is the "Beer-Lambert law" (which can also be expressed from the light intensity that we will define further below).

We have typically the following order of amplitude:

$$\mu_{\text{yellow}}=10^{-5}\,[\mathrm{m}^{-1}] \quad \mu_{\text{purple}}=4\cdot 10^{-5}\,[\mathrm{m}^{-1}] \quad \mu_{\text{Glas (BKZ)},0.55[\mu\mathrm{m}]}=0.2\,[\mathrm{m}^{-1}]$$

Remark

The variation of the atmospheric absorption coefficient with the wavelength allows in particular to explain the blue color of the sky and because of water light reflection why our oceans looks like blue seen from space (yes don't forget that water don't have color... it's transparent!).

There are many other formulations of the Beer-Lambert law with one fairly used in nuclear physics (see section of the same name in this textbook page 5019) in the framework of radiation protection. Let's see now what it is:

Let us consider a flow Φ of particles striking perpendicularly the surface of a material of thickness $\mathrm{d}z$ and of atomic density ρ_N (in $[\text{atoms}\cdot\mathrm{m}^3]$). If we consider the particles striking a surface S, the latter can theoretically meet $\rho_N S\mathrm{d}z$ targets atoms in this layer. The number of interacting particles will be proportional to the intensity times this number, and we have:

$$\mathrm{d}\Phi S=-\sigma\Phi_0 NS\mathrm{d}z \tag{10.5.8}$$

where σ is a proportionality constant named "microscopic cross section." Its units are often expressed as "barn" ($1\,[\text{barn}]=10^{-26}\,[m]$).

Remark

The atomic density ρ_N is equal to:

$$\rho_N=\frac{\rho N_{\text{A}}}{M_{\text{Mol.}}}$$

where ρ is the density in $\mathrm{kg}\cdot\mathrm{m}^{-3}$, N_{A} is the Avogadro's number $6.022\cdot 10^{23}\,[\text{atoms}\cdot\text{mole}^{-1}]$ and $M_{\text{mol.}}$ the molar mass of the target expressed in $[\mathrm{kg}\cdot\text{mole}^{-1}]$.

If we now assume that the scattering centers are the electrons and not the target atoms, then we must replace ρ_N by ρ_{N_e} where $N_e=\rho_N Z$ with Z being the number of electrons interacting by target atom. Therefore:

If we now admit that the scattering centers are the electrons, not the target atoms, then we must replace N by N_e where $N_e = NZ$ where Z being the number of electrons interacting with the target atom. From where:

$$\Phi = \Phi_e^{-\sigma N_e z} = \Phi_0 e^{-\sigma Z \frac{\rho N_{\text{Av}}}{M_{\text{mol}}} z} \tag{10.5.9}$$

By identifying with the first formulation of the Beer-Lambert law, we see that μ plays the same role as:

$$\mu = \sigma Z \frac{\rho N_{\text{Av}}}{M_{\text{mol}}} \qquad \text{and} \qquad \sigma = \frac{\mu}{\rho} \frac{M_{\text{mol}}}{Z N_{\text{Av}}} \tag{10.5.10}$$

And the hypothesis that the electron is a "sphere of action" having a front surface πr_e^2, where r_e is the radius of this sphere, then:

$$\sigma = \pi r_e^2 = \frac{\mu}{\rho} \frac{M_{\text{mol}}}{Z N_{\text{Av}}} \tag{10.5.11}$$

and we have for the radius of the sphere of action of the electron:

$$r_e = \sqrt{\frac{\mu}{\rho} \frac{M_{\text{mol}}}{Z N_{\text{Av}} \phi}} \tag{10.5.12}$$

10.5.3.2 Light Intensity (Radiant Intensity)

To describe the energy flow Φ of a source, you must first measure it. The used sensor (thermocouple, bolometer, photocell, eye or others) may receive only one part: that which happens in the solid angle $\mathrm{d}\Sigma$ defined by its section.

Definition (#10.5.490): The "light intensity", "energy intensity" or "radiant intensity" denoted I of a punctual source is radiated flow Φ in the unit solid angle Ω centered around a direction Δ of emission:

$$I = \frac{\mathrm{d}\Phi}{\mathrm{d}\Omega} \tag{10.5.13}$$

The light intensity is expressed in certain professional fields in the photometric units (see summary table further below) "Candela" denoted [Cd] or in photonic units in $[\mathrm{W} \cdot \mathrm{s}^{-1}]$ (remember that the steradians don't have any units as well as for radians). This is why, when you buy screens or lamps in some stores, the units are not the same from one brand to another.

Remark

A source is named an "anisotropic source" or "directional source" if its intensity varies with the direction of observation.

By comparison (as it may help), a Candela unit is equivalent to the intensity of a source in a given direction, which emits a monochromatic radiation of frequency 540.1012 [Hz] (which roughly corresponds to the frequency at which the eye is the most sensitive), and whose luminous flow(or intensity) in that direction of $1/683$ [W] per steradian.

10.5.3.3 Energy Emittance (Radiant Emittance)

Definition (#10.5.491): The "emittance", "exitance" or "illumination" M of a source is the radiated energy flow (power) per unit surface $\mathrm{d}S$ in $[\mathrm{W}\cdot\mathrm{m}^{-2}]$ in all directions of outer space the source and depends on the physico-chemical properties of the emitting surface:

$$M=\frac{\mathrm{d}\Phi_{\text{ext}}}{\mathrm{d}S} \tag{10.5.14}$$

A common mistake is to make a confusion between the emittance and the energy!!!

Remark

"Radiant emittance" is an old term for this quantity. Radiant exitance is often named "intensity" in branches of physics other than radiometry, but in radiometry this usage leads to confusion with radiant intensity.

The emittance is often assimilated in the contemporary vocabulary to the "luminosity" of a light source which sometimes leads to confusion with the concept of light intensity.

The emittance is expressed by many professional of the field in photometric units named "Lux" denoted [lx] or in photonic units $[\mathrm{W}\cdot\mathrm{m}^{-2}]$ or even worst ... in $[\mathrm{lm}\cdot\mathrm{m}^{-2}]$ or even in $[\mathrm{cd}\cdot\mathrm{srm}^{-2}]$. For example when you buy a car, the headlights are indicated as being about ~ 20 [lx].

If the source is punctual (or considered as!) and its radiation isotropic , its direction has not to be taken into consideration. In the case of the related sphere of radius r, the emittance is then expressed as:

$$M=\frac{\Phi}{4\pi r^2} \tag{10.5.15}$$

In the case of the sphere, one element $\mathrm{d}S$ of the spherical surface receives perpendicularly the radiation. Very generally, an elementary surface can be inclined relative to the direction of radiation with an angle θ. So we have to project the surface perpendicular to the radiation using the basic reasoning of trigonometry (see section Trigonometry page 2503):

$$\boxed{\mathrm{d}\Phi=M\mathrm{d}S\cos(\theta)} \tag{10.5.16}$$

It is this projection that explains (among other factors!) the seasons on Earth: the area swept by the emittance more or less constant and isotropic of the Sun (considered as a punctual source) is maximum at the equator (perpendicular surface) and implies a radiation higher compared to that receives at higher or lower latitude for which the perpendicular projection of the surface in question is smaller than at the equator for the same emittance.

Remarks

R1. The energy emittance is calculated only in the outer half space before (the point from which we look at the source), because only half of the energy exchanged by the points of the surface dS is emitted as radiation. The other half is exchanged with the atoms located in the body.

R2. The emittance is usually also sometimes denoted F or even E. The practitioner will however take care not to confuse the emittance M with the magnitude (denoted by the same letter) that we define in the section of Astrophysics.

Now that we have some basics on radiant emittance let us deal with a quite recurrent question on social networks related to the fact that on most actual videos of the NASA we can't see the stars. This question is related to the calculation of mow many visible photons hit a pixel on a CCD sensor? With a few simplifying assumptions let us see that it not too difficult to calculate an approximation result to this question and get a simple answer to why we can't see distant stars on most videos made by CCD cameras.

Let us recall for this purpose that we have proved in the section of Thermodynamics (see page 3719) that the emittance of the black-body was given by (remember that $\nu=c/\lambda$):

$$\begin{aligned}M(T)&=\frac{c}{4}\int\limits_0^{+\infty}R(\nu,T)\mathrm{d}\nu=\frac{c}{4}\int\limits_0^{+\infty}\frac{h\nu^3}{c^3}\frac{1}{e^{\frac{h\nu}{kT}}-1}\mathrm{d}\nu=2\pi\frac{h}{c^2}\int\limits_0^{+\infty}\frac{\nu^3}{e^{\frac{h\nu}{kT}}-1}\mathrm{d}\nu\\&=2\pi\frac{h}{c^2}\int\limits_0^{+\infty}\frac{\left(\frac{c}{\lambda}\right)^3}{e^{\frac{hc}{kT\lambda}}-1}\left(-\frac{c}{\lambda^2}\mathrm{d}\lambda\right)=2\pi hc^2\int\limits_0^{+\infty}\frac{1}{\lambda^5\left(e^{\frac{hc}{kT\lambda}}-1\right)}\mathrm{d}\lambda\end{aligned}\tag{10.5.17}$$

The power of spectral radiant exitance contained in light within a specified wavelength range is then obviously obtained by integrating:

$$M(\lambda,T)=\frac{2\pi hc^2}{\lambda^5\left(e^{\frac{hc}{kT\lambda}}-1\right)}\tag{10.5.18}$$

over a given range. The result is named "irradiance" E_e and given by:

$$E_e=\int\limits_{\lambda_1}^{\lambda_2}M(\lambda,T)\mathrm{d}\lambda\;[\mathrm{W}\cdot\mathrm{m}^{-2}]\tag{10.5.19}$$

this can be expressed in terms of photons as follows using the Planck-Einstein relation ($E=hc/\lambda$);

$$\boxed{N_{\text{ph}}=\int\limits_{\lambda_1}^{\lambda_2}\frac{M(\lambda,T)\lambda\mathrm{d}\lambda}{hc}=2\pi c\int\limits_{\lambda_1}^{\lambda_2}\frac{1}{\lambda^4\left(e^{\frac{hc}{kT\lambda}}-1\right)}\mathrm{d}\lambda\;[\text{photons}\cdot\mathrm{s}^{-1}\cdot\mathrm{m}^{-2}]}\tag{10.5.20}$$

Such calculation is easily done numerically. For instance the daylight Sun (actually a G2V-type star, aka yellow dwarf) is considered to be a black-body radiator of around temperature $5,300$ [K]. In units better suited to a photographic sensor context it therefore emits about $4.549\cdot10^{13}$ [photons $\cdot\,\mathrm{s}^{-1}\cdot\mu\mathrm{m}^{-2}$] in the standard visible range (380-780) in all directions at its surface (multiplied by the surface of the Sun it gives a number of approximately $1.5\cdot10^{41}$ [photons $\cdot\,\mathrm{s}^{-1}$]).

As we have proved in the section of Electromagnetism, the intensity of the electromagnetic field decrease in the inverse square of the distance ($4\pi R^{-2}$). Then in reality we receive form the Sun:

$$N_{\text{ph}}\cong\frac{1.5\cdot10^{41}}{4\pi R^2}\cong\frac{1.5\cdot10^{41}}{4\pi(149.6\cdot10^9)^2}\cong1.33\cdot10^8\;[\text{photons}\cdot\mathrm{s}^{-1}\cdot\mathrm{m}^{-2}]\tag{10.5.21}$$

Or in units more suited to CCD (in 12019 according to the holocene calendar the typical civil CCD pitch size is a square of $1.51\ [\mu\text{m}]$):

$$N_{\text{ph}} \cong 1.33 \cdot 10^{-4}\ [\text{photons} \cdot \text{s}^{-1} \cdot \mu\text{m}^{-2}] \tag{10.5.22}$$

Keeping in mind that most CCD HD (high definition) civil cameras in the beginning of the 120th century (holocene calendar) have a capture rate of 20 to 30 frames per second! So the reader can easily understand now why cameras having a too fast frame rate, cannot captures stars (that you are in space or on Earth...).

Remark

Notice that for a distant star (the nearest one being at Proxima Centauri at almost $4.37 \cdot 10^{9}$ [km]), the same calculation gives:

$$N_{\text{ph}} \cong 4.97 \cdot 10^{-7}\ [\text{photons} \cdot \text{s}^{-1} \cdot \mu\text{m}^{-2}] \tag{10.5.23}$$

All of these photons do not necessarily make it through the atmosphere which absorbs varying amounts of light energy depending on wavelength. On the other hand a household incandescent bulb at around $3,000$ [K] emits about $1.267 \cdot 10^{12}\ [\text{photons} \cdot \text{s}^{-1} \cdot \mu\text{m}^{-2}]$ most of which make it to our sensors.

To determine what exposure the equivalent quantities above correspond to we simply convert the given irradiance to photometric units by taking into consideration its visible wavelengths only.

The photometric version of irradiance E_e is named "illuminance" and defined by:

$$E_\nu = K_m \int\limits_{380}^{780} M(\lambda, T)V(\lambda)\mathrm{d}\lambda\ [\text{lumens} \cdot \text{m}^{-2}] \tag{10.5.24}$$

where $V(\lambda)$ is the photonic eye response function and K_m the luminous efficiency conversion constant $683\ [\text{lm} \cdot \text{W}^{-1}]$. Remember that $[\text{lumens} \cdot \text{m}^{-2}]$ are named lux [lx]...

Now that we know how to determine how many photons impinge on a sensor we can estimate its Effective Quantum Efficiency (EQE), that is the efficiency with which it turns such a photon flux into photoelectrons (e^-), which will then be converted to raw data to be stored in the captured raw file:

$$\text{EQE} = \frac{N_{e^-}\ \text{produced by average pixel}}{N_{\text{ph}}\ \text{incident on average pixel}} \tag{10.5.25}$$

It represents the probability that a photon arriving on the sensing plane from the scene will be converted to a photo-electron by a typical digital camera sensor. It therefore includes the effect of microlenses, fill factor, CFA and other filters on top of silicon in the pixel. It is usually expressed as a percentage. For instance if an average of 100 photons per pixel within the sensor's passband were incident on a uniformly lit spot of the sensor and on average each pixel produced a signal of 20 photoelectrons we would say that the Effective Quantum Efficiency of the sensor is 20%.

Remark

It seems that the eye can have a some wavelength an EQE of 100% same as some expensive CCD...

10.5.3.4 Radiance and Luminance

Given a non-punctual source which emittance M is known at any point. An element $\mathrm{d}S$ of a surface of this kind of source will by definition not necessarily of isotropic intensity and therefore brighter (more powerful) when we observe it col-linearly to the vector $\mathrm{d}\vec{S}$.

The intensity I that radiates in a direction forming an angle θ with the normal to the emission surface S is always less than that radiated in the direction of the vector $\mathrm{d}\vec{S}$. So by simple application of trigonometry, we get the definition of "luminance" (or "radiance"):

$$L(\theta)=\frac{\mathrm{d}I}{\mathrm{d}S\cos(\theta)}=\frac{\mathrm{d}^2\Phi}{\mathrm{d}S\mathrm{d}\Omega\cos(\theta)} \tag{10.5.26}$$

more often written (to avoid a unit confusion because of the presence of the square on the differential element):

$$L(\theta)=\frac{\mathrm{d}\Phi}{\mathrm{d}S\mathrm{d}\Omega\cos(\theta)} \tag{10.5.27}$$

expressed in certain areas, in "Nits"... photometric units $[\mathrm{Cd}\cdot\mathrm{m}^{-2}]$ or photonic units $[\mathrm{W}\cdot\mathrm{m}^{-2}]$ (without specifying explicitly the steradian).

Radiance is useful because it indicates how much of the power emitted, reflected, transmitted or received by a surface will be received by an optical system looking at that surface from some angle of view. In this case, the solid angle of interest is the solid angle subtended by the optical system's entrance pupil. Since the eye is an optical system, radiance and its cousin luminance are good indicators of how bright an object will appear. For this reason, radiance and luminance are both sometimes named "brightness", even if this usage is now discouraged.

Remark

When we are concerned only with the human visible part of light, the luminance and radiance of a source is named by practitioners "brightness" (note this is not the case when we deal of shining as we will see it in the section of Astrophysics).

Luminance is a measure of how much power (energy over time) is emitted in a particular direction (basically how much light your TV will produce), Radiance broadly speaking, measures how much of the luminance you'll actually see. Finally brightness doesn't really measure anything it's broadly a catch-all term describing both luminance and radiance.

We can obviously write by making some elementary algebra that:

$$I(\theta)=\int\limits_{\Sigma} L(\theta)\cos(\theta)\mathrm{d}S \tag{10.5.28}$$

that gives us the energy intensity that radiates a source of luminance L in a given direction.

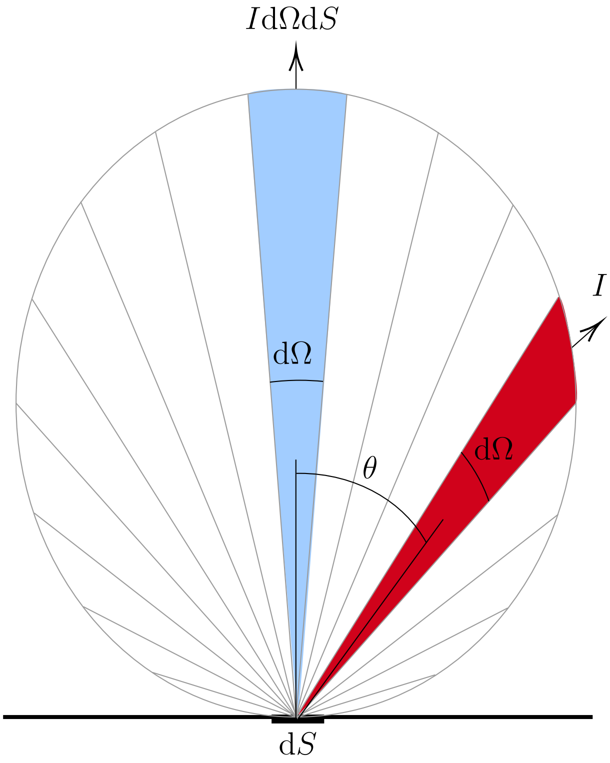
Johann Heinrich Lambert (11728-11777 according to holocene calendar) has observed that the energy intensity of some anisotropic sources (among all imaginable types of sources...) decreases as the cosine of the angle θ, around the direction perpendicular to the surface source, such that:

$$\boxed{I(\theta)=I_0\cos(\theta)} \tag{10.5.29}$$

and that we name "Lambert's cosine law". A source that respect this law is named "Lambert's source" (the Sun is considered as a near-perfect black-body and Lambert's source in broad stellar modelling).

Caution! There is often a confusion from students that make them think that there is a contradiction because the black-body emitter (that is "Lambertian") has a radiation that is independent of direction. A Lambertiam emitter appears equally bright from all viewing angles too! That is, the power per unit perceived area stays the same! It is both the power received and the solid angle it arrives from decrease as $\cos(\theta)$ leaving their ratio unchanged!

So the radiant intensity or luminous intensity observed from an ideal diffusely reflecting surface or ideal diffuse radiator is directly proportional to the cosine of the angle θ between the direction of the incident light and the surface normal:



$I\mathrm{d}\Omega\mathrm{d}S$
$I\cos(\theta)\mathrm{d}\Omega\mathrm{d}S$
$\mathrm{d}\Omega$
θ
$\mathrm{d}\Omega$
$\mathrm{d}S$

Figure 10.133: **Lambertian emittor**

A surface which obeys Lambert's law is said to be "Lambertian surface". The apparent brightness of a Lambertian surface to an observer is the same regardless of the observer's angle of view. More technically, the surface's luminance is isotropic, and the luminous intensity obeys Lambert's cosine law. Unfinished wood exhibits roughly Lambertian reflectance, but wood finished with a glossy coat of polyurethane does not, since the glossy coating generates specular highlights. Not all rough surfaces are Lambertian reflectors, but this is often a good approximation when the characteristics of the surface are unknown.

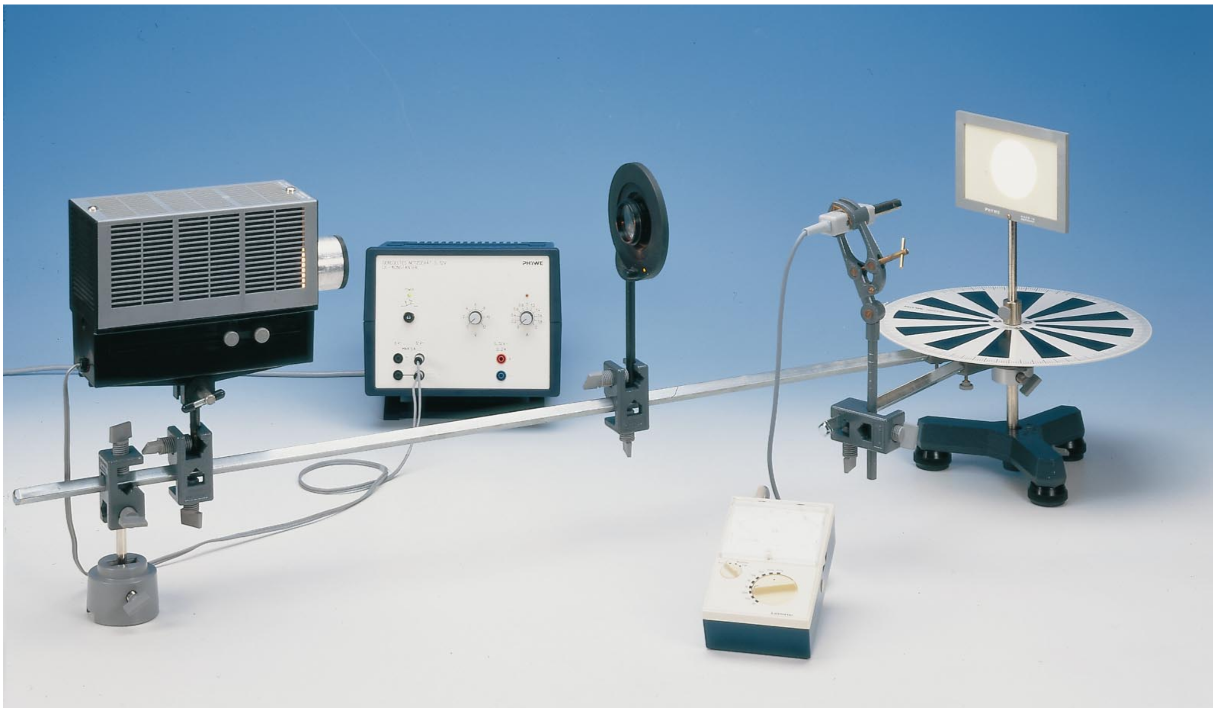


Figure 10.134: **Typical experimental setup used in universities to check Lambert's cosine law**

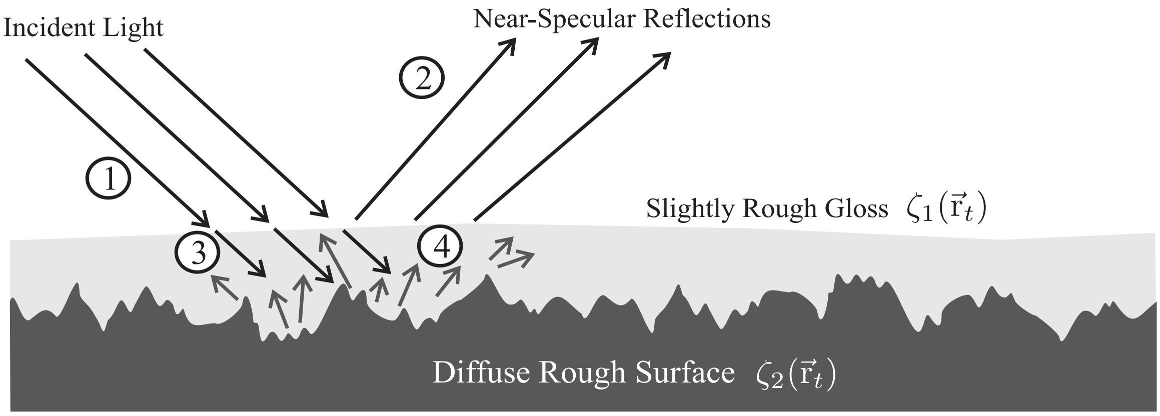
Remark

We speak of "luminance" of a source of "illumination" of an object (by a source).

Consider the physical diagram of the figure, which illustrates the composition of a typical object surface at the microscopic level. Many objects possess a glossy veneer that undulates very slightly across the surfaces. Incident light - whether from a coherent or incoherent source - would partially reflect and partially transmit through this first interface. The transmitted portion of the light then travels through the dielectric surface to the much rougher material interface below. This surface, usually regarded as Lambertian, then scatters the light in nearly every direction (as well as coloring the light with frequency-selective absorption). The diffusely scattered light then partially transmits back into the scene from the surface. Thus, there are two potential components to the light emanating from a surface at optical frequencies: a near-specular component and a diffuse, Lambertian component.



Incident Light
Near-Specular Reflections
①
②
③
④
Slightly Rough Gloss $\zeta_1(\vec{r}_t)$
Diffuse Rough Surface $\zeta_2(\vec{r}_t)$

In the figure above whe have 1) incident light partially reflects off a 2) smooth, slightly undulating surface. Then 3) transmitted light enters the second medium and strikes the Lambertian surface which re-radiates diffuse power away from the surface in all directions.

The basic physical model of the figure above helps to explain why objects look the way they do to our eyes. First of all, the diffuse scattering of light allows us to see surfaces even when angle-of-observation is not equal to angle-of-incidence to a light source. However, there can be a strong near-specular component present, which provides a glossy sheen and acts as an imperfect mirror for any image that falls upon the surface. Capturing this behavior is the key part of realistic computer graphic rendering for digital art, web illustrations, and video games!

In light of our knowledge of rough surface scattering, we will parse one of the most famous empirical models in computer graphics - the heurestic "Phong reflection model" (see [442]). This reflection model estimates the light intensity contribution I (in Watts) at observation point $(\vec{v})$ due to a surface point $\vec{r}_s$ in a scene may be computed with the following summation over the light sources present:

$$I(\vec{r})=\sum_{m=1}^{\substack{\#\text{ of}\\ \text{sources}}}\left(\underbrace{\kappa_a}_{\text{ambient}}+\underbrace{\kappa_d\cos(\theta_{nm})}_{\text{diffuse}}+\underbrace{\kappa_s\cos^{\alpha}(\theta_{rm})}_{\text{specular}}\right)I_m \qquad (10.5.30)$$

where:

$$\cos(\theta_{rm})=\hat{k}_{rm}\circ\frac{(\vec{r}-\vec{r}_s)}{\|\vec{r}-\vec{r}_s\|}\qquad\cos(\theta_{nm})=\hat{n}\circ\frac{(\vec{r}_m-\vec{r}_s)}{\|\vec{r}_m-\vec{r}_s\|} \qquad (10.5.31)$$

with (see the figure below for a geometrical representation):

- I_m is the intensity of the m th light source
- κ_a is the ambient coefficient due to multiple diffusely scattered waves
- κ_d is the diffuse scattering coefficient due to Lambertian roughness
- κ_s is the specular reflection coefficient from glossy layer
- α is the shininess factor (0 is pure Lambertian, ∞ is a perfect mirror)

- $\vec{r}$ is the point of observation
- $\vec{r}_s$ is the surface point under observation
- $\vec{r}_m$ is the location vector of the m th source
- $\hat{n}$ is the surface normal vector
- $\hat{k}_{rm}$ is the direction of specular reflection due to m th source

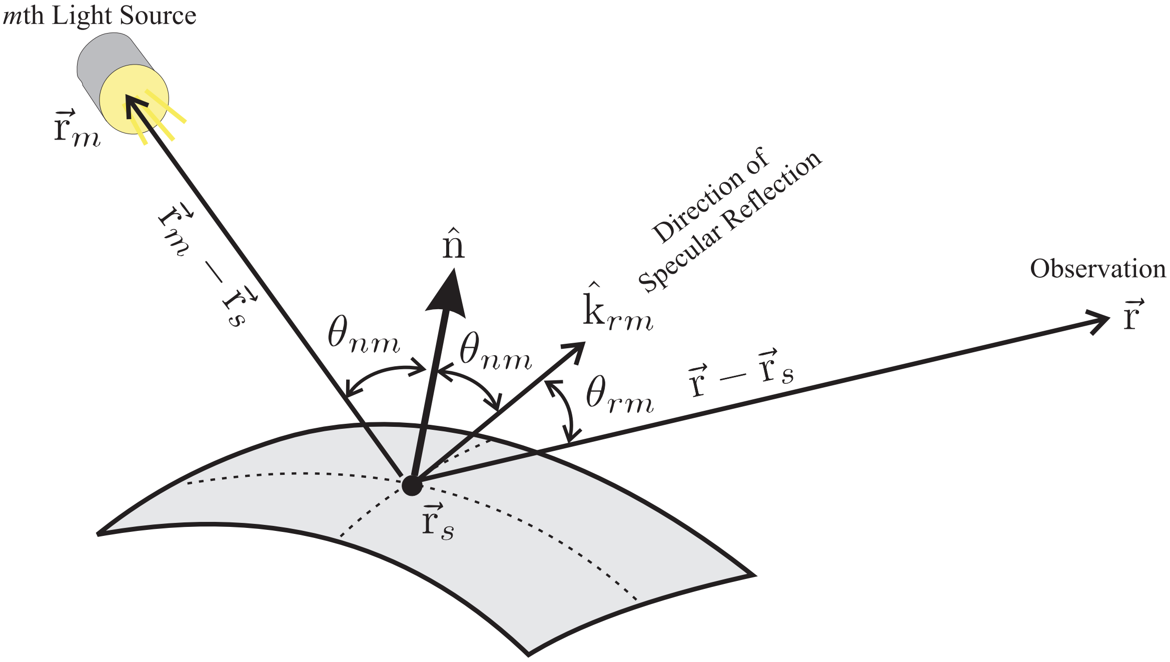


Figure 10.135: **Geometry used in the Phong reflection model**

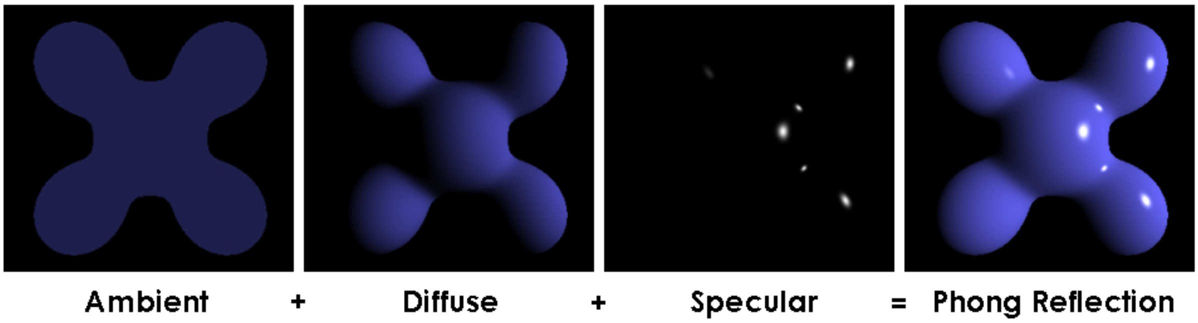
The model described by the heurestic equation above (Phong equation) breaks down the optical contribution of a point on a surface into specular, diffuse, and ambient components:

- *Ambient Term*: This term is physically linked to the "ambient" light in the environment which is mostly due to light that has already diffusely scattered from a source. This component provides a dull, soft illumination of a surface point from nearly every direction and to every direction. Though we would expect the reflection of ambient illumination to vary across a realistic scene, the omnipresence of diffuse scattering at optical frequencies allows us to approximate ambient illumination as uniform. Captured by a single coefficient κ_a, this model of ambient illumination - the most empirical part of the Phong reflection model - provides enough realism for most graphics applications. In the Phong equation, the ambient contribution will scale with the total intensity of the sources in the scene.
- *Specular Term*: This component imparts a rough, mirror-like sheen to points on the surface of an object. In addition to the material-dependent coefficient κ_s, which measures overall intensity of the specular reflection, there is a shininess term α. When $\alpha = 0$, the specular reflection takes on a pseudo-Lambertian pattern where light reflects equally in all

directions. When α becomes very large, this reflection contribution only occurs in specular directions. In our rough surface analysis, we would describe the glossy layer surface displacement function $\zeta_1\left(\vec{r}_t\right)$ as having increasing wavenumber content as α decreases.

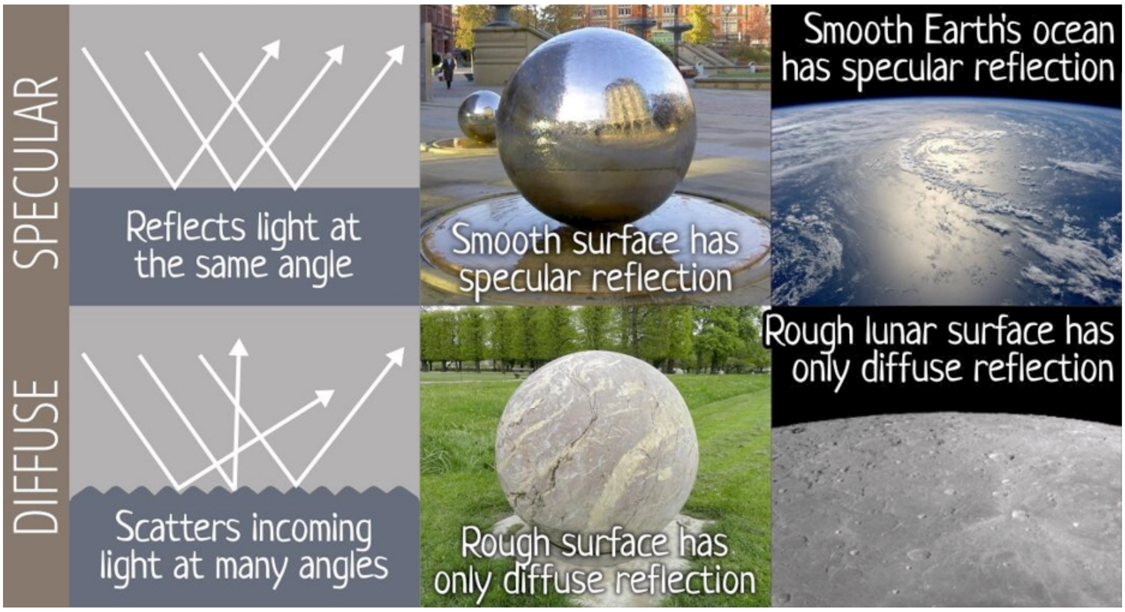
- *Diffuse Term*: This component is due to the underlying, highly rough reflective layer under any glossy veneer. Its surface displacement function, $\zeta_2\left(\vec{r}_t\right)$ would have near-uniform wavenumber content over the interval $\|\vec{k}\|<4\pi/\lambda$. The scattering in this case is near-Lambertian and radiates as a function of observation angle with respect to the surface normal.

Visual illustration of the Phong equation: here the light is white, the ambient and diffuse colors are both blue, and the specular color is white, reflecting a small part of the light hitting the surface, but only in very narrow highlights. The intensity of the diffuse component varies with the direction of the surface, and the ambient component is uniform (independent of direction):



These terms are often applied for each color of light in an illumination spectrum. Although the heuresticc Phong reflection model is highly empirical, it is easy to see how it approximately reproduces the physical behavior in the electromagnetic interactions of a realistic rough surfaces. Because the eye is very forgiving, the approximate behavior is sufficient for many types of realistic scene renderings.

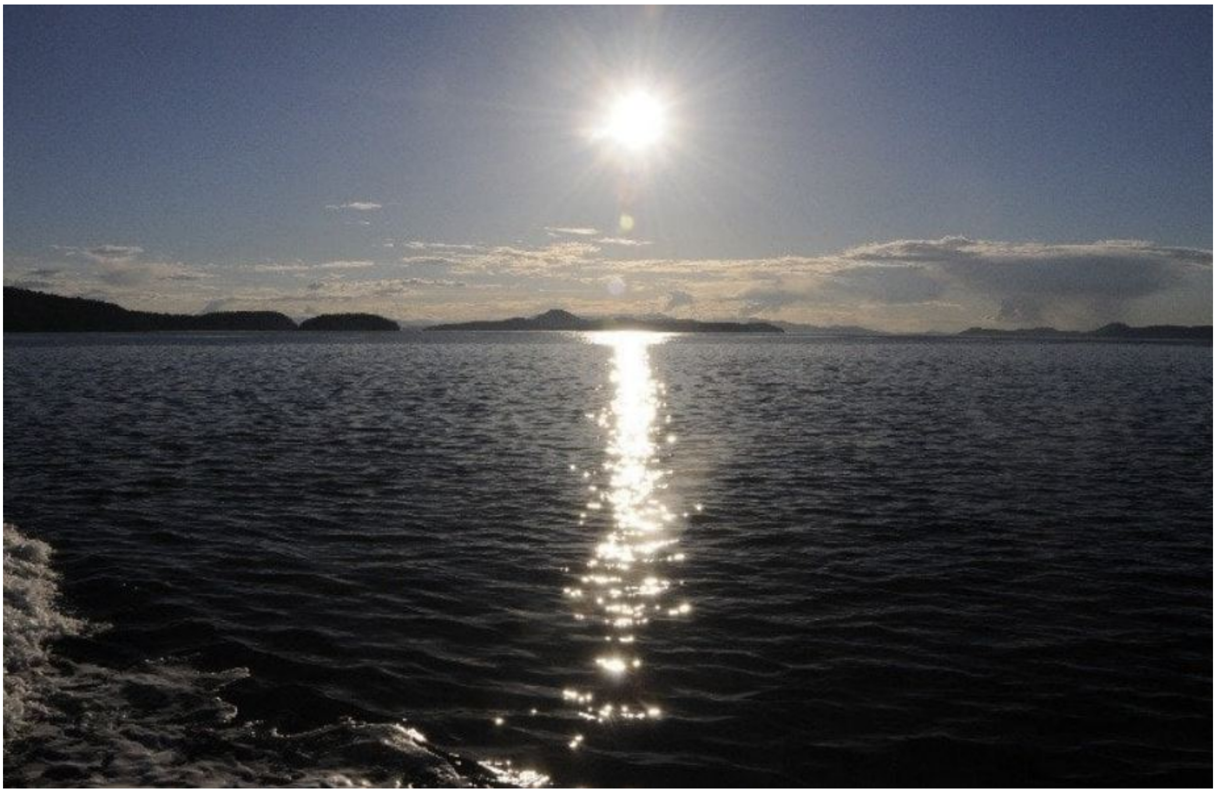
For more advanced models see [392], or [417] or [142].



SPECULAR
Reflects light at the same angle
Smooth surface has specular reflection
Smooth Earth's ocean has specular reflection
DIFFUSE
Scatters incoming light at many angles
Rough surface has only diffuse reflection
Rough lunar surface has only diffuse reflection

Figure 10.136: **Specular vs Diffuse reflection**

And the Phong reflection model reproduces among everything we see in real life the well known Sun glitter pattern (collection of specular reflections of the Sun - or "glints" - on the surface of water) on the surface of a liquid that has a rough surface (otherwise on a calm surface of liquid this pattern doesn't appear and we just have a mirror image of the Sun's disc):



10.5.3.4.1 Lambert's law

A light source follows the Lambert's cosine law if its luminance (or radiance) is the same in all direction. Indeed, if we put first:

$$I=\frac{\mathrm{d}\Phi}{\mathrm{d}\Omega}=I_0 \tag{10.5.32}$$

we have:

$$L(\theta)=\frac{I}{S\cos(\theta)}=\frac{I_0\cos(\theta)}{S\cos(\theta)}=\frac{I_0}{S} \tag{10.5.33}$$

and we have:

$$\Phi=\int\limits_{2\pi} I\mathrm{d}\Omega=\int\limits_{2\pi} I_0\cos\theta)\mathrm{d}\Omega \tag{10.5.34}$$

But we have proved in the section of trigonometry that:

$$\mathrm{d}\Omega=2\pi\sin(\theta)\mathrm{d}\theta \tag{10.5.35}$$

Which brings us to write:

$$\begin{aligned}\Phi&=\int\limits_{2\pi} I_0\cos(\theta)\mathrm{d}\Omega=\int\limits_{2\pi} I_0\cos(\theta)2\pi\sin(\theta)\mathrm{d}\theta=I_02\pi\int\limits_0^{2\pi}\cos(\theta)\sin(\theta)\mathrm{d}\theta=I_02\pi\int\limits_0^{2\pi}\frac{\sin(2\theta)}{2}\mathrm{d}\theta\\&=I_0\pi\int\limits_0^{\pi/2}\sin(2\theta)\mathrm{d}\theta=I_0\pi\left(-\frac{1}{2}\cos(2\theta)\right)\Bigg|_0^{\pi/2}=I_0\pi\left(\frac{1}{2}-\left(-\frac{1}{2}\right)\right)=I_0\phi\end{aligned} \tag{10.5.36}$$

The energy emittance being equal to:

$$M=\frac{\Phi}{S}\Rightarrow M=\frac{I_0\pi}{S}=\frac{I_0}{S}\pi=L\pi \tag{10.5.37}$$

This result is important for the study of black-body radiation, since the luminance value measured by a sensor gives the possibility to deduce the emittance M, so the energy flow from the source is equal to:

$$\Phi=SL\pi \tag{10.5.38}$$

Here is a small summary of what we have seen so far as sometimes it can be quite confusing:

Radiometry			**Photometry**		
Quantity	**Symbol**	**Units**	**Units**	**Symbol**	**Quantity**
Radiant Energy	E_r	J	lm s	E_r	Luminous Energy
Radiant Flow	Φ	W	lm s	Φ	Luminous Radiant
Light Intensity	I	W/sr	Cd	I	Radiant Intensity
Emittance	M	W/m^2	lm/m^2	M	Radiant Emittance
Radiant Intensity	I	W/sr	lm/sr	I	Luminous Intensity
Radiance	L	W/(m^{2}sr)	lm/(m^{2}sr)	L	Luminance

Table 10.11: **Radiometric and Photometric quantities**

10.5.3.5 Kirchhoff's law of Radiation

Any body irradiated by an energy source sees the incident energy flow incident divided into three intuitive terms:

$$\Phi=\Phi_r+\Phi_t+\Phi_a \tag{10.5.39}$$

where:

- $\Phi_r=\rho\Phi$: is the energy flow reflected or diffused.
- $\Phi_t=\tau\Phi$: is the energy that flow through the body without interactions (full transparency).
- $\Phi_a=\alpha\Phi$: is the energy flow transformed into other forms of energy.

The three coefficients respectively named "reflectance factor ρ" or more simply "albedo", "transmittance factor τ" and "absorption factor α" depend obviously on the wavelength λ (and therefore the frequency) of the incident light and the of the temperature of receiver body.

For each object we have obviously:

$$\rho+\tau+\alpha=1 \tag{10.5.40}$$

which is the expression of the "simple Kirchhoff law" in photometry (at the opposite of the differential one).

The albedo is an important concept in climatology as we will use it in the corresponding section of the book (in the legend of the image below, the years are given based on the holocene calendar).

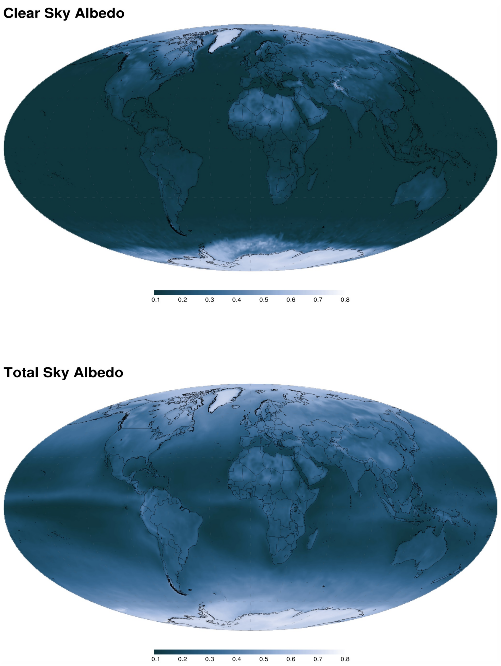


Figure 10.137: 12003–12004 mean annual clear-sky and total-sky albedo (source: Wikipedia)

A interesting (funny) but also very useful modern material for space telescopes imagery quality is Vantablack whose albedo is of 0.00035...! The result is quite mind blowing as you can see in the photo below:

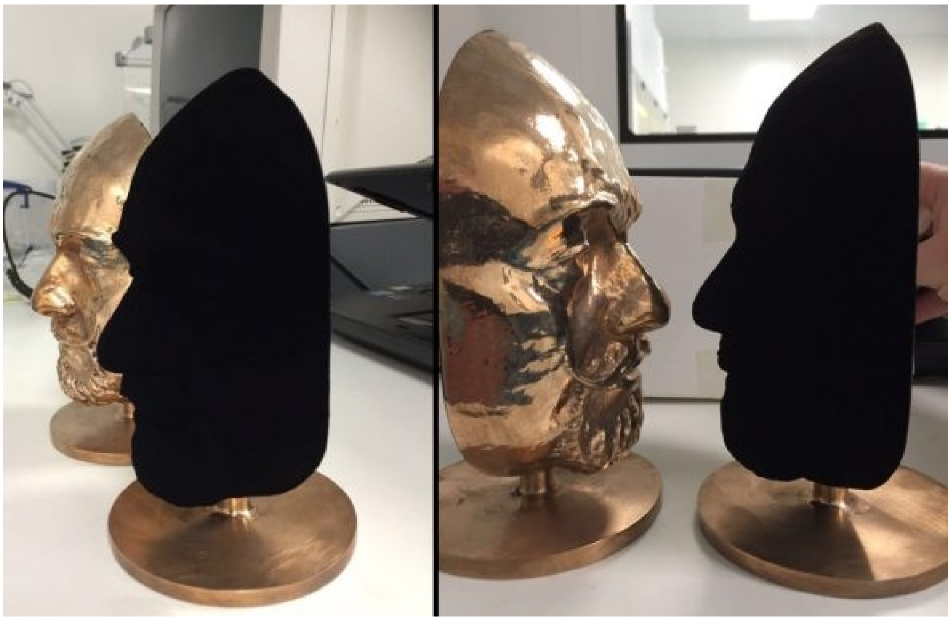

Figure 10.138: **Vantablack painted face...**

Looks like quite unreal isn't it? ;-)

10.5.3.6 Spectral Decomposition

From what has been said above, it follows that all the previously defined quantities can be related to their spectral decomposition in wavelength λ. This results comes from the superposition principle: any radiation can be treated as the superposition of monochromatic radiation (even if we will prove during our study of quantum physics later that a monochromatic radiation does not really exists).

Thus, we define:

$$\Phi=\int_{\lambda}\Phi(\lambda)\mathrm{d}\lambda \quad I=\int_{\lambda}I(\lambda)\mathrm{d}\lambda \quad L=\int_{\lambda}L(\lambda)\mathrm{d}\lambda \quad M=\int_{\lambda}M(\lambda)\mathrm{d}\lambda \tag{10.5.41}$$

Where we also write to simplify the notations:

$$\Phi(\lambda)=\Phi_{\lambda} \quad I(\lambda)=I_{\lambda} \quad L(\lambda)=L_{\lambda} \quad M(\lambda)=M_{\lambda} \tag{10.5.42}$$

Remark

The units AND values of spectral decomposed energy flow, spectral intensity, spectral luminance/radiance, spectral emittance and also the spectral absorption factor, spectral reflectance factor and spectral transmission factor are of course not equivalent to their integrated expression.

We will need for the density of the emittance in the study of black-body in the section of Thermodynamics of the chapter Mechanics. Remember only that we have in S.I. units based on the spectral decomposition principle (and vice versa superposition):

$$M\,[\mathrm{W}\cdot\mathrm{m}^{-2}] \qquad M(\lambda)\,[\mathrm{W}\cdot\mathrm{m}^{-3}] \tag{10.5.43}$$

Remark

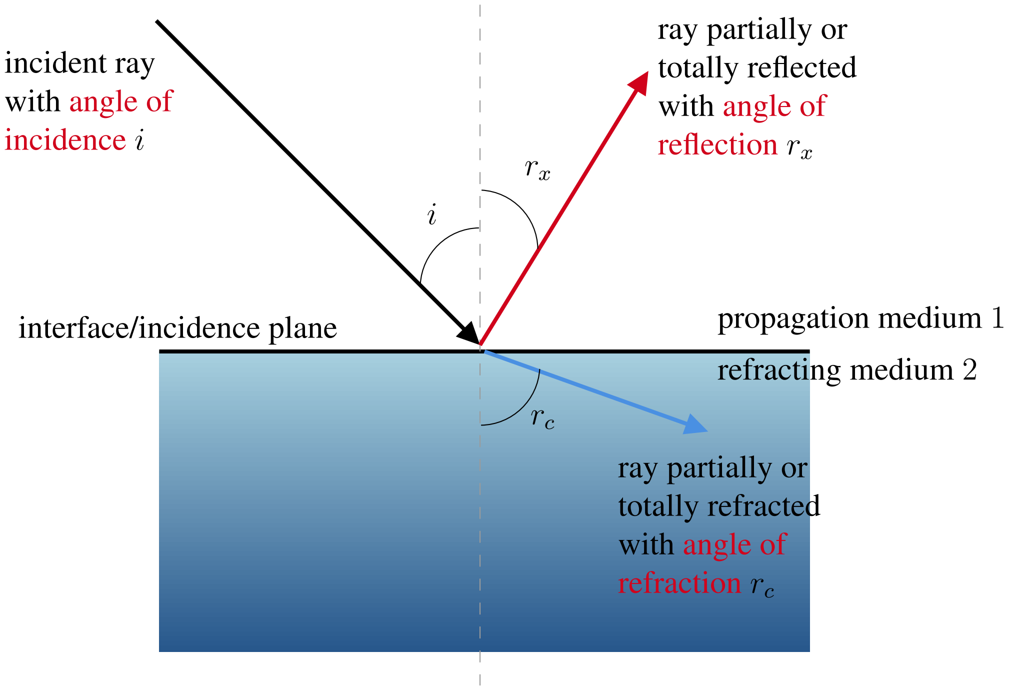
We have seen in the section of Thermodynamic that parameters defined above, being dependent on wavelength, they are also dependent on the temperature of the source which emits these waves.

10.5.4 Law of Refraction and Reflection

The law of refraction, which is generally known as "Snell's law", governs the behaviour of light-rays as they propagate across a sharp interface between two transparent dielectric media.

Pierre de Fermat proposed that light rays (electromagnetic waves) met a very general principle that the path taken by the light to travel from one point to another was the one for which the travel time was minimum (actually an extremum which may be a minimum or maximum). This proposal, known as "Fermat's principle of least time", a fundamental principle of geometrical optics is based on the principle of least action (principle we have already introduced in the section of Analytical Mechanics) as we prove it later below.

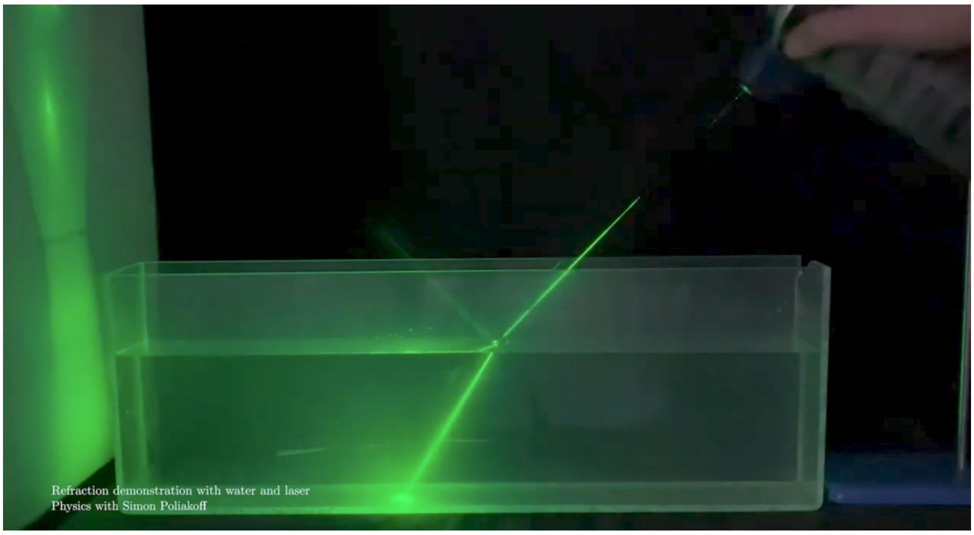
Before starting the developments let us give some important definitions and introduce some concepts. some of which are related to the figure below:



incident ray
with angle of
incidence i
ray partially or
totally reflected
with angle of
reflection r_x
r_x
i
interface/incidence plane
propagation medium 1
refracting medium 2
r_c
ray partially or
totally refracted
with angle of
refraction r_c

Figure 10.139: **Vocabulary for the study of geometrical optics**

Or in real life a demonstration of refraction and reflection with a LASER, a recipient of water (and a spray to highlight the reflected light):



Refraction demonstration with water and laser
Physics with Simon Poliakoff

Definitions (#10.5.492):

D1. A "refracting medium" is a medium that causes the deflection of an incident light ray.

D2. The "incident ray" is the ray of light propagating in a medium 1, pass wholly or partially in a refracting medium 2, the rest being absorbed or partially reflected.

D3. The "angle of incidence", sometimes denoted i is the angle by which the incident beam enters the refracting medium.

D4. The "totally or reflected ray" is the part of the light ray that having met the interface between the propagation medium and the refractive medium, continues his path in the propagation medium.

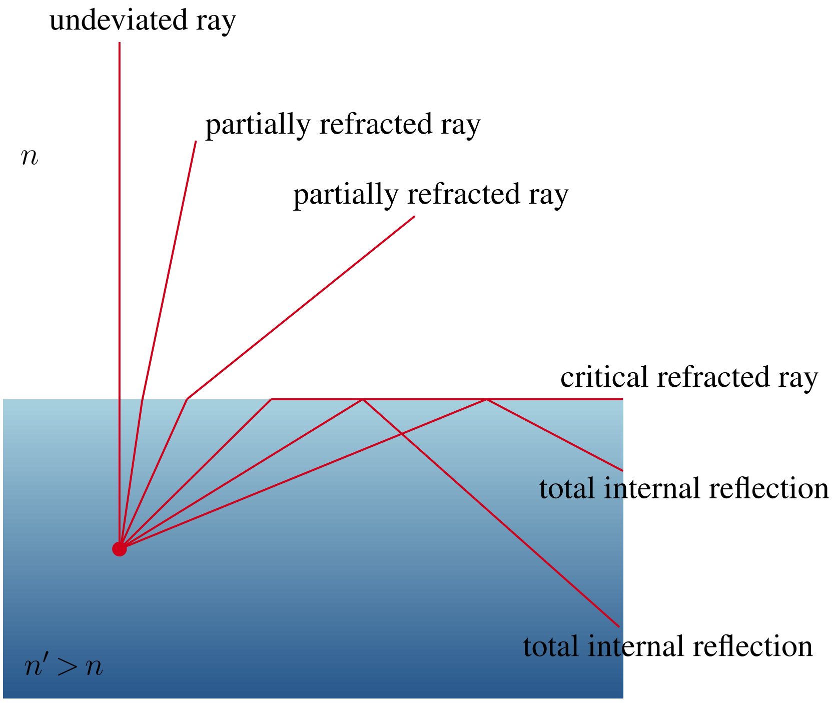
D5. The "reflection angle", sometimes denoted r_x or simply r if there is no possible confusion, is the angle by which the ray is reflected from the plane representing the interface between the propagation medium and itself. We will prove that the incident and reflected angles are equal in absolute values.

D6. The "partially or totally refracted ray" is the portion of the light ray having met the interface between the propagation medium and the refractive medium, continues its path in the refracting medium.

D7. The "angle of refraction", sometimes denoted r_c or sometimes simply r if there is no confusion, is the angle by which the ray is refracted by the plane representing the interface between the propagation medium and refracting medium. The incident and refracted angles are linked by a relation we prove further below.

D8. "Dioptrics" is the branch of optics dealing with refraction, especially by lenses. In contrast, the branch dealing with mirrors, reflection, is known as "catoptrics" (that's why telescopes that create their image with an objective that is a convex lens - refractors - are said to be "dioptric" telescopes).

An illustration that could help to understand some of these definitions better is the following:



undeviated ray
partially refracted ray
n
partially refracted ray
critical refracted ray

Figure 10.140: **Types of refractions and reflections**

For example with water this can give quite funny observations:

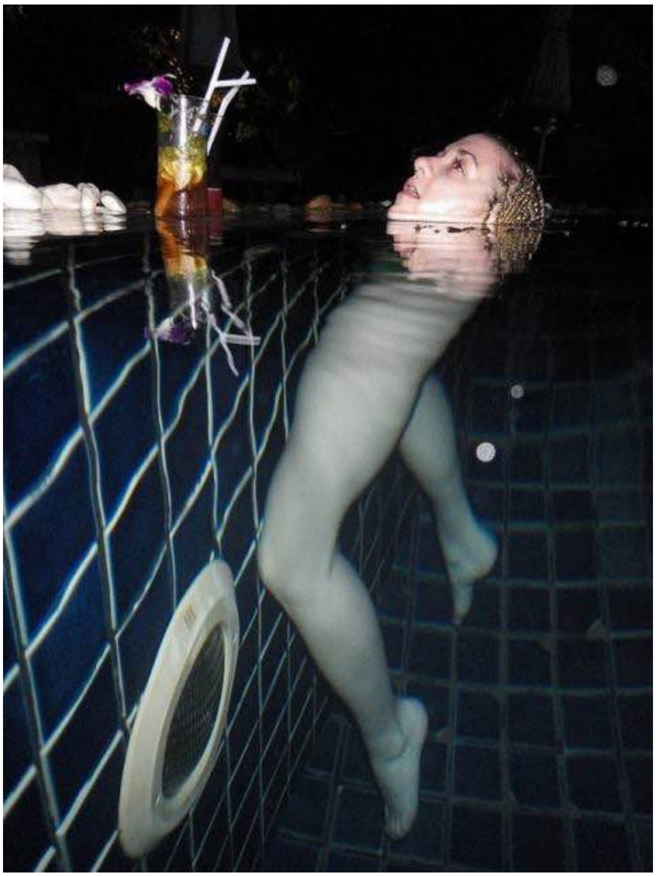

Figure 10.141: **Funny water reflection effect**

with its corresponding schematic explanation:

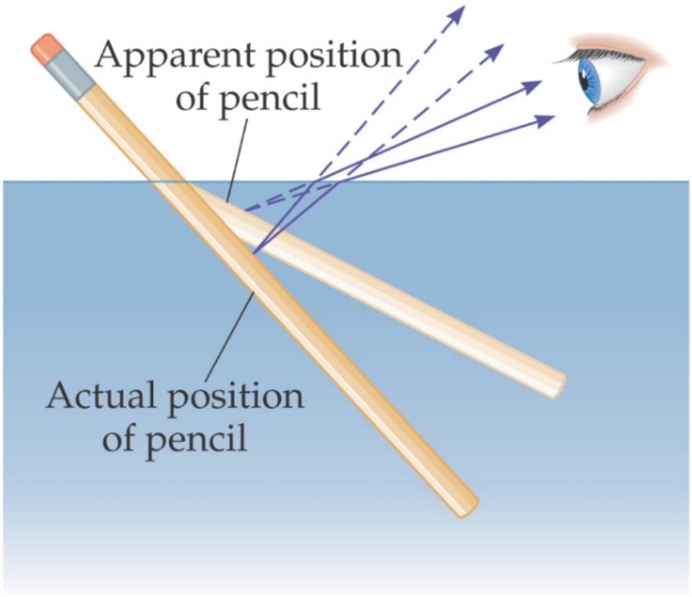

Figure 10.142: Water reflection ray diagram

Or a more tricky example that can be reproduced at home:

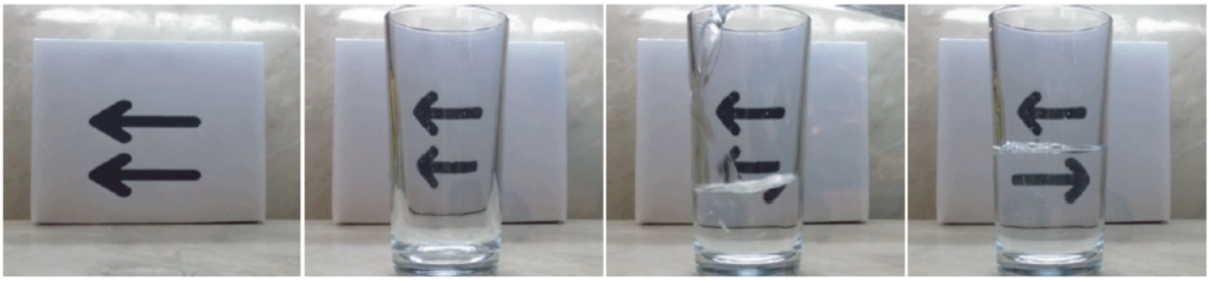

Figure 10.143: Source: Maric Vladimir

Before we continue, something important must be understand (or recall): "ideal refraction" must be discerned form "diffused refraction"! Since the light strikes different parts of the surface at different angles, it is reflected in many different directions, or diffused. So when we study refraction we in physics, we consider an "ideal refraction" with a "directional source of light"!

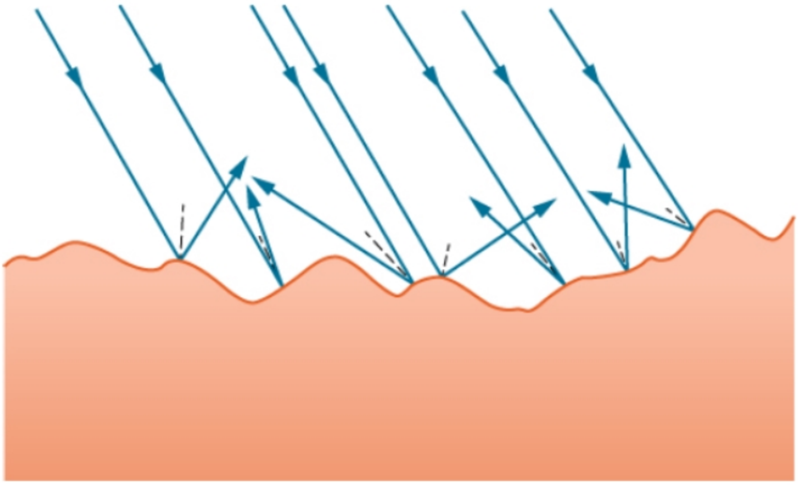

Figure 10.144: **Light is diffused when it reflects from a rough surface (source: OpenStax)**

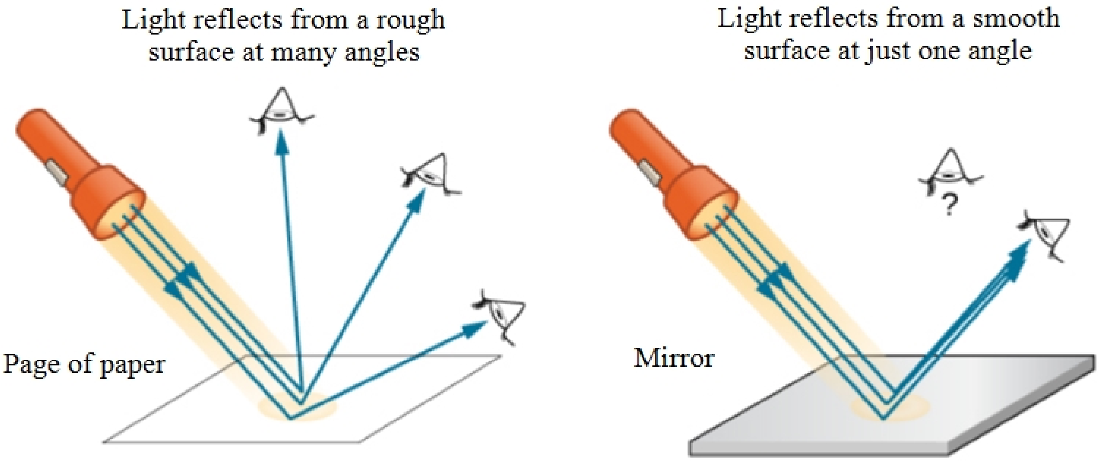
Diffused light is what allows us to see a sheet of paper from any angle:



Light reflects from a rough surface at many angles
Light reflects from a smooth surface at just one angle

10.5.4.1 Refractive index

The "absolute refractive index n_λ" of a medium at a given wavelength λ (and hence at a given frequency ν) measure the reduction factor of the phase velocity of light, denoted v_n in Geometric Optics, in the considered medium relatively to the speed of light in vacuum and is given quite generally by the "Cauchy's formula" (see section Electrokinetics page 4244):

$$n_\lambda=\frac{c}{v_n}=A+\frac{B}{\lambda^2}+\frac{C}{\lambda^4}+\ldots\cong A+\frac{B\nu^2}{c^2} \tag{10.5.44}$$

where A and B are experimentally determined constants. We can notice through the Cauchy's formula that the absolute refractive index decreases as the wavelength increases (verbatim when the frequency decrease).

Anyway, the theory of light-matter interaction on which Cauchy based this equation was later found to be incorrect. The "Sellmeier equation" is a later development of Cauchy's work that handles anomalously dispersive regions, and more accurately models a material's refractive index across the ultraviolet, visible, and infra-red spectrum and that is given by (see proof earlier above page 4243):

$$n_\lambda=\frac{c}{v_n}\cong\sqrt{1+\frac{B_1\lambda^2}{\lambda^2-C_1}+\frac{B_2\lambda^2}{\lambda^2-C_2}+\frac{B_3\lambda^2}{\lambda^2-C_3}} \tag{10.5.45}$$

Following what we have seen in the section of Electrodynamics it comes immediately:

$$n=\frac{c}{v_n}=cv_n^{-1}=\frac{1}{\sqrt{\varepsilon_0\mu_0}}\left(\frac{1}{\sqrt{\varepsilon_r\varepsilon_0\mu_r\mu_0}}\right)^{-1}=\frac{\sqrt{\varepsilon_r\varepsilon_0\mu_r\mu_0}}{\sqrt{\varepsilon_0\mu_0}}=\sqrt{\varepsilon_r\mu_r} \tag{10.5.46}$$

Therefore:

$$\boxed{n_\lambda=\frac{c}{v_n}\cong\sqrt{\varepsilon_r\mu_r}\cong\sqrt{1+\frac{B_1\lambda^2}{\lambda^2-C_1}+\frac{B_2\lambda^2}{\lambda^2-C_2}+\frac{B_3\lambda^2}{\lambda^2-C_3}}} \tag{10.5.47}$$

Remark

Obviously in reality all that stuff is also a function of the temperature and... not only...

All pure materials have absolute refractive index of a positive value greater than 1. More a medium is dense, more the phase velocity of light is slowed down, more the absolute refractive index is high.

Remark

There exist however material with smaller than 1 refractive index and even negative-index meta-material.

The process of describing light transport via the quantum mechanical description isn't trivial to explain the "slow down" of the phase velocity. The use of photons to explain such process involves the understanding of not just the properties of photons, but also the quantum mechanical properties of the material itself (something one learns in Solid State Physics courses).

A common explanation that has been provided is that a photon moving through the material still moves at the speed of c, but when it encounters the atom of the material, it is absorbed by the atom via an atomic transition. After a very slight delay, a photon is then re-emitted. This explanation is incorrect and inconsistent with empirical observations. If this is what actually occurs, then the absorption spectrum will be discrete because atoms have only discrete energy states. Yet, in glass for example, we see almost the whole visible spectrum being transmitted with no discrete disruption in the measured speed. In fact, the index of refraction (which reflects the speed of light through that medium) varies continuously, rather than abruptly, with the frequency of light.

Secondly, if that assertion is true, then the index of refraction would ONLY depend on the type of atom in the material, and nothing else, since the atom is responsible for the absorption of the photon. Again, if this is true, then we see a problem when we apply this to carbon, let's say. The index of refraction of graphite and diamond are different from each other. Yet, both are made up of carbon atoms. In fact, if we look at graphite alone, the index of refraction is different along different crystal directions. Obviously, materials with identical atoms can have different index of refraction. So it points to the evidence that it may have nothing to do with an "atomic transition".

When atoms and molecules form a solid, they start to lose most of their individual identity and form a "collective behaviour" with other atoms. It is as the result of this collective behaviour that one obtains a metal, insulator, semiconductor, etc. Almost all of the properties of solids that we are familiar with are the results of the collective properties of the solid as a whole, not the properties of the individual atoms. The same applies to how a photon moves through a solid.

A solid has a network of ions and electrons fixed in a "lattice". Think of this as a network of balls connected to each other by springs. Because of this, they have what is known as "collective vibrational modes", often named "phonons" as we will see it during our study of semi-conductors in the section Electrokinetics. These are quanta of lattice vibrations, similar to photons being the quanta of EM radiation. It is these vibrational modes that can absorb a photon. So when a photon encounters a solid, and it can interact with an available phonon mode (i.e. something similar to a resonance condition), this photon can be absorbed by the solid and then converted to heat (it is the energy of these vibrations or phonons that we commonly refer to as heat). The solid is then opaque to this particular photon (i.e. at that frequency). Now, unlike the atomic orbitals, the phonon spectrum can be broad and continuous over a large frequency range. That is why all materials have a "bandwidth" of transmission or absorption. The width here depends on how wide the phonon spectrum is.

On the other hand, if a photon has an energy beyond the phonon spectrum, then while it can still cause a disturbance of the lattice ions, the solid cannot sustain this vibration, because the phonon mode isn't available. This is similar to trying to oscillate something at a different frequency than the resonance frequency. So the lattice does not absorb this photon and it is re-emitted but with a very slight delay. This, naively, is the origin of the apparent slowdown of the light speed in the material. The emitted photon may encounter other lattice ions as it makes its way through the material and this accumulate the delay.

Moral of the story: the properties of a solid that we are familiar with have more to do with the "collective" behaviour of a large number of atoms interacting with each other. In most cases, these do not reflect the properties of the individual, isolated atoms.

Finally, the "relative refractive index n_{12}" specifically refers to comparing (ratio) of the absolute refractive index of an optically dense media to another background media such that:

$$n_{12}=\frac{n_1}{n_2}=\frac{\dfrac{c}{v_{p_1}}}{\dfrac{c}{v_{p_2}}}=\frac{v_{p2}}{v_{p1}} \tag{10.5.48}$$

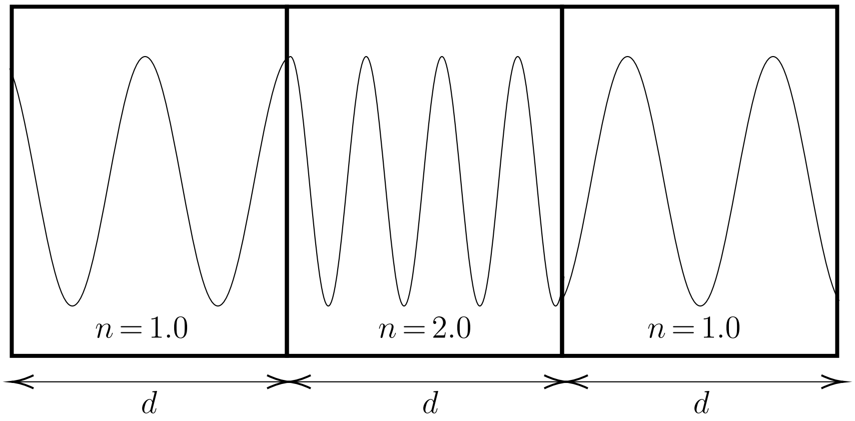
We can also use wavelengths to calculate refractive index. By substituting (notice that by conservation of energy the frequency is assumed to be the constant as $E=h\nu$):

$$v_{p_1}=\nu\lambda_{p_1} \qquad v_{p_2}=\nu\lambda_{p_2} \tag{10.5.49}$$

then:

$$\boxed{n_{12}=\frac{n_1}{n_2}=\frac{\dfrac{c}{v_{p_1}}}{\dfrac{c}{v_{p_2}}}=\frac{v_{p2}}{v_{p1}}=\frac{\lambda_{p2}}{\lambda_{p1}}} \tag{10.5.50}$$

This can be depicted by the following figure:



10.5.4.1.1 Index of refraction rate of change with altitude

The index of refraction obviously doesn't only depend on the wavelength as proven by the Sellmeier equation introduced earlier above. It depends also on temperature, pressure, medium density and gravitational acceleration when studied in the context of gases in Earth atmosphere. This point is especially important to understand some visual mirages (see further below at page 4397).

To determine the most famous relation of the index of refraction rate of change with altitude let us remind the Ideal Gas law (see section Continuum Mechanics page 3903)

$$PV=nRT \tag{10.5.51}$$

Now we have knowing the moral mass M_m:

$$PV=\frac{m}{M_m}RT \tag{10.5.52}$$

Hence:

$$\rho=\frac{m}{V}=\frac{PM_m}{mRT} \tag{10.5.53}$$

Assuming pressure and temperature are functions of altitude z:

$$\rho(z):=\frac{M_mP(z)}{RT(z)} \tag{10.5.54}$$

Let us take the derivative of density with respect to altitude:

$$\frac{\mathrm{d}}{\mathrm{d}z}\rho(z)\rightarrow\frac{M_m\frac{\mathrm{d}}{\mathrm{d}z}P(z)}{RT(z)}-\frac{M_mP(z)\frac{\mathrm{d}}{\mathrm{d}z}T(z)}{RT(z)^2} \tag{10.5.55}$$

Let us reorganize that:

$$\frac{\mathrm{d}p}{\mathrm{d}z}(z)=\frac{M_m}{R}\left(\frac{\frac{\mathrm{d}P(z)}{\mathrm{d}z}T(z)-\frac{\mathrm{d}T}{\mathrm{d}z}P(z)}{T^2(z)}\right) \tag{10.5.56}$$

Now remember that:

$$\rho=\frac{M_mP}{RT} \tag{10.5.57}$$

and also that[15] (see page):

$$\frac{\mathrm{d}P}{\mathrm{d}z}=-\rho(z)g \tag{10.5.58}$$

Let us define the "lapse rate":

$$\gamma:=-\frac{\mathrm{d}T}{\mathrm{d}z} \tag{10.5.59}$$

Injecting these three relations into:

$$\frac{\mathrm{d}p}{\mathrm{d}z}(z)=\frac{M_m}{R}\left(\frac{\frac{\mathrm{d}P(z)}{\mathrm{d}z}T(z)-\frac{\mathrm{d}T}{\mathrm{d}z}P(z)}{T^2(z)}\right) \tag{10.5.60}$$

we get:

$$\frac{\mathrm{d}\rho}{\mathrm{d}z}(z)\cong\frac{M_m}{R}\left(-\frac{g\rho(z)}{T(z)}+\frac{\gamma P(z)}{T^2(z)}\right) \tag{10.5.61}$$

Let us choose a simple model is that the index of refraction varies linearly with atmospheric density ρ, which is a function of altitude z:

$$n(z)\cong\alpha\rho(z)+1\Leftrightarrow\rho(z)\cong\frac{n(z)-1}{\alpha} \tag{10.5.62}$$

---

[15] We know that g is not constant in height but that a good approximation for the first few kilometres of altitude to assume it constant!

where α is a given dimensional constant.

Therefore we also have:

$$\alpha\frac{\mathrm{d}\rho(z)}{\mathrm{d}z}\cong\frac{\mathrm{d}n(z)}{\mathrm{d}z}\Leftrightarrow\frac{\mathrm{d}\rho(z)}{\mathrm{d}z}\cong\frac{1}{\alpha}\frac{\mathrm{d}n(z)}{\mathrm{d}z}\qquad(10.5.63)$$

Hence:

$$\begin{aligned}\frac{\mathrm{d}\rho}{\mathrm{d}z}(z)&\cong\frac{M_m}{R}\left(-\frac{g\rho(z)}{T(z)}+\frac{\gamma P(z)}{T^2(z)}\right)\\&=-\frac{M_m g}{TR}\left(\frac{n(z)-1}{\alpha}\right)+\frac{M_m}{R}\frac{\gamma P(z)}{T^2(z)}\\&=-\frac{\rho(z)g}{P(z)}\left(\frac{n(z)-1}{\alpha}\right)+\frac{\gamma}{T(z)}\left(\frac{n-1}{\alpha}\right)\end{aligned}\qquad(10.5.64)$$

In the last equality:

$$\frac{\mathrm{d}\rho}{\mathrm{d}z}(z)=-\frac{\rho(z)g}{P(z)}\left(\frac{n(z)-1}{\alpha}\right)+\frac{\gamma}{T(z)}\left(\frac{n-1}{\alpha}\right)\qquad(10.5.65)$$

We can substitute:

$$\frac{\mathrm{d}\rho(z)}{\mathrm{d}z}\cong\frac{1}{\alpha}\frac{\mathrm{d}n(z)}{\mathrm{d}z}\qquad(10.5.66)$$

So we get:

$$\frac{1}{\alpha}\frac{\mathrm{d}n(z)}{\mathrm{d}z}=-\frac{\rho(z)g}{P(z)}\left(\frac{n(z)-1}{\alpha}\right)+\frac{\gamma}{T(z)}\left(\frac{n-1}{\alpha}\right)\qquad(10.5.67)$$

So:

$$\frac{\mathrm{d}n}{\mathrm{d}z}\cong-(n(z)-1)\left(\frac{\rho(z)g}{P(z)}-\frac{\gamma}{T(z)}\right)=-\frac{(n(z)-1)}{T(z)}\left(\frac{\rho(z)gT(z)}{P(z)}-\gamma\right)\qquad(10.5.68)$$

Finally:

$$\boxed{\frac{\mathrm{d}n}{\mathrm{d}z}\cong-\frac{(n(z)-1)}{T(z)}\left(\frac{\rho(z)gT(z)}{P(z)}+\frac{\mathrm{d}T}{\mathrm{d}z}\right):=-\frac{(n(z)-1)}{T(z)}(\gamma_g-\gamma)}\qquad(10.5.69)$$

✍**Example:**

Let us take the following quite well known common lapse rate assumption:

$$\gamma=0.0113\,[\Delta°\mathrm{C}\cdot\mathrm{m}^{-1}]$$

And a typical air temperature:

$$T=295.15\,[\mathrm{K}]$$

But also a typical air pressure at sea level:

$$P=101,325\,[\mathrm{Pa}]$$

We take for the average acceleration on Earth at sea level gravity:

$$g = 9.80665\,[\text{m}\cdot\text{s}^{-1}]$$

and the index of refraction of air at $0\,[^\circ\text{C}]$ and at the sea level:

$$n = 1.000293$$

For the density of air at standard ambient temperature and pressure:

$$\rho_{\text{SATP}} = 1.168\,[\text{kg}\cdot\text{m}^{-3}]$$

Then we get:

$$\begin{aligned}
n' &\cong -\frac{(n(z)-1)}{T(z)}\left(\frac{\rho(z)gT(z)}{P(z)}-\gamma\right)\\
&\cong -\frac{(1.000293-1)}{295.15}\left(\frac{1.168\cdot 9.80665\cdot 295.15}{101,325}-0.0113\right)\\
&\cong -2.1904\cdot 10^{-8}\,[\text{m}^{-1}]
\end{aligned}$$

10.5.4.2 Snell's law

Let us consider (see figure below) two respective medium[16] M_n and M_m of refractive indices n and m (implicitly dependent on the wavelength as we will consider constant temperature) and whose contact surface is flat. Consider two points A and B respectively in the medium of index n (point A) and in the medium of index m (point B).

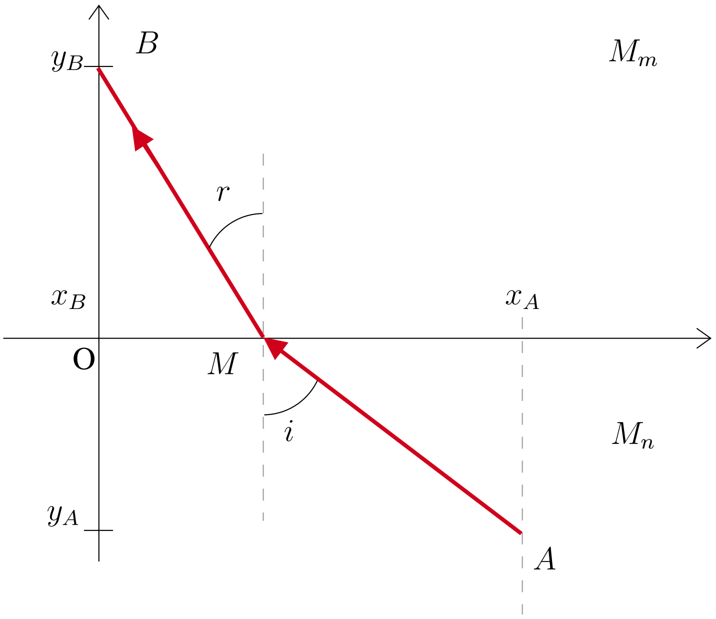
Consider the path of light going from A to B. Fermat's principle teaches us that the path taken by the light is such that the time taken to travel is minimum.

Therefore we propose in a first time to apply a standard method to calculate the path of the light ray and secondly, we will show that Fermat's principle can be stated as a variational principle!!!

Let us choose a reference frame that simplifies the problem: let us make coincide the x-axis with the contact plane of both medium and the y-axis through point B. In such a reference frame, points A and B have the following coordinates: $A(x_A, y_A)$, $B(0, y_B)$.

Let us denote by $M(x, 0)$, the point where the light beam passes through the contact surface between the two medium. The time t taken by light to get from A to B is by applying simple kinematics relations:

$$t=\frac{\overline{AM}}{v_n}+\frac{\overline{MB}}{v_m}=\frac{n\overline{AM}}{c}+\frac{m\overline{MB}}{c} \tag{10.5.70}$$



where:

$$v_n=\frac{c}{n} \quad \text{and} \quad v_m=\frac{c}{m} \tag{10.5.71}$$

are the phase velocity of light in the medium M_n and M_m.

---

[16] It can also be one medium but with two different physical properties values like different temperature, different density and different pressure.

We can observe on the figure above that the incident rays are refracted on the other side of the axis perpendicular to the interface. This is a typically characteristic of material having a positive refraction index. But it is physically possible to build since the 11990s (holocene calendar) artificial composites "meta-materials" having negative refraction index:

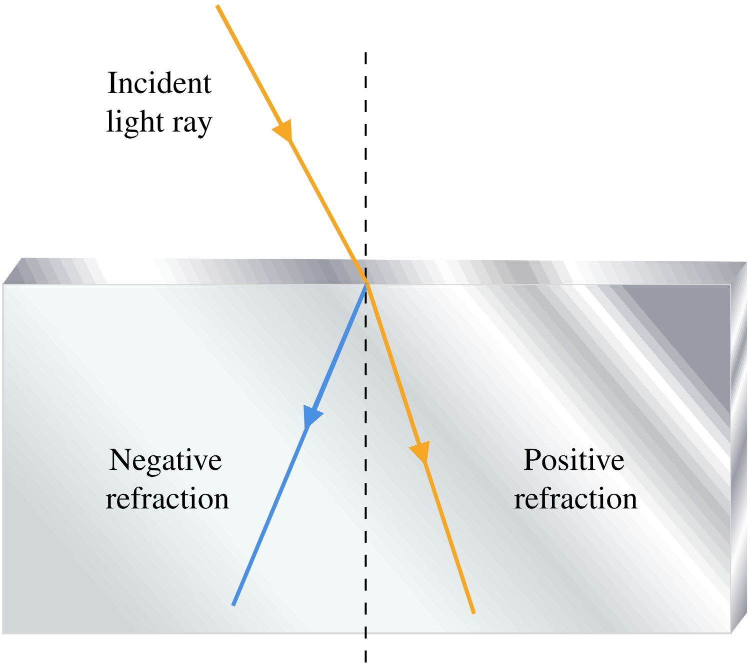


Figure 10.145: **Positive and negative refraction index material behaviour**

The writing of the two previous relations:

$$v_n=\frac{c}{n}\quad \text{and} \quad v_m=\frac{c}{m} \tag{10.5.72}$$

Developing the values of $\overline{AM}$ and $\overline{MB}$ we get the following dependence of t as a function of the position x of M:

$$t(x)=\frac{n\sqrt{(x_A-x)^2+y_A^2}}{c}+\frac{m\sqrt{x^2+y_B^2}}{c} \tag{10.5.73}$$

According to Fermat's principle, the path taken by the light is the one for which t is minimum. The extremum of $t(x)$ is reached when the derivative with respect to x is zero. Therefore:

$$\frac{\mathrm{d}t}{\mathrm{d}x}=\frac{n}{c}\frac{x-x_A}{\sqrt{(x_A-x)^2+y_A^2}}+\frac{m}{c}\frac{x}{\sqrt{x^2+y_B^2}} \tag{10.5.74}$$

Notice that:

$$\frac{x-x_A}{\sqrt{(x_A-x)^2+y_A^2}}=\frac{x-x_A}{\overline{AM}}=-\sin(i)\quad \text{and} \quad \frac{x}{\sqrt{x^2+y_B^2}}=\frac{x}{\overline{MB}}=\sin(r) \tag{10.5.75}$$

The condition of an extremum time brought by the light is then expressed by:

$$\frac{\mathrm{d}t}{\mathrm{d}x}=0\Leftrightarrow -\frac{n}{c}\sin(i)+\frac{m}{c}\sin(r)=0 \tag{10.5.76}$$

It is sufficient that the angles of incidence and refraction meet that condition so that the path travelled by light is actually the one that takes the least time.

Hence we get the relation, known as the "Snell's law" (which is not anymore a law as we just proved it):

$$\boxed{n\sin(i)=m\sin(r)} \tag{10.5.77}$$

We write more frequently the Snell-Descartes law in physics as following:

$$\boxed{n_{12}=\frac{n}{m}=\frac{n_1}{n_2}=\frac{\sin(r)}{\sin(i)}} \tag{10.5.78}$$

where the i stands for "incident" (often denoted θ_1) and the r for "refracted" (often denoted θ_2).

Remarks

R1. We will see during our study of wave optics that we can fall back (prove) the same relation but without the assumptions bases of geometrical optics. Therefore, the latter relation is named "Descartes-Snell relation " or just "Snell's law".

R2. When we speak of the relative refractive index of a given medium without reference to another medium, the default environment is the vacuum.

R3. Some materials do not have an absolute isotropic index of refraction : it then depends on the direction of propagation and the polarization state of light. This property is named "birefringence".

Let us now study the relation between the relative refractive index and the phase velocity of light in the various medium through which it passes.

A light ray connects two points A_1 and A_2 located on either side of an interface S between the two mediums. This light ray is not shown in the figure below. Only are drawn the path located on either side of the light ray that satisfy the extremum (we rely now on the study of the maximum path length). By hypothesis, they are extremely close, so the distance $\overline{PQ}$ is very small:

$$\overline{PQ}\ll\overline{A_1A_2} \tag{10.5.79}$$

We will admit that they correspond to the same travel time.

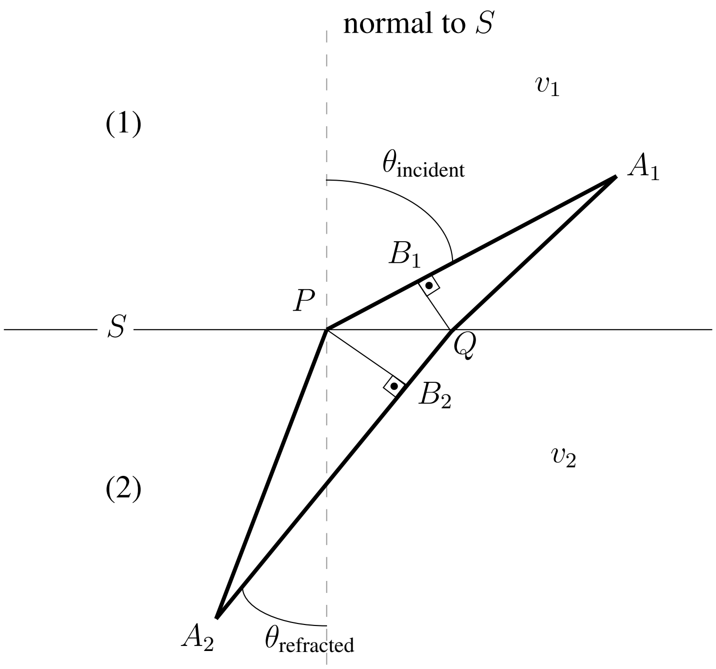

Figure 10.146: **Figure allowing to connect phase velocity and refractive index**

Since both paths are very close, we can assume the equality of the distances $\overline{A_1B_1}$ and $\overline{A_1Q}$ one hand, and of $\overline{PA_2}$ and $\overline{B_2A_2}$ of the other one. Thus, by hypothesis:

$$\frac{\overline{PB_1}}{v_1}=\frac{\overline{QB_2}}{v_2} \tag{10.5.80}$$

But, under the same hypothesis:

$$\begin{aligned}\overline{PB_1}=\overline{PQ}\cos\left(\frac{\pi}{2}-\theta_i\right)=\overline{PQ}\sin(\theta_i)\\ \overline{PB_2}=\overline{PQ}\cos\left(\frac{\pi}{2}-\theta_r\right)=\overline{PQ}\sin(\theta_r)\end{aligned} \tag{10.5.81}$$

such that:

$$\frac{\sin(\theta_r)}{\sin(\theta_i)}=\frac{\sin(r)}{\sin(i)}=\frac{v_2}{v_1} \tag{10.5.82}$$

The "refraction law" is finally stated in general as following:

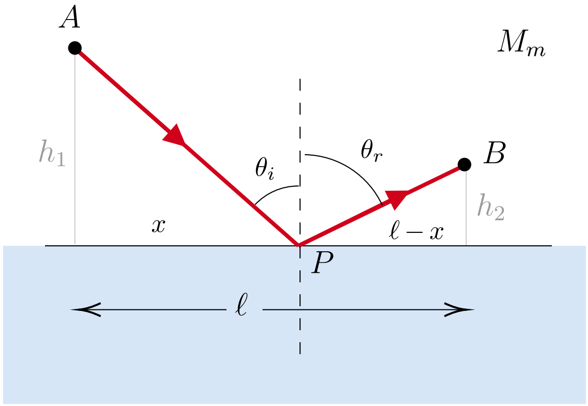
$$\boxed{n_{12}=\frac{v_2}{v_1}=\frac{n_1}{n_2}=\frac{\sin(r)}{\sin(i)}} \tag{10.5.83}$$

Remark

The angle $\pi/2-i$ (or often denoted $\pi/2-\theta_1$) is commonly named the "grazing angle".

And about the reflection angle, as we have already stated, it remains equal to the angle of incidence if the reflective surface is perfectly smooth and flat. This can also be proven using Fermat principle!

Indeed, consider the light ray shown in the figure below:



A ray of light starting at point A reflects off the surface at point P before arriving at point B, a horizontal distance ℓ from point A. We calculate the length of each path and divide the length by the speed of light to determine the time required for the light to travel between the two points:

$$t(x)=\frac{\sqrt{x^2+h_1^2}}{c}+\frac{\sqrt{(\ell-x)^2+h_2^2}}{c} \tag{10.5.84}$$

To minimize the time we set the derivative of the time with respect to x equal to zero. We also use the definition of the sine as opposite side over hypotenuse to relate the lengths to the angles of incidence and reflection. Hence:

$$0=\frac{\mathrm{d}t}{\mathrm{d}x}=\frac{x}{c\sqrt{x^2+h_1^2}}+\frac{-(\ell-x)}{c\sqrt{(\ell-x)^2+h_2^2}} \tag{10.5.85}$$

Rearranging and simplifying we get:

$$\frac{x}{\sqrt{x^2+h_1^2}}=\frac{(1\ell-x)}{\sqrt{(\ell-x)^2+h_2^2}} \tag{10.5.86}$$

Using the definition of sine this lead us to write:

$$\sin(\theta_i)=\sin(\theta_r) \tag{10.5.87}$$

So finally we get the "law of reflection":

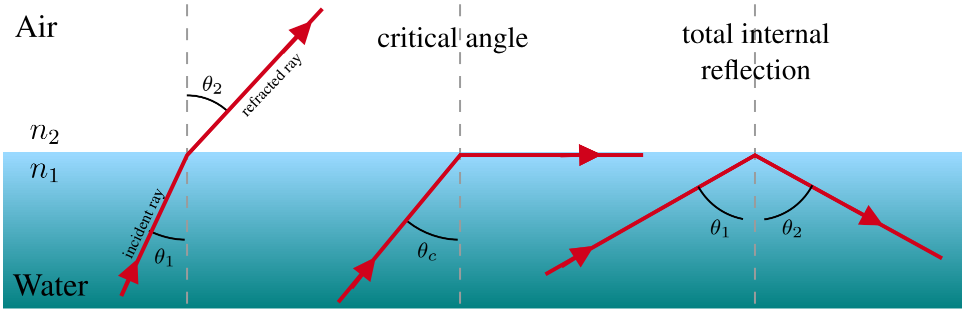
$$\boxed{\theta_i=\theta_r} \tag{10.5.88}$$

The law of reflection states then that on reflection from a smooth surface, the angle of the reflected ray is always equal to the angle of the incident ray!

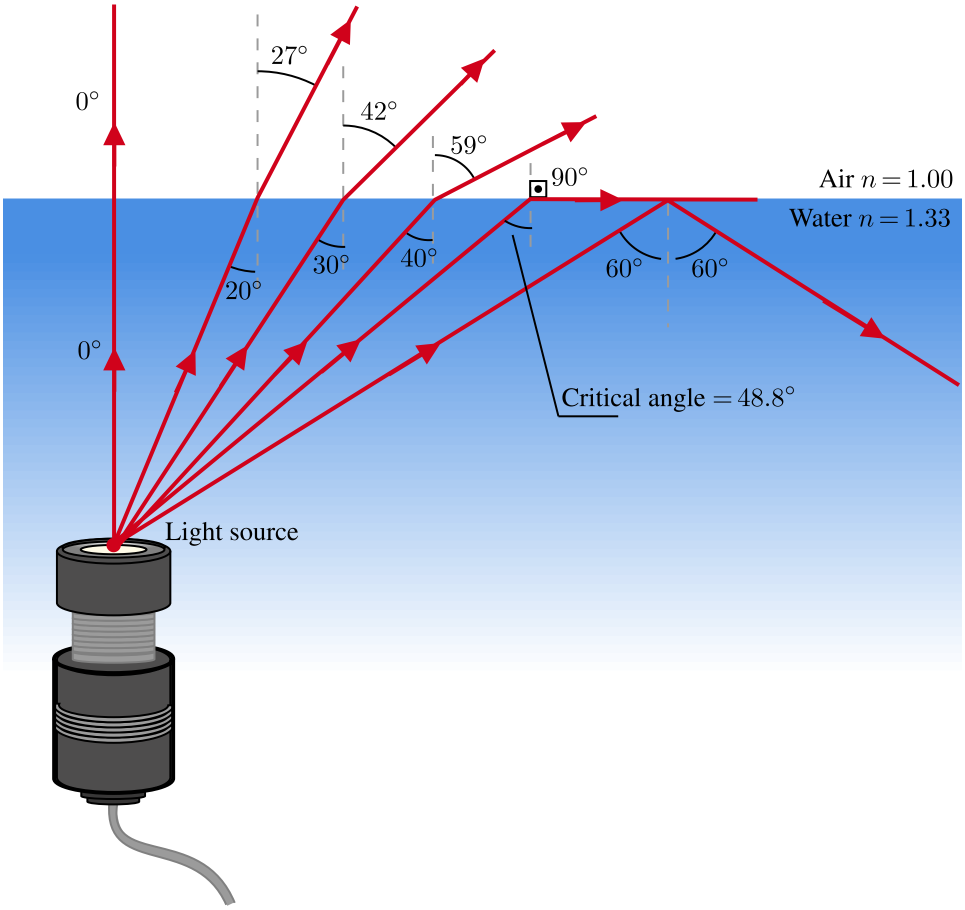
Now let us come back to the law of refraction and rearranging it as following:

$$\sin(i)=\frac{n_2}{n_1}\sin(r) \tag{10.5.89}$$

and the case where $n_1>n_2$ (for example passage from water to air). Then, for values close to 1, that is to say for grazing angles of incidence (incident beam close to the surface), the Snell's law gives a value greater than 1. We then get out of the validity domain of the law. This corresponds to situations where there is no refraction but only for reflection, then we speak of "total reflection":



Air
n_2
n_1
Water
θ_2
refracted ray
incident ray
θ_1
critical angle
θ_c
total internal reflection
θ_1
θ_2



0°
27°
42°
59°
90°
Air $n = 1.00$
Water $n = 1.33$
20°
30°
40°
60°
60°
0°
Critical angle = 48.8°
Light source

Figure 10.147: **Critical angle schematic illustration (raytracing)**

To find the "critical angle", we find the value for θ_i when θ_r is equal to $\pi/2$ and thus $\sin(\theta_r) = 1$. The resulting value of θ_i is equal to the critical angle θ_c.

Now, we can solve for θ_i, and we get the equation for the critical angle:

$$\boxed{\theta_c = \theta_i = \arcsin\left(\frac{n_2 \sin(90^\circ)}{n_1}\right) = \arcsin\left(\frac{n_2}{n_1}\right)} \tag{10.5.90}$$

In the case of a water-air boundary where $n_1 = 1.33$ and $n_2 = 1$ then the critical angle is $\theta_c =$

$48.7°$. Note this only happens when transitioning from more dense (high index of refraction) to less dense (lower index of refraction) medium!

For angles greater than the critical angle, the incident light is totally reflected, obeying the law of reflection.

So in the real life we can get such things:

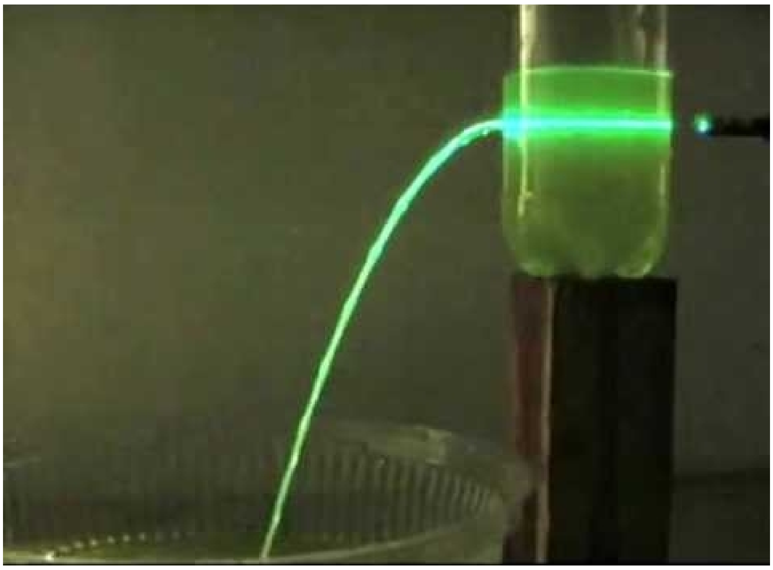


Figure 10.148: Air-Water total reflection example

Remark

Total internal reflection is used to carry light in fiber optics as we will see later below when introducing the mathematics of these information transmitters. The critical angle for a diamond-to-air surface is only $24.4°$, and so when light enters a diamond, it has trouble getting back out. Although light freely enters the diamond, it can exit only if it makes an angle less than $24.4°$ when he enters it.

Fermat's principle therefore has obvious similarities with the principle of least action in that it consists of a minimum principle. Even if a rigorous description of light requires the introduction of Quantum Mechanics, it is however possible to apprehend it with the tools of Analytical Mechanics and to apply on it, under certain assumptions, the principle of least action. We will prove just now that we then fall back on the Fermat's principle.

The calculations that we will present, introduce many hazardous assumptions, but this process should be considered as an approximation. It must be known to the reader that Fermat's principle also carries an approximation that we can qualify of "classical limit".

Now let us Imagine for the proof that light is composed of material "grains". We must admit that these grains obey to rather unusual physical properties: its mass is zero since according to the classical description, the light rays are not deflected by the gravitational field. This lack of mass thus makes them insensitive to the Earth's gravitational field (be careful and don't forget: we are in a "classical" description of the light as it was done in 119th century and before!!!!).

Let us write the action for one of these grains of light (see section Analytical Mechanics page

3162):

$$S=\int(T-V)\mathrm{d}t \tag{10.5.91}$$

Now by assuming that the only existing potential field V is that one that derives from the gravitational field and that we assume that light as it is insensitive to it (we know in General Relativity that this is wrong but we said just now that we would stay in classical point of view!!!), it follows that the action of light can be written:

$$S=\int T\mathrm{d}t \tag{10.5.92}$$

But no force applied to the light, so the kinetic energy T is a constant of motion. Applying the variational principle of least action we then have:

$$\delta S=0=\delta\left(\int T\mathrm{d}t\right)=T\delta\int\mathrm{d}t \tag{10.5.93}$$

Hence we get:

$$\delta\int\mathrm{d}t=0 \tag{10.5.94}$$

This equation means that the time taken by the light along its path is minimum (or more generally, is an extremum). We then fall back indeed on Fermat's principle. So we have proved that the under the classical limit Fermat's principle follows directly from the principle of least action.

Caution! The Fermat's principle doesn't explain anything, even if it's accurate that light follow the shortest path! That's why most textbooks introducing refraction as we did above geometrically (named sometimes the "marching soldier analogy", but wrong as nothing explain why the solders don't continue you walk straight) or using the variational principal (i.e. "Fermat's principle") are quite misleading. Using Huygens principle as we will see further below (see page 4470) is also wrong! In fact we should use Maxwell equation to understand better what happens physically!

10.5.4.3 Rainbow

A rainbow is an optical and meteorological phenomenon that makes the spectrum of light visible when the Sun (actually a G2V-type star, aka yellow dwarf) shines through the rain and the observer looks at the sky in a direction opposite to that of the Sun. It is a coloured arc with red on the outside and purple inside (excepted for higher order rainbows...).

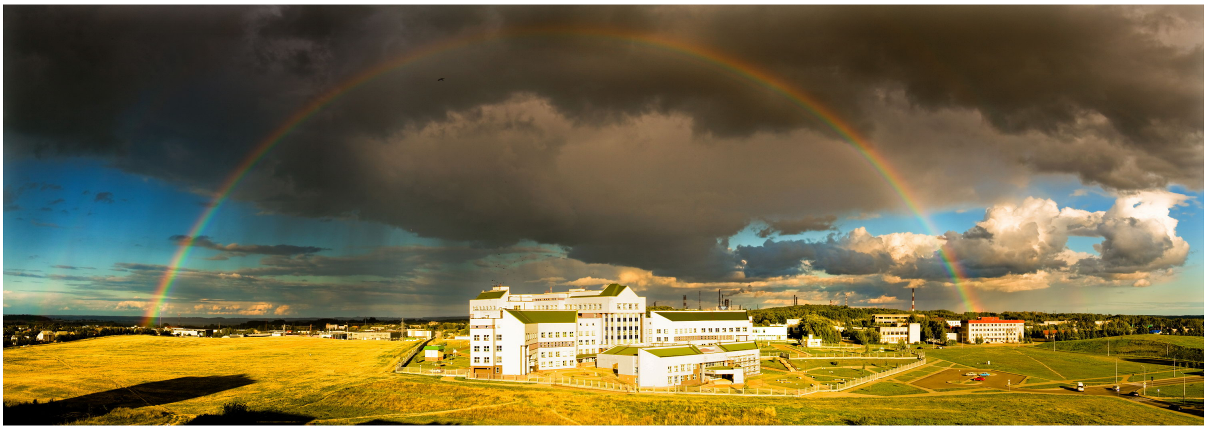

Figure 10.149: **Sun Rainbow after the rain, Grodno, Belarus (source: Wikipedia)**

The rainbow is caused by the scattering of sunlight by raindrops approximately spherical. The light is first refracted by penetrating the surface of the drop, then undergoes a partial reflection at the back of the drop and is refracted again on leaving (see figure below). The overall effect is that the incoming light is mainly refracted back at an angle of approximately $40-42^\circ$ (see proof below), regardless of the size of the drop. The precise value of the refraction angle depends on the wavelength (color) of light components as we know.

In the case of entry in a refracting medium, the angle of refraction of the blue light is lower than that of red light (phenomenon highlighted in the study of triangular prisms). Thus, after reflection at the water-air interface, the blue light comes out of a drop above the red light (see again figure below). The observer being fixed (at rest), he sees light from different drops of water with different angles with respect to the sunlight. Red therefore appears higher in the sky than the blue.

Sometimes a less bright second rainbow can be seen above the primary rainbow. It is caused by a double reflection of sunlight inside the raindrops and appears in a $50-53^\circ$ angle still in the opposite direction to the Sun. Due to the additional reflection, the colors of the second arc are reversed relative to the primary arc, with the blue outside and red inside, and the arc is less bright. That is why it is more difficult to observe.

quote
10.5:4372.#64

> *Understanding how a rainbow works doesn't make it less beautiful, it makes it more beautiful. That is Science!*
>
> Richard Dawkins

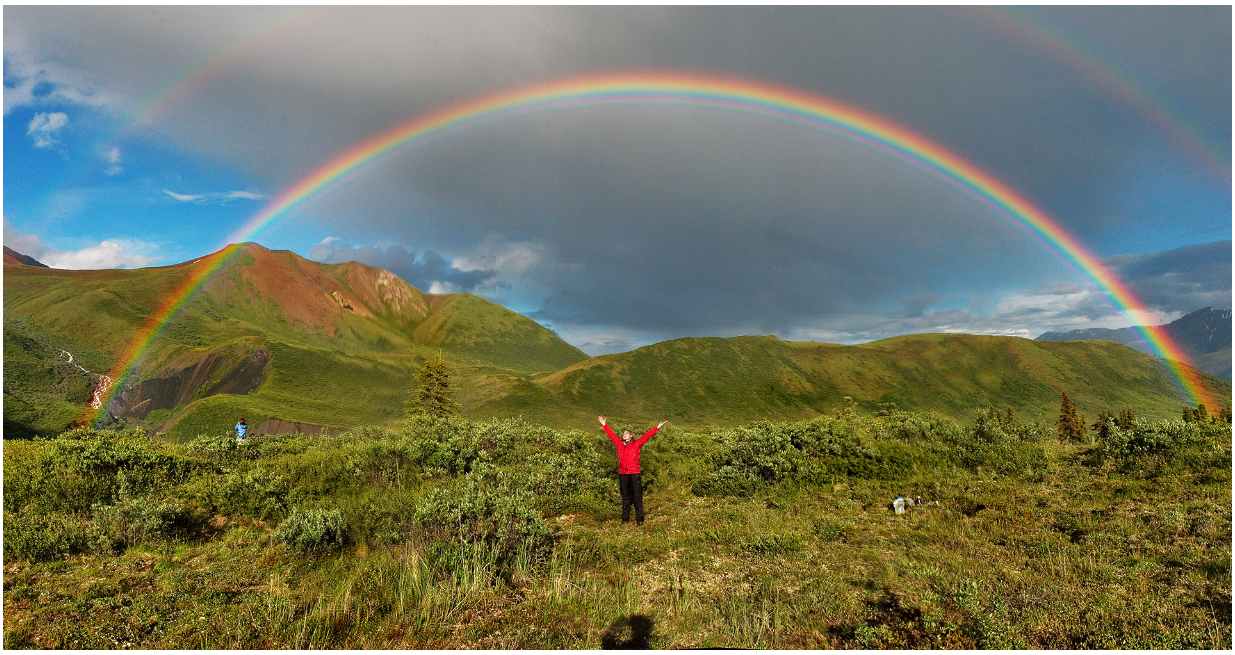

Figure 10.150: **Double Sun rainbow and supernumerary rainbows on the inside of the primary arc. The shadow of the photographer's head on the bottom marks the antisolar point (source: Wikipedia, Eric Rolph)**

A third rainbow sky may be present near the second, and inverted with respect thereto (i.e., identical to the first)...

However, third rainbow is much less bright and observable only under exceptional conditions. In practice it is not very easy to distinguish supernumerary arcs associated with the secondary arc. It corresponds to the light rays having undergone five reflections in the water drops.

Two rainbows inverted with respect to each other can also be observed in the opposite direction, about $45°$ from the Sun (therefore in the direction of it), but this is particularly difficult because of the proximity to the Sun. The few observations of these two arcs mention pieces of rainbows visible intermittently. These two rainbows correspond to light rays having undergone three and four reflections in the water drops. As they are located facing the Sun, it is not the same drops of water that contribute to it. In practice, favourable configurations to their observation are much fewer than those who favour the observation of the secondary arc, especially because of their proximity to the Sun.

To study the phenomenon let first consider the spherical water drop below with an incident beam of light (one refraction, two reflections) we represented the red and purple component (the angles are approximate) and the refractive indices water and air:

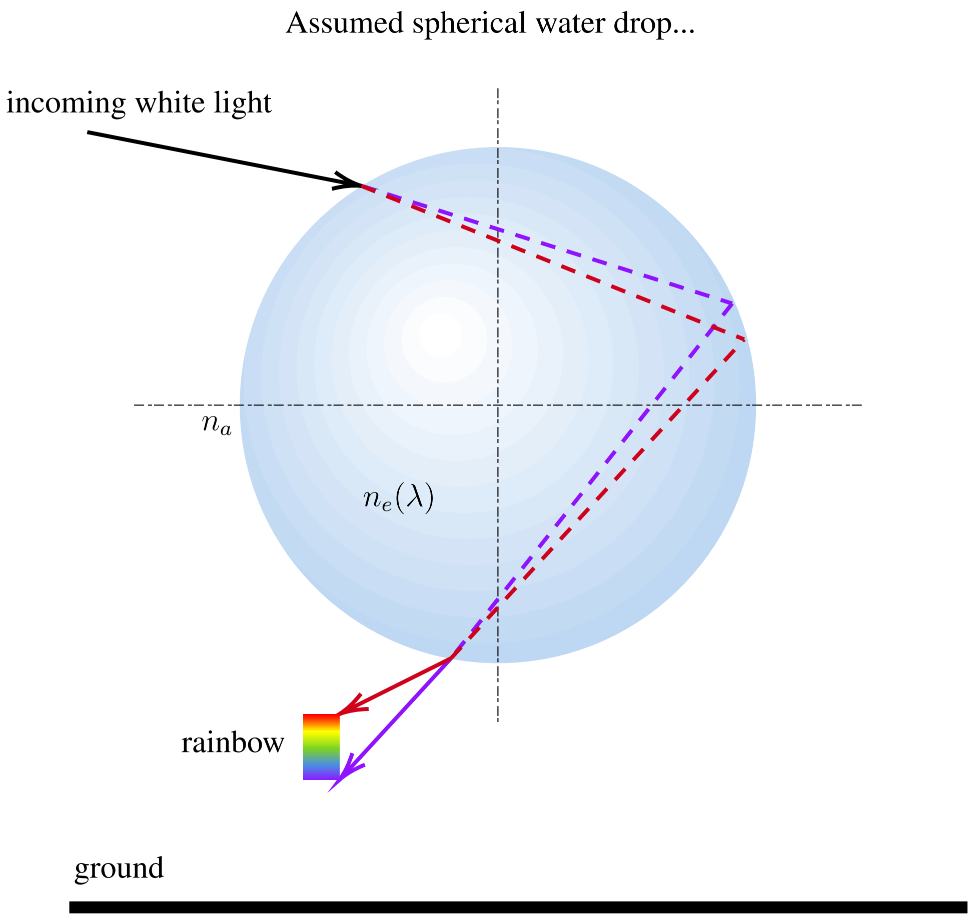

Figure 10.151: **Spherical water drop generating the rainbow sky**

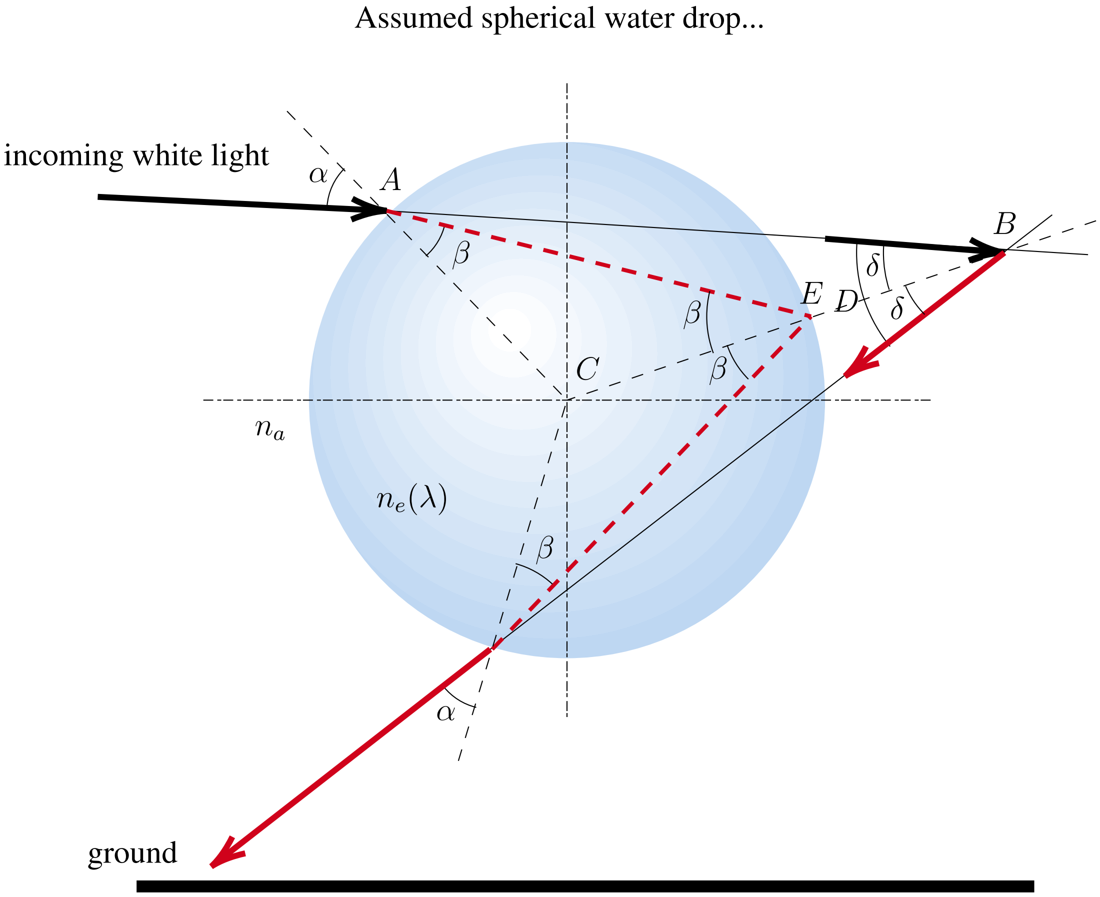
We seek to determine the angle between the incoming light ray (beam considered to contain all components of visible light) and the outgoing light beam (opposite the Sun: antisolar). Thus, the angle difference for two colors gives us the angle by which we must change our view to observe two different colors in the rainbow sky.

Remark

There is no sense to me to calculate the angle we must look at relatively with the ground (assumed plane) to observe a rainbow as some books mention it. Indeed, anyway if we turn our eyes to a rainbow sky will seen anyway over a large angle from the ground. The only thing that really makes sense, is the angle difference between two "monochromatic" colors.

For this study, we will consider the following approximate figure:



Assumed spherical water drop...
incoming white light
α
A
β
B
δ
E
D
δ
β
C
β
n_a
$n_e(\lambda)$
β
α
ground

Figure 10.152: Path travelled by light in a spherical water drop

With the Snell-Descartes law we have initially:

$$\frac{\sin(\alpha)}{\sin(\beta)}=\frac{n_e}{n_a}=n(\lambda) \quad (10.5.95)$$

What interests us here is the angle of apparent reflection 2δ, which we will denote D (careful! Some teachers choose the convention $D=\pi-2\delta$). To determine this, we start from the following relation of the triangle ABE:

$$(\alpha-\beta)+\delta+(\pi-\beta)=\pi \quad (10.5.96)$$

Therefore it comes:

$$\delta=2\beta-\alpha \quad (10.5.97)$$

Hence:

$$2\delta=4\beta-2\alpha=D \quad (10.5.98)$$

What we will write finally:

$$D=4\beta-2\alpha \quad (10.5.99)$$

and as:

$$\sin(\beta)=\sin(\alpha)\frac{n_a}{n_e}\rightarrow\beta=\arcsin\left(\frac{n_a}{n_e}\sin(\alpha)\right) \quad (10.5.100)$$

Therefore it comes:

$$\boxed{D(n_a,n_e,\alpha)=4\arcsin\left(\frac{n_a}{n_e}\sin(\alpha)\right)-2\alpha} \tag{10.5.101}$$

which is sometimes abusively written:

$$D(n_a,n_e,\alpha)=4\arcsin\left(n\sin(\alpha)\right)-2\alpha \tag{10.5.102}$$

If we make a practical application we have for red 750 [nm] with for example an incidence angle of 30° in the spherical water drop:

$$D(n_a,n_e,\alpha)=D(1.00,1.32,\pi/6)=4\arcsin\left(\frac{1.00}{1.32}\sin\left(\frac{\pi}{6}\right)\right)-2\frac{\pi}{6}\cong 0.506=29.03^\circ \tag{10.5.103}$$

and for purple 400 [nm] with the same angle of incidence of 30° in the spherical water drop:

$$D(n_a,n_e,\alpha)=D(1.00,1.34,\pi/6)=4\arcsin\left(\frac{1.00}{1.34}\sin\left(\frac{\pi}{6}\right)\right)-2\frac{\pi}{6}\cong 0.482=27.63^\circ \tag{10.5.104}$$

Thus an angle difference of about 2.4°.

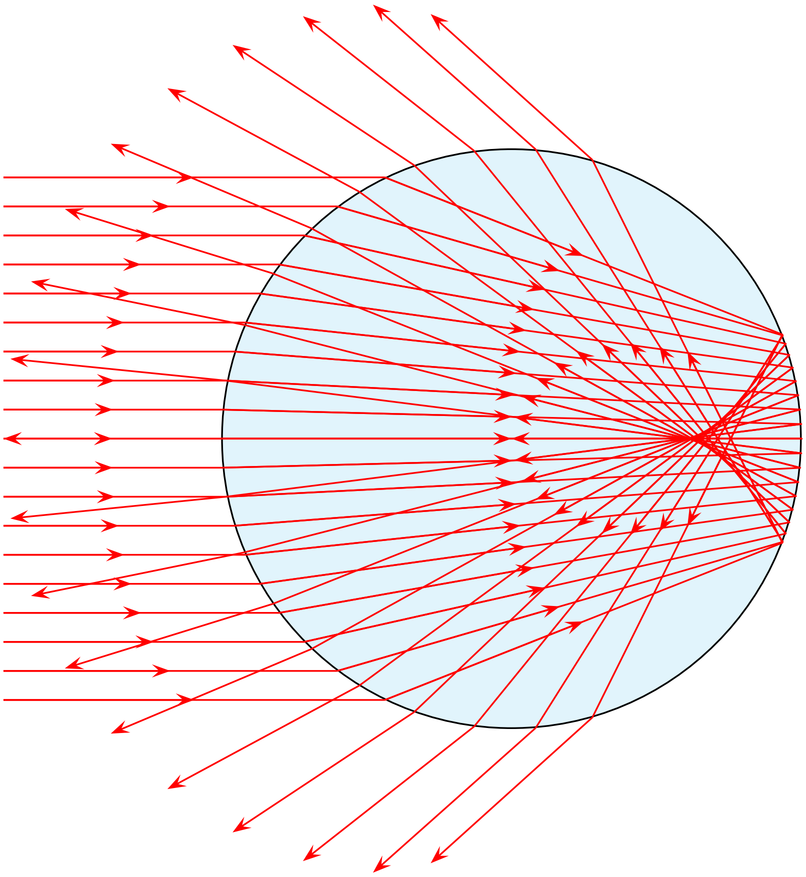


Figure 10.153: **Case of a bundle of parallel rays of identical color in a spherical rain drop**

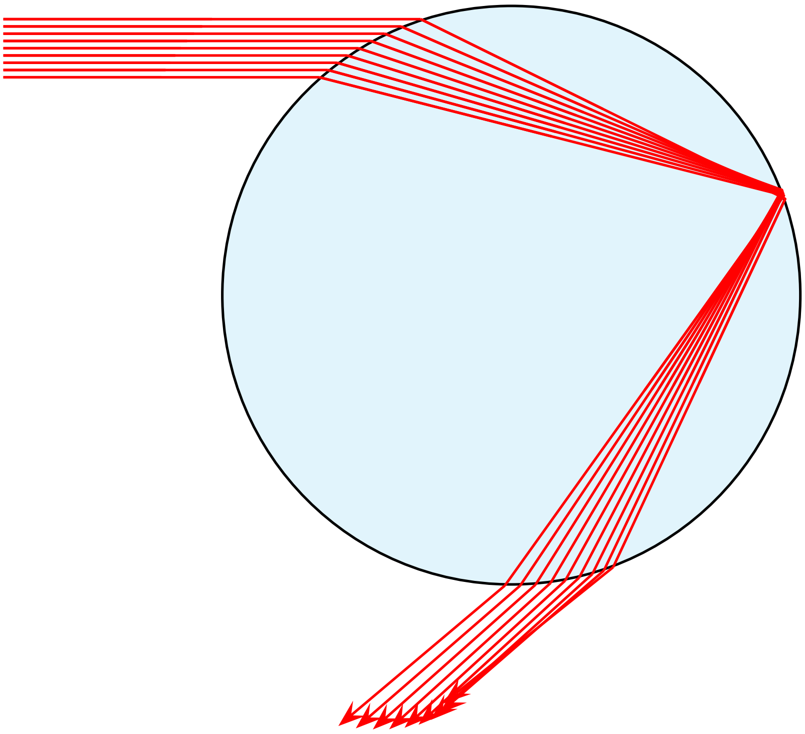
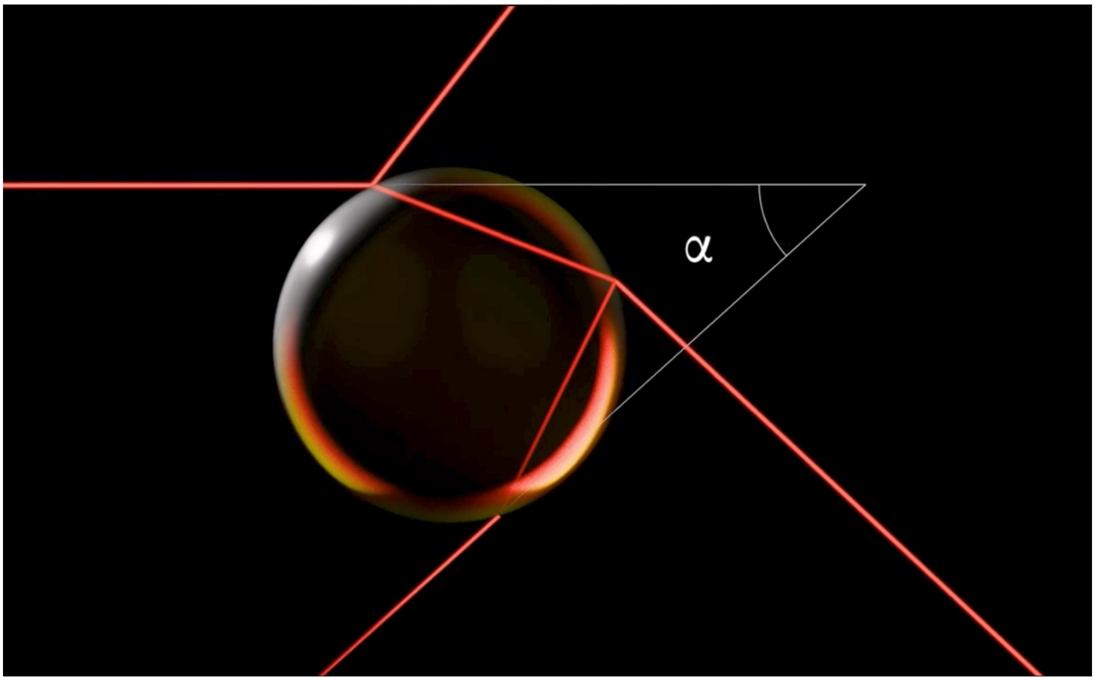
It is obvious that only the incident rays which strike the drop in its upper hemisphere will reach the eye of the terrestrial observer, after an internal reflection.

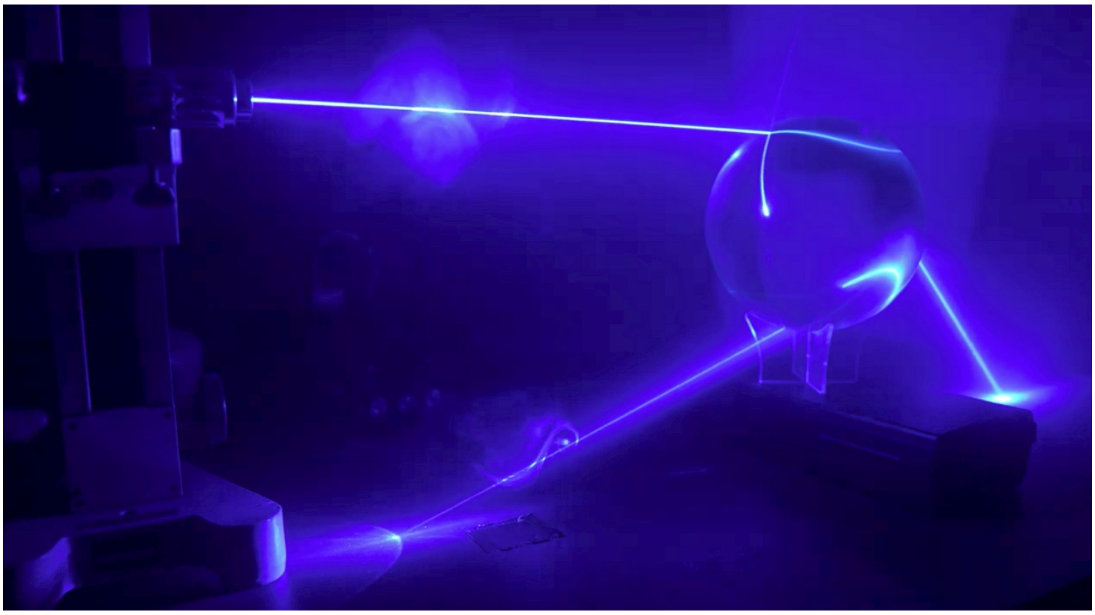
We redo the drawing, limiting ourselves to the upper incident rays:



If we do the illustration by including refracted and reflect rays the reader must not forget that the reality is much closer to the following illustration:



Or in real life with a LASER (whatever the color) and a spherical ball made of glass:



Finally, we could be interested in the angle α at which the angle D is maximum (which corresponds to the angle of the most visible rainbow sky in term of size in reality). We start then of:

$$f(\alpha)=-2\alpha+4\arcsin(n\sin(\alpha)) \tag{10.5.105}$$

and we seek the solutions of:

$$f'(\alpha)=0 \tag{10.5.106}$$

with $\alpha\in[0,\pi/2]$ and $n\in]0,1[$.

Let us recall that we have proved in the section of Differential and Integral Calculus that:

$$\arcsin'(x)=\frac{1}{\sqrt{1-x^2}} \tag{10.5.107}$$

Then we have:

$$f'(\alpha)=-2+\frac{4n\cos(\alpha)}{\sqrt{1-n^2\sin^2(\alpha)}}=0 \tag{10.5.108}$$

Hence:

$$\begin{gathered}\frac{2n\cos(\alpha)}{\sqrt{1-n^2\sin^2(\alpha)}}=1\Leftrightarrow\frac{4n^2\cos^2(\alpha)}{1-n^2\sin^2(\alpha)}=\Leftrightarrow\frac{4n^2\cos^2(\alpha)}{1-n^2(1-\cos^2(\alpha))}=1\\ \Leftrightarrow 4n^2\cos^2(\alpha)=1-n^2+n^2\cos^2(\alpha)\Leftrightarrow\cos^2(\alpha)=\frac{1-n^2}{3n^2}\end{gathered} \tag{10.5.109}$$

From there we get:

$$|\cos(\alpha)|=\frac{\sqrt{1-n^2}}{\sqrt{3}n} \tag{10.5.110}$$

that is to say:

$$\cos(\alpha)=\frac{\sqrt{1-n^2}}{\sqrt{3}n} \tag{10.5.111}$$

as we seek for solutions with $\alpha\in[0,\pi/2]$ and that the cosine is positive on this interval.

Therefore:

$$\alpha_{D_{\max}}=\arccos\left(\frac{\sqrt{1-n^2}}{\sqrt{3}n}\right) \tag{10.5.112}$$

He then comes for $n\cong 0.746$ (purple):

$$\alpha_{D_{\max}}=\arccos\left(\frac{\sqrt{1-n^2}}{\sqrt{3}n}\right)\cong 1.029\cong 60^\circ=\frac{\pi}{3} \tag{10.5.113}$$

This corresponds fairly well to the reality (the angle at which we raise our heads to see the most visible / larger part of the rainbow).

The corresponding deviation is then:

$$D=4\arcsin\left(n\sin(\alpha)\right)-2\alpha\cong 4\arcsin\left(0.746\sin\left(\frac{\pi}{3}\right)\right)-2\frac{\pi}{3}\cong 0.715\cong 40.97^\circ \tag{10.5.114}$$

and is named "rainbow angle" for purple:

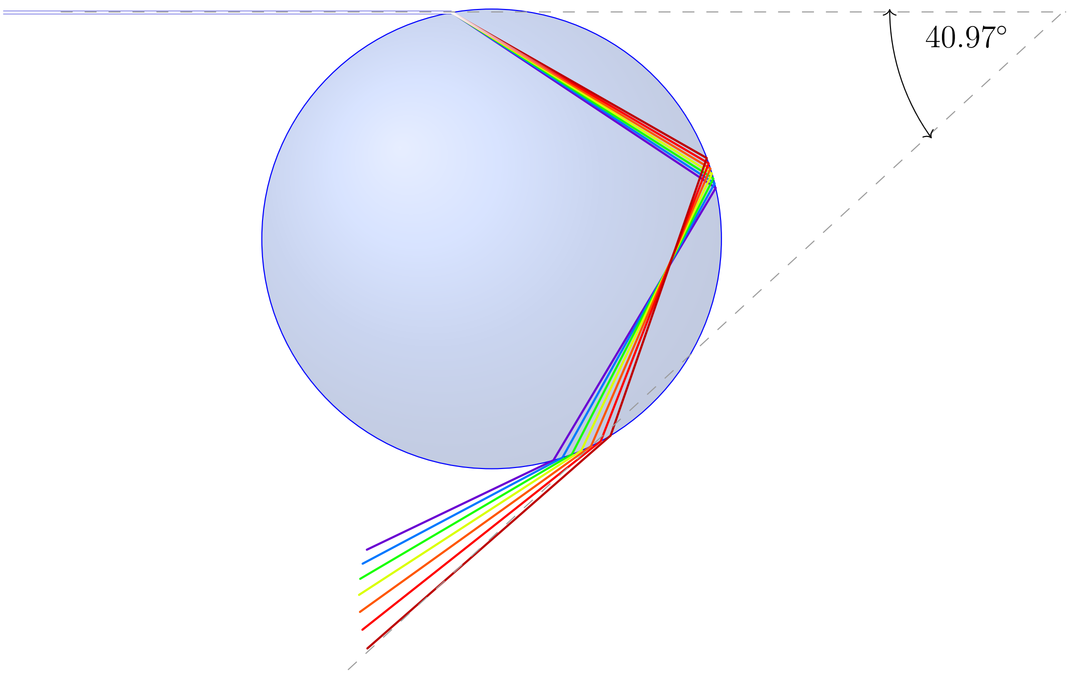


Figure 10.154: **Rainbow angle**

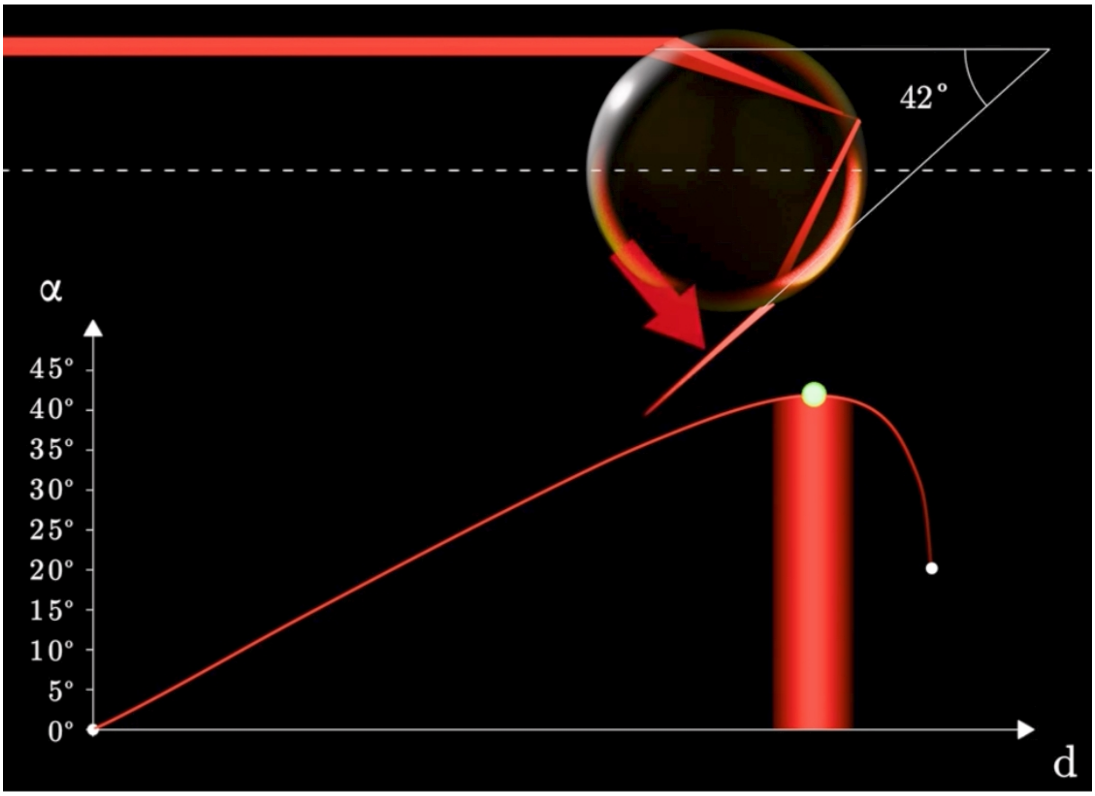
For the blue we get:

$$D=4\arcsin\left(n\sin(\alpha)\right)-2\alpha\cong 4\arcsin\left(0.757\sin\left(\frac{\pi}{3}\right)\right)-2\frac{\pi}{3}\cong 44^\circ \tag{10.5.115}$$

So the average gives the famous 42° that we can read in many textbooks (average corresponding to approximately to the red color).



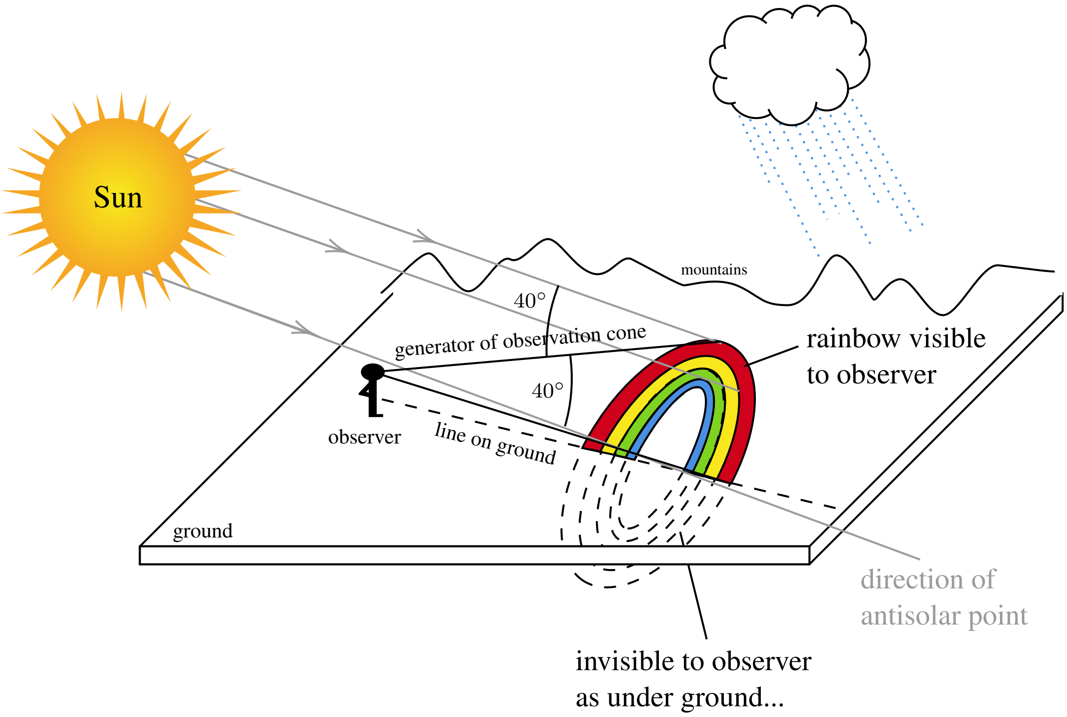
The reader must keep in mind that we have proved the Cauchy formula (see page 4244) that gives:

$$n \approx n_0 + \frac{C}{\lambda_0^2} \qquad (10.5.116)$$

with for water $n_0 = 1.3246$ and $C = 3092$, if the wavelength of λ_0 is expresse in nanometers. For the two extreme colors of the spectrum we have for $\lambda = 800$ [nm] (red) the value $n = 1.332$ and for $\lambda = 400$ [nm] (purple) the value $n = 1.345$.

Each color will therefore be deflected differently and this is what gives the phenomenon of the rainbow as depicted in the figure above. The angle between the extreme colors is very small, but the observer receiving this coloured beam being situated several kilometres away will see an arc of greater thickness the farther he is from it.

Thus, the light rays received by the observer and in which the red (outer edge of the rainbow) dominates correspond to all the rays coming from the wall of rain and making angle of about 40° with the direction of the sunlight (see figure below). The light rays forming each color of the rainbow sky then form the top of the cone observer's eyes and for axis the solar ray passing through the eyes of the observer:



Sun

ground
direction of
antisolar point
invisible to observer
as under ground...

Figure 10.155: Naive illustration of the generation of the primary rainbow (objects are not to scale!)

That gives in real life:

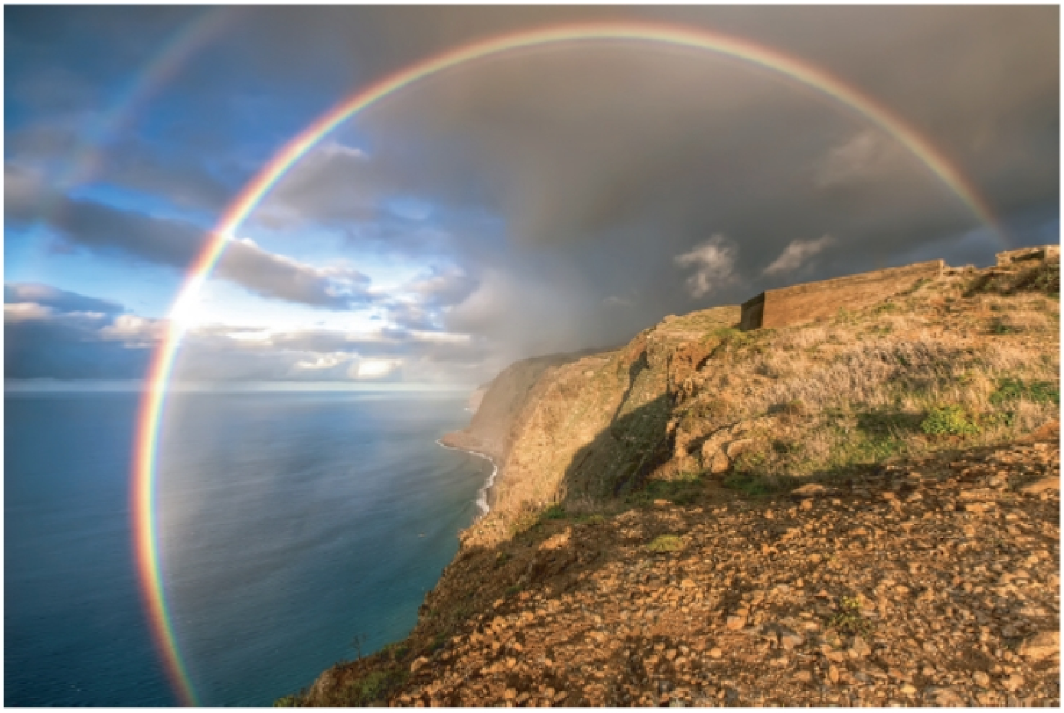

Figure 10.156: Full-circle rainbow (source: ed g2s, Christophe Afonso)

To observe a secondary rainbow (see the photo above in the upper left corner), it is necessary to consider the rays which strike the lower hemisphere of the drop of water and which after two successive reflections leave again downwards, towards the possible observers:

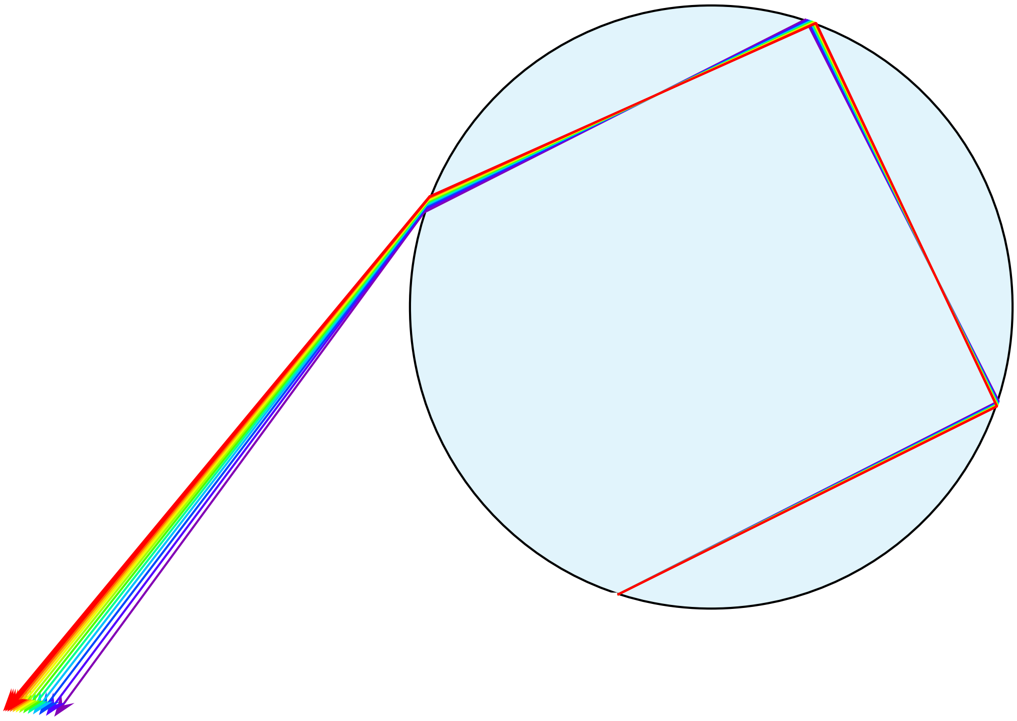

Figure 10.157: **Double rainbow mechanism**

We can see in the figure above that the order of colors is reversed (as we can also see it in the previous photo) and the spectrum is wider. However, due to the additional reflection, the secondary rainbow is much less luminous!

Remark

Even if in reality the rainbow has almost an infinity of colors a lot of people like to associate to the latter seven colors that can be remember with the following mnemonic technique: "*Richard (red) Of (orange) York (yellow) Gave (green) Battle (blue) In (indigo) Vain (violet)*"

The Sun rainbow is easy to reproduce experimentally at the macroscopic level as illustrated in the well-known case below in a photo:

However we have not been able to find a laboratory photo to this date (in a scientific paper) of a single drop of water which scatters the light into a rainbow (if anyone knows of such a photo, please do not hesitate to contact us!).

A "moonbow" (also known as a "moon rainbow" or "lunar rainbow") is a rainbow produced by moonlight rather than direct sunlight. Other than the difference in the light source, its formation is the same as for a solar rainbow: It is caused by the refraction of light in many water droplets, such as a rain shower or a waterfall, and is always positioned in the opposite part of the sky from the Moon relative to the observer.

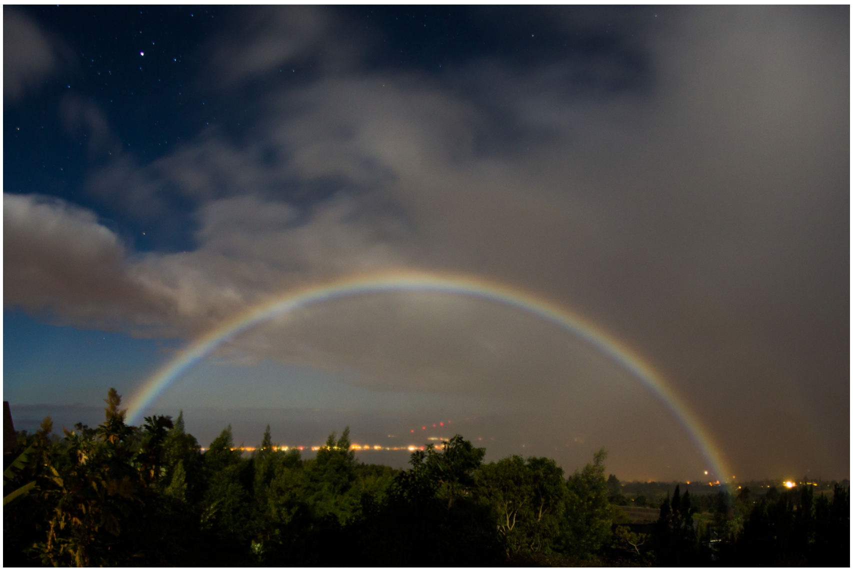

Figure 10.158: Moonbow over the town of Kihei, seen from Kula, on Maui, Hawaii, US on the 28th February 12016 (source: Wikipedia, author: Arne-kaiser)

A "Brocken spectre", well known and badly missinterpreted by religious people, is the magnified (and apparently enormous) shadow of an observer (individual, airplane, bird, crowd, etc.) cast upon clouds opposite the Sun's direction. The figure's head is often surrounded by the halo-rainbow like rings of coloured light forming a glory, which appears opposite to the Sun's direction when uniformly-sized water droplets in clouds refract and backscatter sunlight:

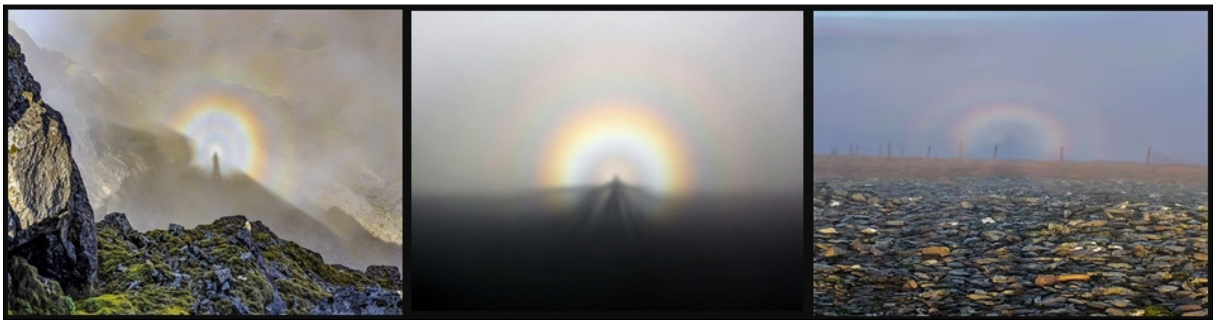

Figure 10.159: **Different photos of Brocken spectrums**

10.5.4.4 The 22° Halo

Under certain atmospheric conditions, a number of different halo phenomena occur, producing rings, arcs, columns, crosses or false suns from reflected or refracted sunlight. These are distinct from other atmospheric optical phenomena such as rainbows in that the surfaces of reflection and refraction are those of ice crystals, and not of liquid water droplets! This immediately suggests an explanation for the plethora of halos as compared to the limited number and form of bows and coronas, since the shape of ice crystals is much more varied than that of water droplets. Their reduced symmetry means that a given ice crystal can produce different halos depending upon orientation, and that a given halo can change shape as the Sun (actually a G2V-type star, aka yellow dwarf) changes height.

A "22° halo" is an atmospheric optical phenomenon that consists of a halo with an apparent radius of approximately 22° around the Sun or Moon. Around the Sun, it may also be named a "Sun halo". Around the Moon, it is also known as a "moon ring", "storm ring", or "winter halo".

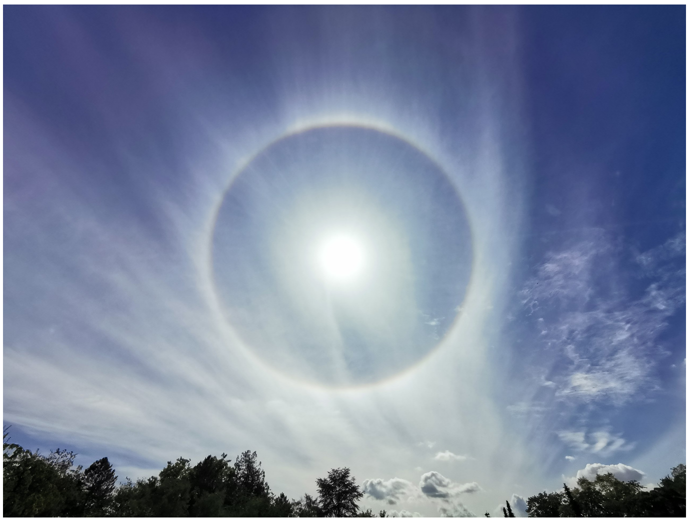

Figure 10.160: 22° **Sun Halo**

It forms as sunlight or moonlight is refracted by millions of hexagonal ice crystals (60° faces) suspended in the atmosphere in thin cirro-stratus clouds:

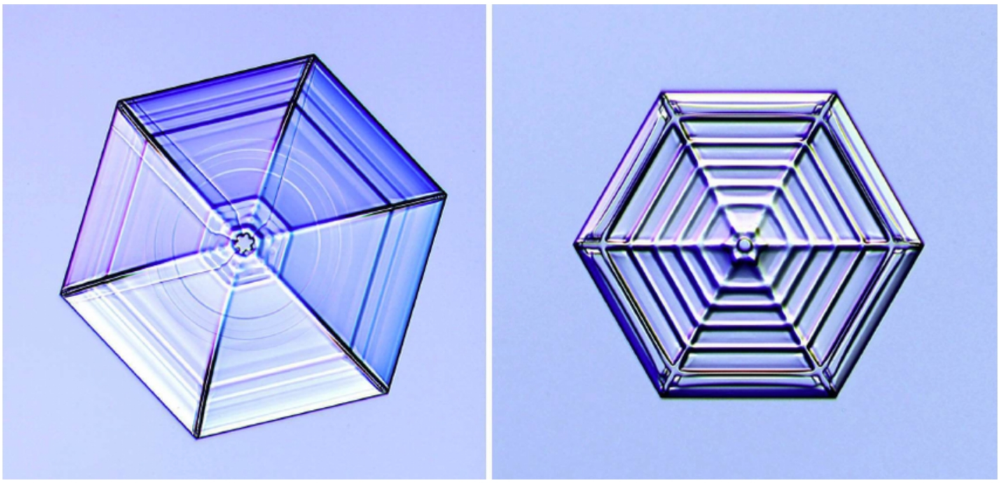

Figure 10.161: Photographs showing two hexagonal POP ice crystals with several commonly seen morphological

Atmospheric ice crystals form as hexagonal prisms, referred to as "plates" if the axis is much shorter than the diameter, and as "needles" if it is much longer. The ends of the prisms can be either flat, or have pyramidal caps.

Remark

Even though it is one of the most common types of halo, the shape and orientation of the ice crystals responsible for the 22° halo are the topic of debate. Hexagonal, randomly oriented columns are usually put forward as the most likely candidate, but this explanation presents problems, such as the fact that the aerodynamic properties of such crystals leads them to be oriented horizontally rather than randomly. Alternative explanations include the involvement of clusters of bullet-shaped ice columns.

As light passes through the 60° apex angle of the hexagonal ice prisms, it is deflected twice, resulting in deviation angles ranging from 22° to 50°. Given the angle of incidence onto the hexagonal ice prism $\theta_{\text{incidence}}$ and the refractive index inside the prism n, then the angle of deviation $\theta_{\text{deviation}}$ can be derived from Snell's law:

$$\theta_{\text{deviation}}=\theta_{\text{incidence}}+\sin^{-1}\left[n\sin\left(\dfrac{\pi}{3}-\sin^{-1}\dfrac{\sin(\theta_{\text{incidence}})}{n}\right)\right]-\dfrac{\pi}{3} \tag{10.5.117}$$

The ice crystals in the clouds all deviate the light similarly, but only the ones from the specific ring at 22° contribute to the effect for an observer at a set distance. As no light is refracted at angles smaller than 22°, the sky is darker inside the halo.

Let us prove the relation above! First let us remind that all the interior angles of a hexagon are equal to $\pi/3$ (see section Geometric Shapes page 2909):

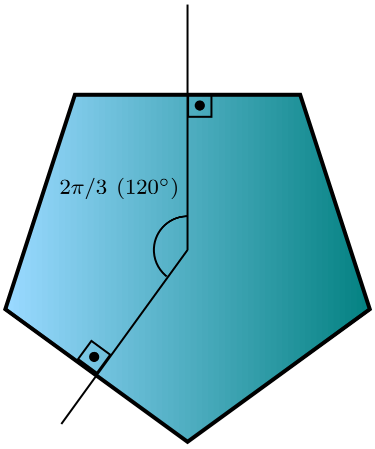
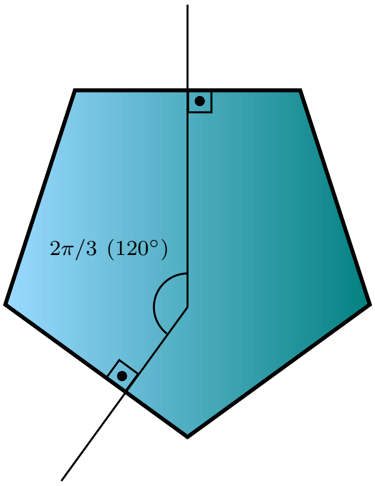
Figure 10.162: **Regular hexagon details (source: Wikipedia)**

Therefore it's quite obvious that we have:



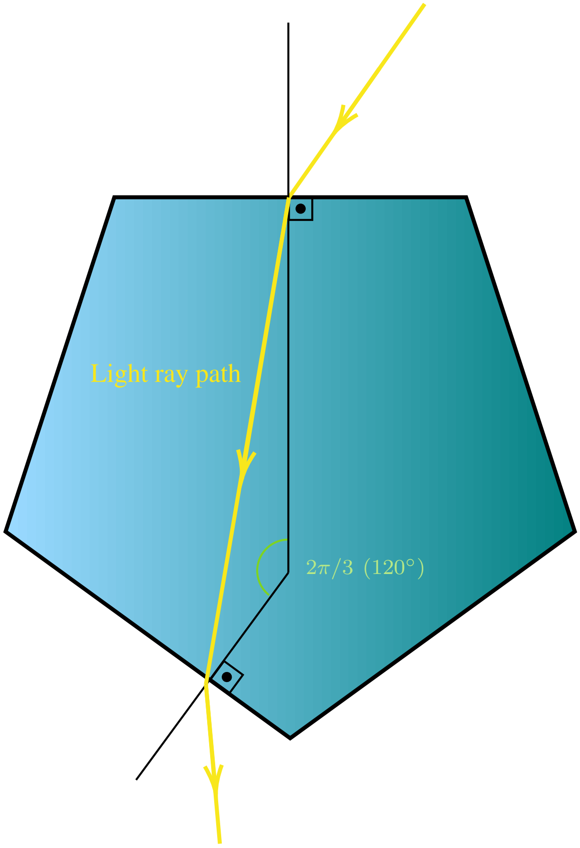
Notice that the angle visible above remain the same if we translate the hexagon as following:



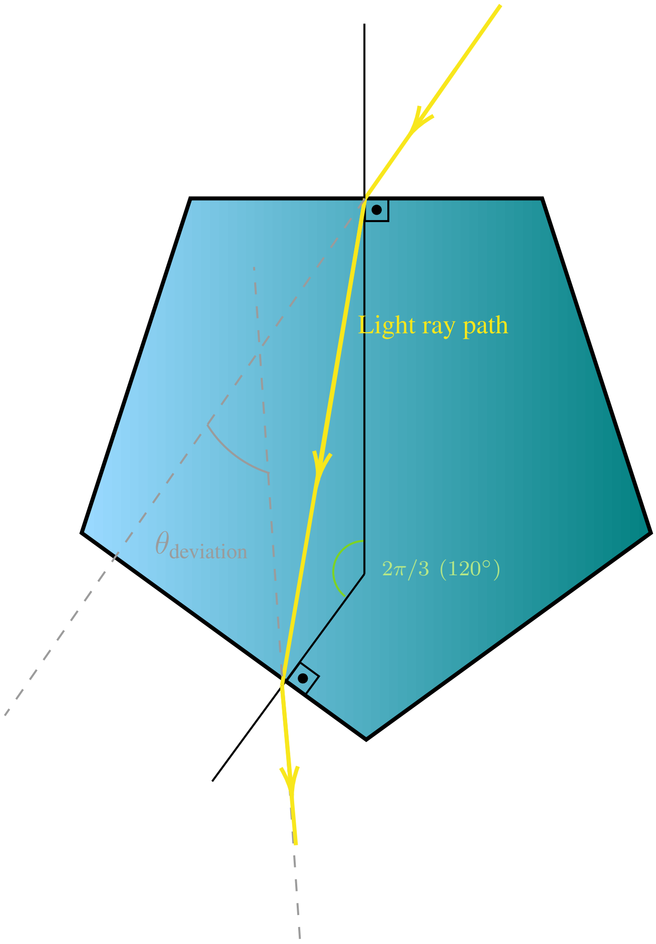
Remark

In atmospheric optics, a "photometeor" is a bright object or other optical phenomenon appearing in the Earth's atmosphere when sunlight or moonlight creates a reflection, refraction, diffraction or interference under particular circumstances. The most common examples include halos, rainbows, fogbows, cloud iridescences (or irisation), glories, Bishop's rings, coronas, crepuscular rays, sun dogs, light pillars, mirages, scintillations, and green flashes.

Now consider a ray path as illustrated below in the special case that lights when entering the ice crystal makes only two refractions:

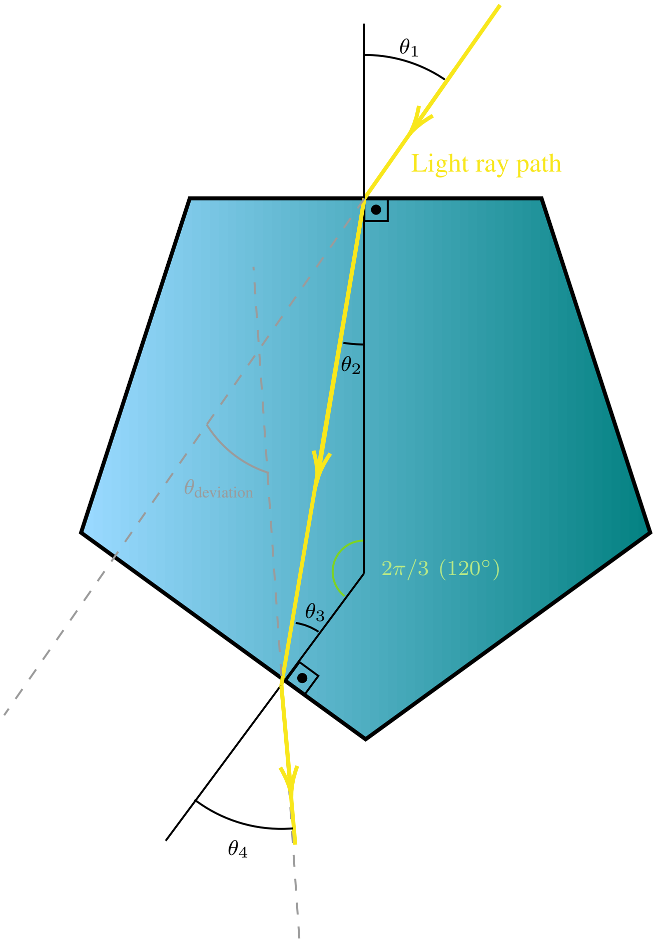


What is of interest for us is the $\theta_{\text{deviation}}$ visible in gray below:



Light ray path
$\theta_{\text{deviation}}$
$2\pi/3$ (120°)

To determine $\theta_{\text{deviation}}$ let us complete the figure above as following:



From Snell's law we have first trivially:

$$\frac{\sin(\theta_1)}{\sin(\theta_2)}=n \qquad \frac{\sin(\theta_4)}{\sin(\theta_3)}=n \tag{10.5.118}$$

Secondly we have we have (still trivially) for the central triangle, applying the Triangle Sum Theorem:

$$120+\theta_2+\theta_3=180 \tag{10.5.119}$$

And finally (still by looking the figure it should be quite trivial):

$$\theta_{\text{deviation}}=(\theta_1-\theta_2)+(\theta_4-\theta_3) \tag{10.5.120}$$

Now we will mix together these three relations. We start first by rearranging them (easy work!):

$$\begin{gathered}\theta_2=\sin^{-1}\left(\frac{\sin(\theta_1)}{n}\right)\\ \theta_3=60-\theta_2=\frac{\pi}{3}-\theta_2\\ \theta_4=\sin^{-1}\left(n\sin(\theta_3)\right)\\ \theta_{\text{deviation}}=\theta_1+\theta_4-60=\theta_1+\theta_4-\frac{\pi}{3}\end{gathered} \tag{10.5.121}$$

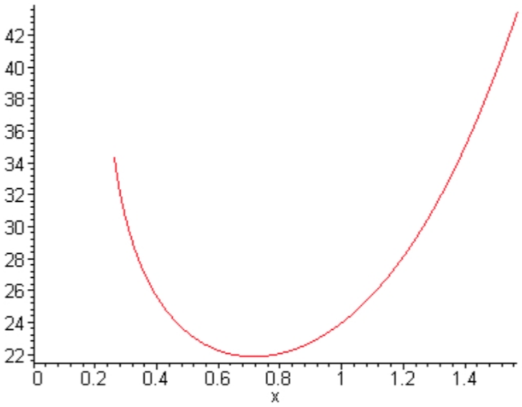
Therefore:

$$\begin{aligned}\theta_{\text{deviation}} &= \theta_1 + \theta_4 - \frac{\pi}{3}\\ &= \theta_1 - \frac{\pi}{3} + \sin^{-1}\left(n\sin\left(\frac{\pi}{3} - \sin^{-1}\left(\frac{\sin(\theta_1)}{n}\right)\right)\right)\\ &= \theta_1 + \sin^{-1}\left(n\sin\left(\frac{\pi}{3} - \sin^{-1}\left(\frac{\sin(\theta_1)}{n}\right)\right)\right) - \frac{\pi}{3}\end{aligned} \tag{10.5.122}$$

Hence we fall back on relation presented at the beginning:

$$\boxed{\theta_{\text{deviation}} = \theta_{\text{incidence}} + \sin^{-1}\left[n\sin\left(\frac{\pi}{3} - \sin^{-1}\frac{\sin(\theta_{\text{incidence}})}{n}\right)\right] - \frac{\pi}{3}} \tag{10.5.123}$$

For $n = 1.309$, the angle of minimum deviation is almost $22°$ ($21.76°$, when $\theta_{\text{incidence}} = 40.88° \cong 0.71$ [rad]):



More specifically, the angle of minimum deviation is $21.84°$ on average ($n = 1.31$); $21.54°$ for red light ($n = 1.306$) and $22.37°$ for blue light ($n = 1.317$). This wavelength-dependent variation in refraction causes the inner edge of the circle to be reddish while the outer edge is bluish (see photo below).

Sadly as far as we know there are no closed formal solution to find the optimum analytically of:

$$\frac{d\theta_{\text{deviation}}}{d\theta_{\text{incidence}}} = 0 \tag{10.5.124}$$

Even if we can get (we don't provide the details here):

$$\frac{d\theta_{\text{deviation}}}{d\theta_{\text{incidence}}} = 1 - \frac{\cos(\theta_{\text{incidence}})\cos\left(\arcsin\left(\frac{\sin(\theta_{\text{incidence}})}{n}\right) - \frac{\pi}{3}\right)}{\sqrt{1 - \frac{\sin^2(\theta_{\text{incidence}})}{n^2}}\sqrt{1 - n^2\sin^2\left(\arcsin\left(\frac{\sin(\theta_{\text{incidence}})}{n}\right) - \frac{\pi}{3}\right)}} \tag{10.5.125}$$

The problem is to solve when we put the latter equal to zero...

The figure below depicts most common Halos in the sky, for a solar elevation of $26°$. This view is looking straight up toward the zenith, as what could be photographed using an all-sky camera (with a fisheye lens). The outermost thick green circle represents the horizon, and the zenith point is marked as a dot in the center of this circle. Some of these halos are extremely rare. Most would not be seen at the same time, because they require ice crystals of different shapes and having perfect orientation. This fish-eye view distorts the 9°, 22°, and 46° halos, which would appear as circles to the observer. The halos of other diameters (including the 28° Scheiner's halo) are not plotted.

Figure 10.163: **Most common types of Sun Halos and Arcs**

Halos constitute a vast subject of atmospheric optics, coupled with meteorology and ice crystallography. The variety of halos and their properties depend on the geometry of the crystals and their degree of orientation in space. Some remain of uncertain or even unknown explanation; this is the case, for example, of elliptical halos and Moilanen's "V"-shaped arc which lies halfway between the Sun and the upper part of the halo at 22°. What information about crystals do these halos give us? Conversely, choosing a geometry, what halos can we form? Finally, what about on other planets? Numerical simulation and observation are essential to answer these questions. Hopefully this article on some aspects of terrestrial halos will have aroused the reader's curiosity about these beautiful photometeors and will encourage them to look up to the sky. May everyone be a careful observer and sharpen their physical mind. Because we are all potential halo discoverers!

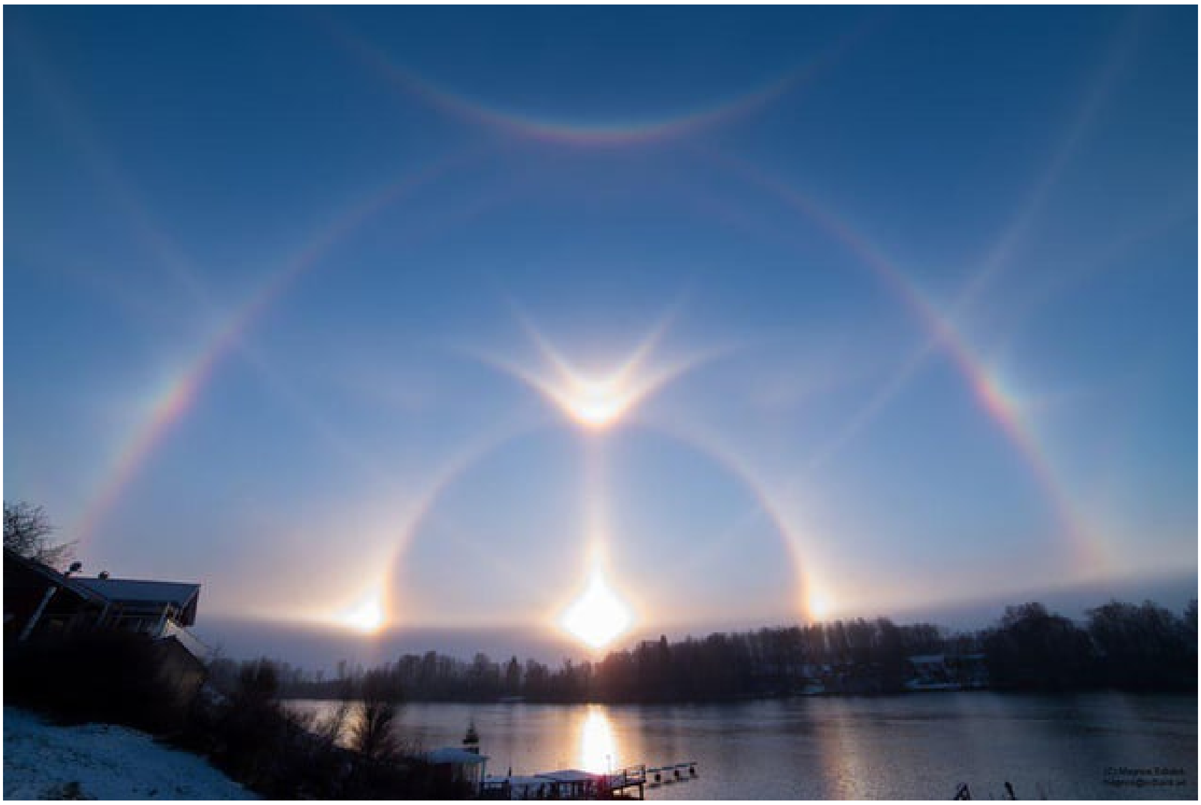

Figure 10.164: **Various types of Halos in one shot in real life**

For people who wants more detailed and general derivations but also laboratory tests we recommend the lecture (in increasing order of complexity) of [140], [107] and [493].

This stunning picture taken by Michael Schneider in Switzerland shows a multitude of other optical phenomena. Note that the 22° halo crosses in front of the mountains behind. It follows that these effects were due to ice crystals between the photographer and the mountains. In fact, they are probably due to minute crystals in the air immediately surrounding the photographer:

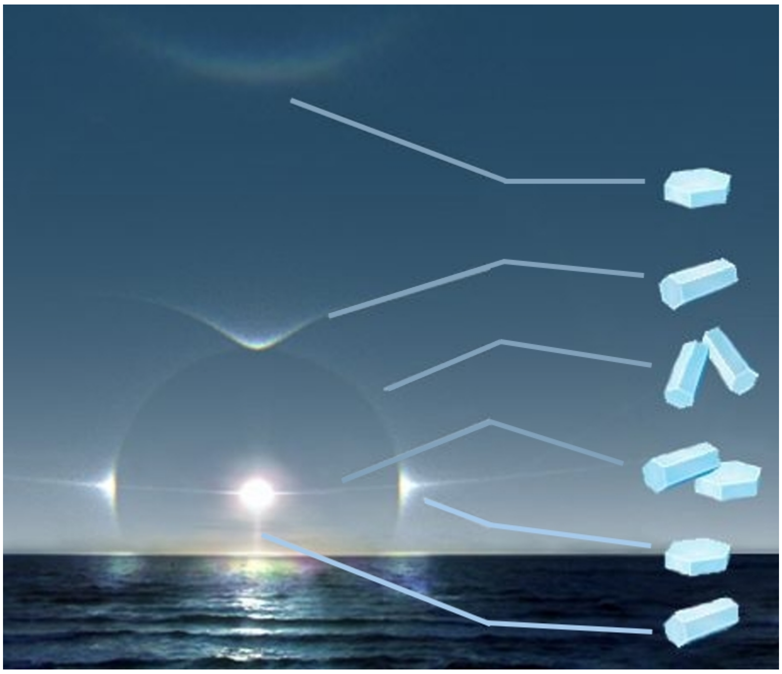
It is supposed (because as far as we know such atmospheric optical structure has never been reproduced yet in a laboratory controlled environment) that the different curves are made by different crystals in different orientations as illustrated below:



Even if such a thing was never reproduced in laboratory and is much harder to reproduce that a rainbow for any human there are specialized university free softwares that implement millions (or billions) ray tracing with the possibility to configure various crystal mixtures, densities and orientations like HaloSim 3.6 developed by Les Cowley and Michael Schroeder. Let us see a few screenshots of HaloSim 3.6 with various settings:

Let us mention also "cloud iridescence" or "irisation" that is a colorful optical phenomenon that occurs in a cloud (that's why it is also named "rainbow cloud") and appears in the general proximity of the Sun or Moon produce by the same mechanisms of the Sun halos.

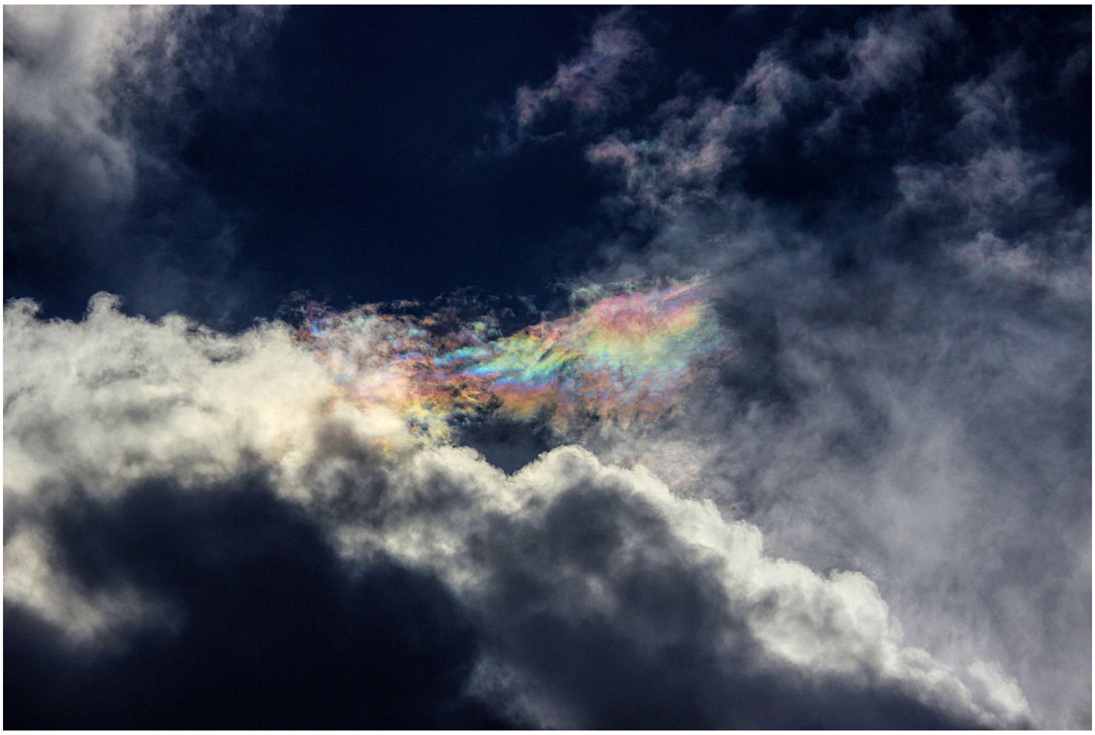

Figure 10.165: Cloud iridescence, seen above the clouds covered with grey clouds (source: Wikipedia, place: Pondicherry (India), date: 29th November 12015 by Karthik Easvur)

10.5.4.5 Optical Mirages

Mirages are generated when light passes through air of different temperatures. There are commonly two types of mirages:

- An "inferior mirage" occurs when you have a dense layer of cold air sitting on above of your line of sight, with a layer of less dense warmer air below your line of sight. This happens frequently on hot summer days when the Sun (actually a G2V-type star, aka yellow dwarf) shines on a black asphalt highway, and the hot ground heats the bottom centimeters of air. When rays of light coming down from the sky get close to the hot air near the ground, the light rays are bent (refracted) back up toward your eyes.

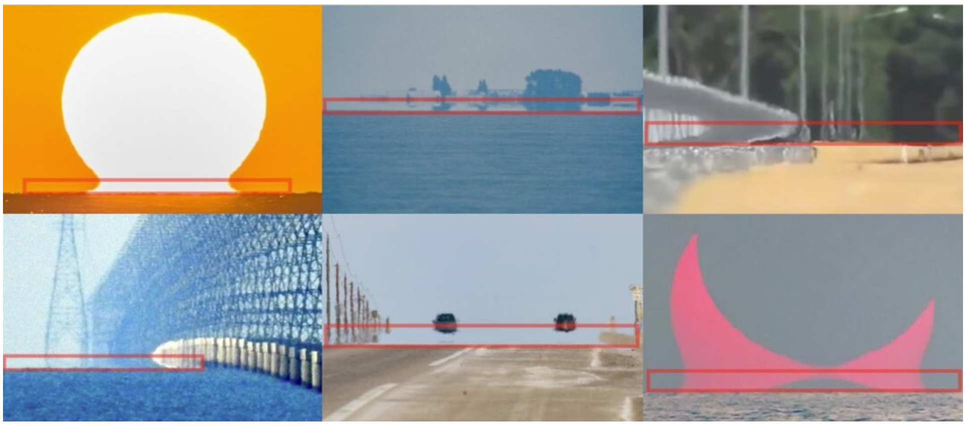
  This is your typical 'oasis in the desert' mirage, where you look down toward the highway or desert sands and see what appears as a pool of blue water. In reality, it is light the blue sky bending back up toward your eyes. Since warm air rises and cool air sinks, the air layers are likely to mix and inferior mirages will not last long unless there is continued heating by the sun.

  Inferior mirages happen less frequently over the ocean because the ocean surface usually doesn't get extremely hot. However, it can occur over the ocean when very cold arctic blows over unfrozen water.

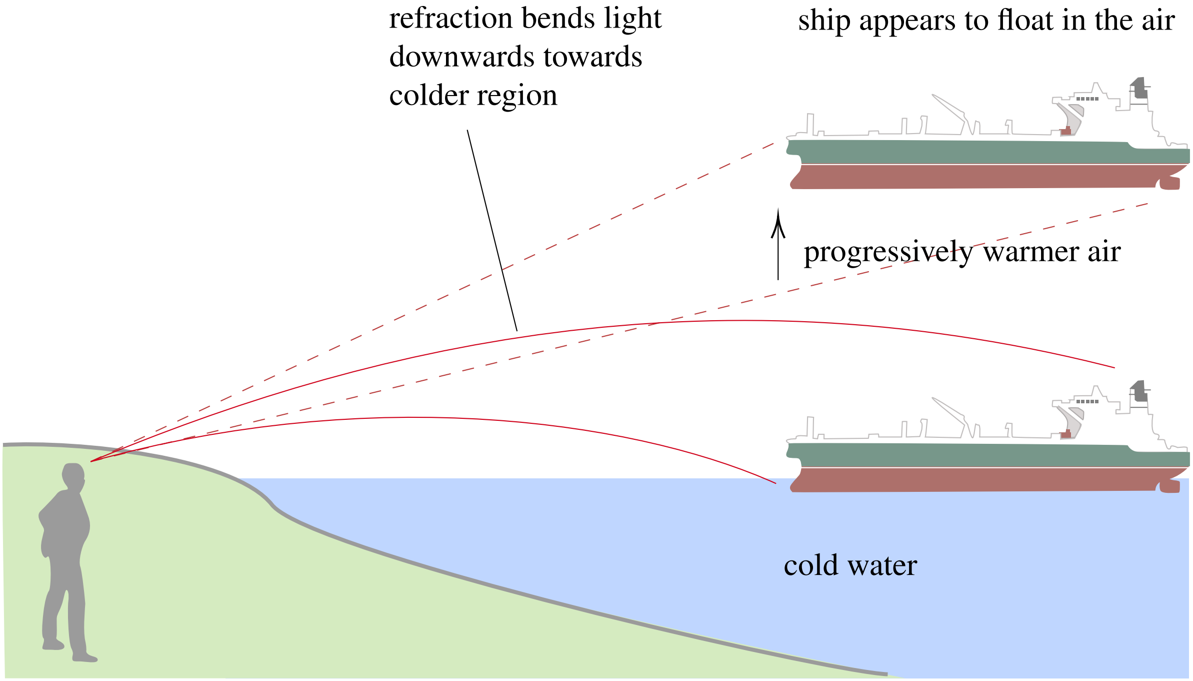
  Note in the image below, an inferior mirage makes it look like there is water on the pavement, when in fact there is not:

  
  Figure 10.166: **Sky inferior mirage (credit: U-ichiro Murakami - Own work, Public Domain)**

  and some other well known inferior images:



- A "superior mirage" occurs when a layer of warm air sits above your line of sight with a cool layer beneath it. The mirage above is caused by a meteorological phenomenon named a "temperature inversion". Normally, the air temperature drops with increasing altitude, making mountaintops colder than the foothills. But in a temperature inversion, warm air sits on top of a band of colder air, playing havoc with our visual perception. In case of temperature inversion light bends down towards the denser air, but because our eyes assume the light we see travels straight, the object we are seeing appears higher than it actually is. Therefore we see the image, or inversions of it, above where it actually is.



refraction bends light downwards towards colder region
ship appears to float in the air
progressively warmer air
cold water

Figure 10.167: **Guardian graphic. Source: HyperPhysics, Georgia State University (vertical scale exaggerated)**

Or for a real photo[17] (notice that the mirage obviously reproduce the colors and the details of the original object as it is just deflected light!):

---

[17] Respectively in this type of thermal configuration, objects lying below the horizon due to the curvature of the Earth give the impression of being at the level of the horizon and therefore that the Earth is flat (reason for which some flat earthers, observing with binoculars the other shore of a large body of water, are convinced that the Earth is flat because of the fact that they slept during Optics lessons...

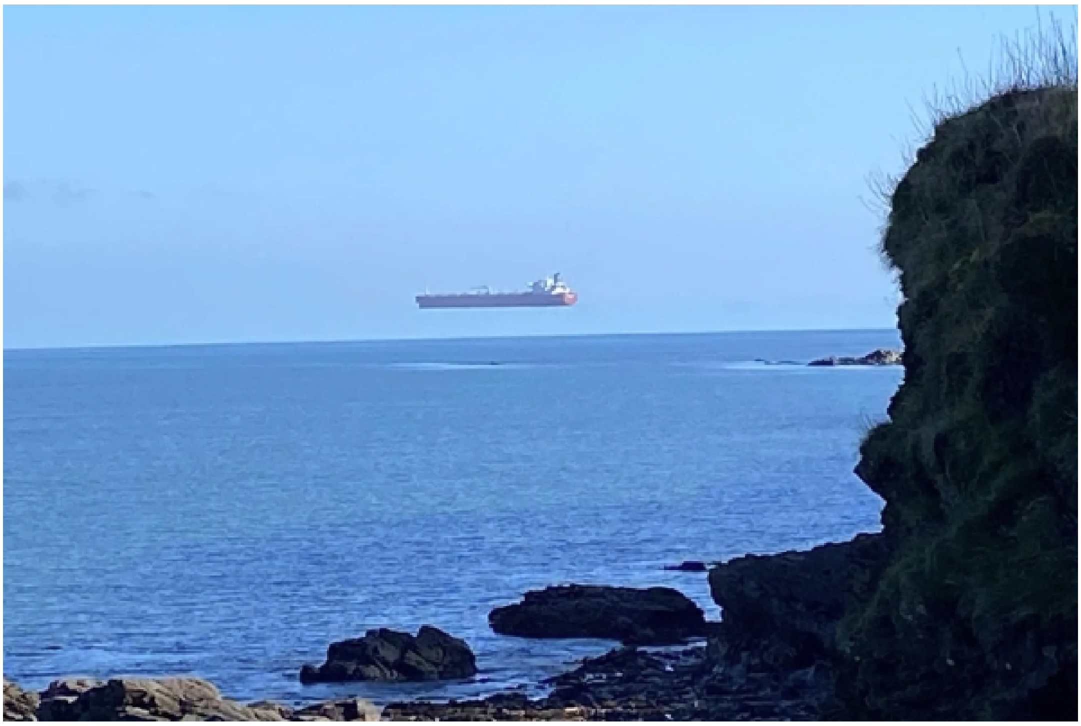


Figure 10.168: **Ship hovering above the surface of the sea off southwestern England (credit: David Morris/Apex)**

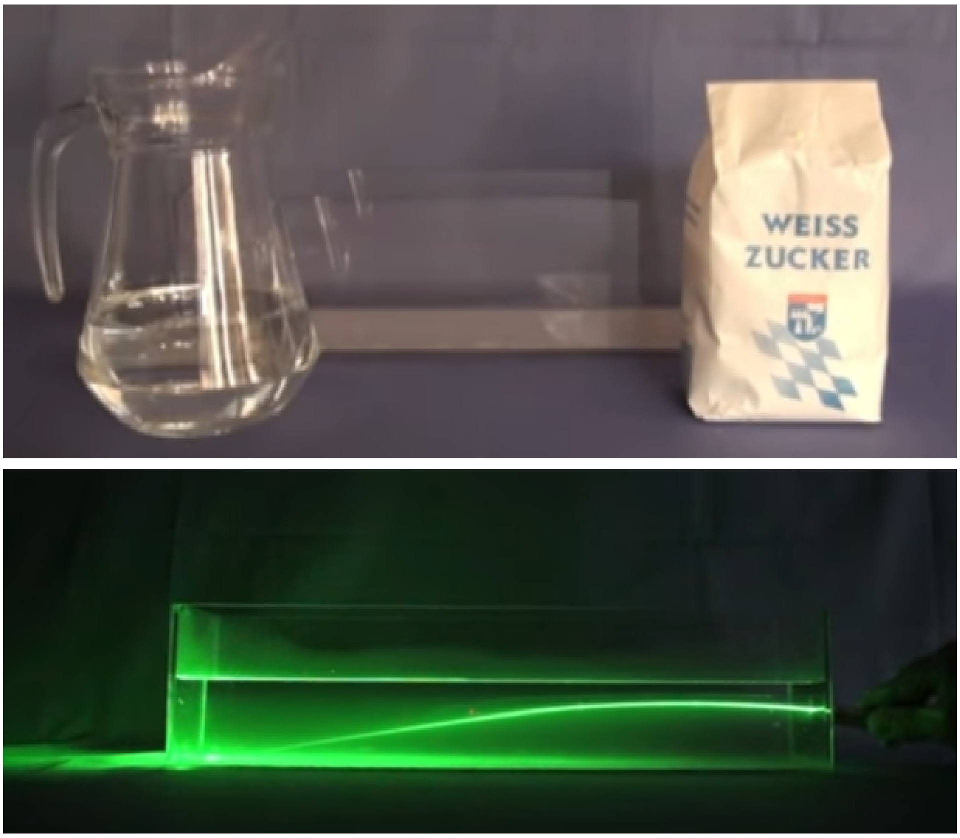
> In the case of the virtual image of a superior mirage is completely distorted or inversed, we speak then of a "Fata Morgana".

More run-of-the-mill optical illusions are the “inferior mirages” that give rise to apparent oases in the desert and puddles on hot summer roads, caused by cooler air sitting on a layer of hot air, directly above a road, for example. When sunlight coming down from the sky approaches the air near the hot surface, it is bent back upwards to the observer’s eye, making the blue sky appear to be reflected on the road like water.

As atmosphere is a fluid, and water is also a fluid (just with different characteristics), the bending of light can be easily tested and observed easily with a domestic LASER, hot water and a parallelepiped recipient and waiting a few hours after the mixing the both. Then we can observe the bending of water:



10.5.4.5.1 Lagrangian approach to optical mirage

The approach of using the Lagrangian to determine the path equation of light for an inferior mirage is the most technical and mathematically the most beautiful one to read. However, as we will see it, the result requires to know three constants that are very hard to measure in practice. Once we will be finished with the derivation of this formal Lagrangian way, we will use other techniques that lead to much more simple result to compute numerically with much less constants!

So as already mentioned, in an inferior mirage the rays bend as shown in the figure below where the observer sees a virtual image of the sky superimposed on the ground:

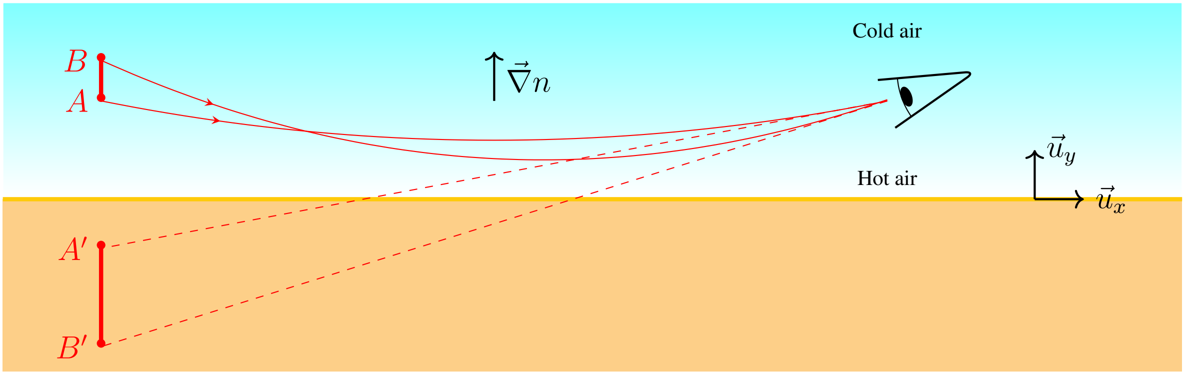


Figure 10.169: **Curvature of the rays near an overheated ground (source: Femto-Physique.fr, creator: Jimmy Roussel)**

Let us establish the differential equation of the radius by supposing that the index only varies according to the altitude y of the place. The optical path is written, in the plane $x\text{O}y$:

$$L=\int n(y)\mathrm{d}s=\int_{\text{A}}^{\text{B}} n(y)\sqrt{\mathrm{d}x^2+\mathrm{d}y^2}=\int n(y)\sqrt{1+y'(x)^2}\mathrm{d}x \tag{10.5.126}$$

Let's assume that the index of refraction varies linearly with y such that:

$$n(y)\cong(1+\alpha y)n_0 \tag{10.5.127}$$

where n_0 is the value of the index of refraction at the ground.

Therefore:

$$L\cong\int(1+\alpha y)n_0\sqrt{1+y'^2}\mathrm{d}x \tag{10.5.128}$$

Let us put:

$$f=(1+\alpha y)n_0\sqrt{1+y'^2} \tag{10.5.129}$$

According to the principle of least action, the path of light is the one that satisfies (see section Analytical Mechanics page 3169):

$$\frac{\partial L}{\partial q_i}-\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial\dot{q}_i}=0 \tag{10.5.130}$$

And let us remind that this has let us to the Beltrami identity (see section Analytical Mechanics page 3177) given by:

$$L-\dot{q}_i\frac{\partial L}{\partial\dot{q}_i}=c^{te} \tag{10.5.131}$$

In our case we have to replace L by f and q_i by y and therefore:

$$f-y'\frac{\partial f}{\partial y'}=(1+\alpha y)n_0\sqrt{1+y'^2}-y'^2(1+\alpha y)n_0\sqrt{\frac{1}{1+y'^2}}=\frac{(1+\alpha y)n_0}{\sqrt{1+y'^2}} \tag{10.5.132}$$

is therefore a constant, that we will denote as c_1. We can solve y' from the equation:

$$\frac{(1+\alpha y)n_0}{\sqrt{1+y'^2}}=c_1 \tag{10.5.133}$$

that is:

$$y'=\frac{\mathrm{d}y}{\mathrm{d}x}=\pm\sqrt{\frac{(1+\alpha y)^2n_0^2}{c_1^2}-1} \tag{10.5.134}$$

Explicited and rearranged:

$$x=\pm\int\frac{\mathrm{d}y}{\sqrt{\frac{(1+\alpha y)^2n_0^2}{c_1^2}-1}} \tag{10.5.135}$$

We can find the integral by a change of variable:

$$\frac{(1+\alpha y)n_0}{c_1}=\cosh(\theta) \tag{10.5.136}$$

Therefore (form the list of all usual derivatives we have detailed):

$$\sinh(\theta)\mathrm{d}\theta=\frac{\alpha n_0}{c_1}\mathrm{d}y \tag{10.5.137}$$

and:

$$\sqrt{\frac{(1+\alpha y)^2n_0^2}{c_1^2}-1}=\sqrt{\cosh^2(\theta)-1}=\sinh(\theta) \tag{10.5.138}$$

Hence:

$$x=\pm\int\frac{\mathrm{d}y}{\sqrt{\frac{(1+\alpha y)^2n_0^2}{c_1^2}-1}}=\pm\frac{c_1}{\alpha n_0}\int\frac{\sinh(\theta)\mathrm{d}\theta}{\sinh(\theta)} \tag{10.5.139}$$

The solution can therefore be written as:

$$x=\pm\frac{c_1}{\alpha n_0}\int\mathrm{d}\theta=\pm\frac{c_1}{\alpha n_0}\theta+c_2 \tag{10.5.140}$$

Where c_2 in the constant of integration. Les us put $c_2:=x_0$. Therefore we can write the latter as:

$$\theta=\pm\frac{\alpha n_0}{c_1}(x-x_0) \tag{10.5.141}$$

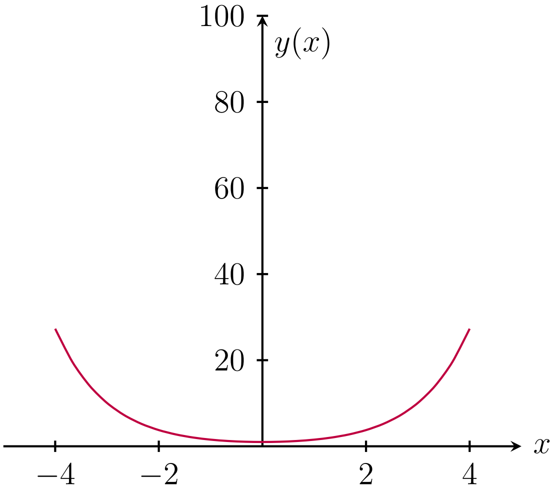
Substituting this θ into the relation we got earlier above, we have :

$$\frac{(1+\alpha y)n_0}{c_1}=\cosh(\theta) \tag{10.5.142}$$

we get after rearranging (and we can keep only the positive sign because $\cosh$ is an even function):

$$\boxed{y\cong\frac{c_1}{\alpha n_0}\cosh\left(\frac{\alpha n_0}{c_1}(x-x_0)\right)-\frac{1}{\alpha}} \tag{10.5.143}$$

The most important information from the solution is that y is always convex as seen in the section of trigonometry page 2538 (or concave up). Below we have the plot of $\cosh(x)$:



Remark

A less technical derivation based on Snell's law exists but it assumes that we already know the trajectory of the light path is a parabola. So the derivation doesn't make too much sense in our opinion...

Let us see now an other approach much less formal but that leads to practical usable result!

10.5.4.5.2 Snell's law differential approach to air mirroring

Let us remind the Snell-Descartes law (i.e. refraction law) given by (see section Electromagnetism page 4364):

$$n_{12}=\frac{n_1}{n_2}=\frac{\sin(r)}{\sin(i)} \tag{10.5.144}$$

where the i stands for "incident" (often denoted θ_1) and the r for "refracted" (often denoted θ_2).

And also remember the following figure:

Light source

Figure 10.170: **Critical angle schematic illustration (raytracing)**

Remark

Remember two things when looking at the figure above:

1. The light ray-tracing is symmetric. The path of light remains the same wherever on which side of the interface separation is the source!
2. Remember also that that below (incident) critical angle the refraction law applies:

$$n_{12} = \frac{n_1}{n_2} = \frac{\sin(\text{refraction})}{\sin(\text{incident})}$$

and beyond the critical angle it's the reflection law that applies:

$$\theta_{\text{incident}}=\theta_{\text{reflection}}$$

and that happens only if light move from a dense medium to a less dense medium!

We shall now generalize this law to the case, where the index of refraction changes continuously in the y-direction, that is, along the normal to the surface of the materials. We shall calculate the infinitesimal deviation, corresponding to an infinitesimal change of the index of refraction $n=n(y)$. The angle that the light ray forms with the normal is denoted θ. So the law of refraction writes:

$$\frac{\sin(\theta)}{\sin(\theta+\mathrm{d}\theta)}=\frac{n(y)}{n(y+\mathrm{d}y)}\quad\Leftrightarrow n(y+\mathrm{d}y)\sin(\theta)=n(y)\sin(\theta+\mathrm{d}\theta) \tag{10.5.145}$$

By subtracting $n(y)\sin(\theta)$ on both sides and putting outside a parenthesis, we have:

$$\sin(\theta)(n(y+\mathrm{d}y)-n(y))=n(y)(\sin(\theta+\mathrm{d}\theta)-\sin(\theta)) \tag{10.5.146}$$

Hence written in a differential form:

$$\sin(\theta)\mathrm{d}n=n(y)\mathrm{d}\sin(\theta) \tag{10.5.147}$$

Therefore:

$$\frac{\mathrm{d}\sin(\theta)}{\sin(\theta)}=\frac{\mathrm{d}n}{n(y)} \tag{10.5.148}$$

This equation can immediately be integrated, i.e.:

$$\int_{\theta_1}^{\theta_2}\frac{\mathrm{d}\sin(\theta)}{\sin(\theta)}=\int_{n_1}^{n_2}\frac{\mathrm{d}n}{n(y)} \tag{10.5.149}$$

We know that that this is equal to:

$$\ln\left(\sin(\theta_2)\right)-\ln\left(\sin(\theta_1)\right)=\ln\left(n(y_2)\right)-\ln\left(n(y_1)\right) \tag{10.5.150}$$

Hence rearranging and taking the exponential, this leads to:

$$\boxed{\frac{\sin(\theta_2)}{\sin(\theta_1)}=\frac{n(y_2)}{n(y_1)}} \tag{10.5.151}$$

Thus, we recover the law of refraction unchanged. The refraction angle depends only on the index of refraction in the upper layer and the lower layer. This means that refraction through a layer with a thickness of hundreds of meters can be treated as refraction in a single borderline!

This has the important consequence that total reflection is possible in layers of air many meters thick, and this is the key to explain the phenomena of air mirroring and mirages.

Now let us remind that we have introduce in the section of Optics the concept of total reflection, (see page 4369 and we have shown that for the transition water/air, the relative index of refraction was about $1/1.33$, which gave us a limit critical angle of:

$$\theta_c = \theta_i = \arcsin\left(\frac{n_2 \sin(90^\circ)}{n_1}\right) = \arcsin\left(\frac{1}{1.33}\right) = 48.7^\circ \qquad (10.5.152)$$

And as we have already mentioned it, the refractive index depends not only on the temperature but also on pressure, composition, and strictly speaking also the wavelength of the light...

In air the index of refraction is much less. At a relative index of refraction $1/1.001$, we find a limiting angle about 87°, which corresponds to a grazing angle of 3°.

Before continuing we can using the empirical Ciddor equation or a modified version of the empirical Edlén equation get the refractive index of the air for different temperatures. For example at a wavelength 633 [nm] and at a pressure of 101.325 [kPa] a 50% relative humidity and for a carbon dioxide content of 450 Micromole per Mole[18] [parts per million, ppm]:

40	1.00025314
42	1.00025139

Table 10.12: **Various index of refraction of air**

The absolute index of refraction for air as we can see in the table above at zero degree Celsius is approximately equal to 1.000292, so the quick conclusion would be that the limiting angle for total reflection in air can at most be $\theta_i = 88.6^\circ$, which corresponds to a grazing angle of 1.4°.

The lower air mirroring example is the most common mirage, since it can be experienced on sunny days, where it appears that there is water on the asphalt road ahead a vision which disappears as soon as we get nearer. We generally consider that when it is really hot in Switzerland, that is to say when the air reaches 30 $[^\circ\text{C}]$ to 40 $[^\circ\text{C}]$ in the Sun (101.325 [kPa]) hence a refractive index of approximately $n = 1.000260748$, the road surface heats up to approximately 60 $[^\circ\text{C}]$ to 70 $[^\circ\text{C}]$ (290 [kPa]) hence a refractive index of approximately $n = 1.000328216$ (remember that hot air is less dense than cold air!). Hence:

$$\theta_c = \theta_i = \arcsin\left(\frac{n(y_2)\sin(90^\circ)}{n(y_1)}\right) = \arcsin\left(\frac{1.000260748}{1.000328216}\right) \cong 89.33^\circ \tag{10.5.153}$$

The explanation is straightforward! Because the air gets heated near the black asphalt lane, this gives it a smaller density, and consequently a less index of refraction (see table above).

As emphasized above, the phenomena of total reflection is independent of whether the reflection takes place at a borderline or it takes place in a gradual change of the index of refraction through an arbitrary thick layer. Hence the puddles that you can see on a dark road in sunny weather is in reality an (inverse) lower mirroring of the sky!

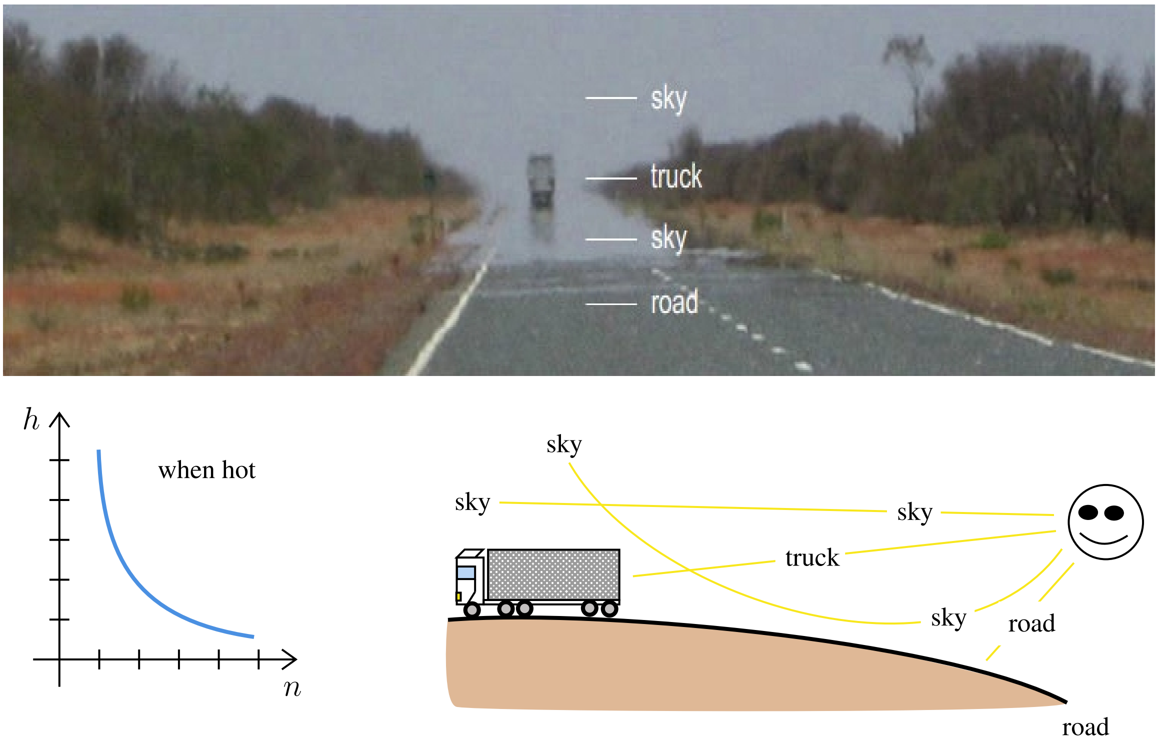

Figure 10.171: **Floating road train on the Stuart Highway, Northern Territory, Australia**

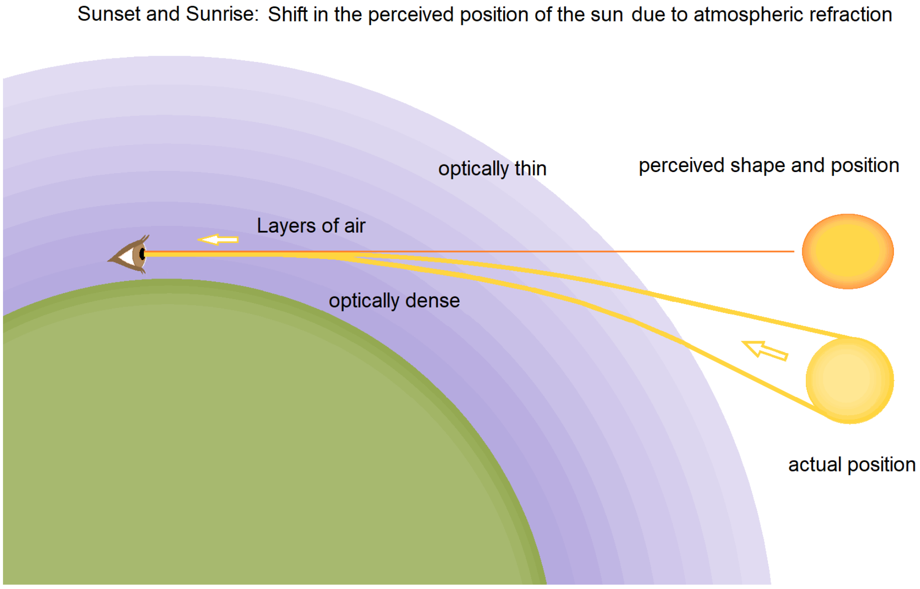
The upper mirroring is the same phenomena, the only difference being that the air near the ground is cooler than the air higher up. The upper mirrorings are much more rare at our latitudes, and surprisingly enough they appear mostly in polar areas.

Common for the two kinds of mirroring is that they produce an inverse image of the object. Concerning the mirages (fata morgana), it is not a mirroring, but instead it is caused by light that is refracted in the same direction as the curvature of the earth. For this reason it is possible to see objects that otherwise are below the horizon. The figures below

Before we move to the next topic, let us consider the figure below:



Sunset and Sunrise: Shift in the perceived position of the sun due to atmospheric refraction
optically thin
perceived shape and position
Layers of air
optically dense
actual position

Figure 10.172: **Shift of the perceived form and position of the Sun due to the atmospheric refraction (source: Wikipedia, author: Sciencia58)**

And remember the relation:

$$\frac{\sin(\theta_2)}{\sin(\theta_1)}=\frac{n(y_2)}{n(y_1)} \qquad (10.5.154)$$

Let us take for $n(y_2)$ the index refraction of air at a temperature of $40\,[^\circ\mathrm{C}]$ (hot ground) and at a pressure of 101.325 [kPa] and for $n(y_1)$ the index refraction of air at a temperature of $-40\,[^\circ\mathrm{C}]$ (high altitude) and at a pressure of 10 [kPa]. Then we have with these two extrema the following limiting angle for sunset/sunrise (as commonly named... a better denomination being nightfall/daybreak) as the refraction angle depends only on the index of refraction in the upper layer and lower layer (under the assumption of a linear change!):

$$\theta_c=\arcsin\left(\frac{n(T=-40,P=10)}{n(T=40,P=101.325)}\right)=\arcsin\left(\frac{1.000033717}{1.000271373}\right)\cong 88.751^\circ \qquad (10.5.155)$$

Hence we can see the sunset/sunrise is some weather conditions when the Sun (actually a G2V-type star, aka yellow dwarf) is in reality already $90^\circ-88.751^\circ\cong 1.24^\circ$ below horizon!

Below we can see an astronomical size mirage diagram (obviously not to scale and oversimplified) due to atmospheric refraction named "selenelion". It is a partial lunar eclipse phenomenon at dusk or dawn. When a partial lunar eclipse occurs near dawn or dusk, you can often see the red Sun in one direction and a part of the red Moon in the opposite direction, with the Sun's light passing over your head:

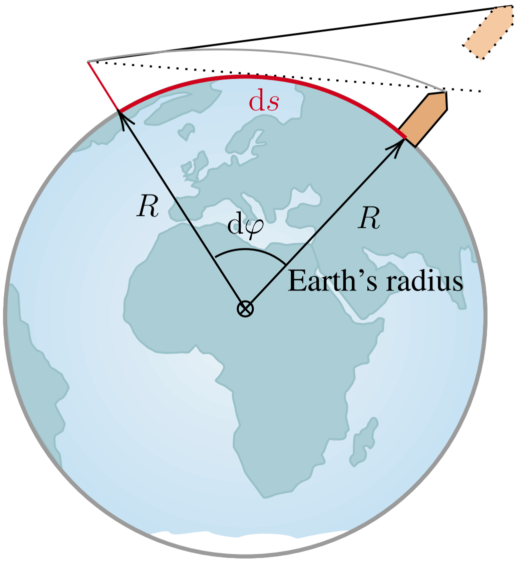
10.5.4.5.3 Differential form of long range mirages

We shall discuss in somewhat more detail the phenomena of mirages (fata morgana), which occurs when a light ray is refracted along the curvature of the Earth.

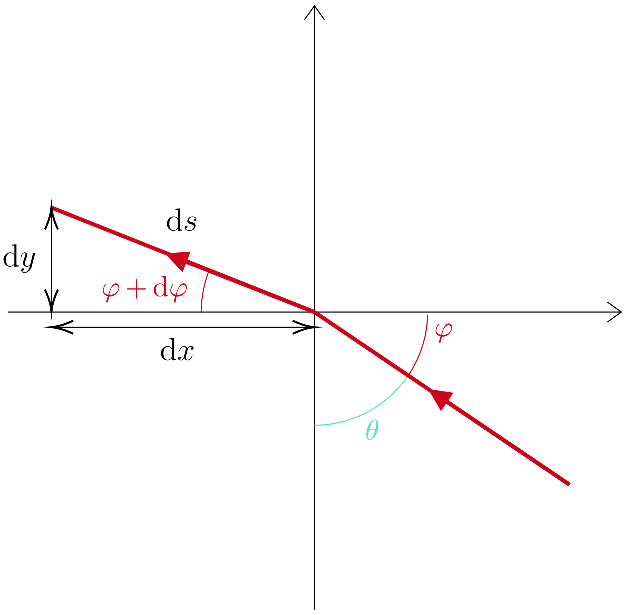
By the way the phenomenology of the analysis that will follow will be useful to us to calculate the visual horizon in the section of Engineering at page 8247.

The figure below shows a kind of tower, which lie below the horizon, which means that it cannot be seen, if the light followed a straight line. If the light ray is bended when passing the atmosphere, however, the tower will be seen in a direction following the tangent to the ray at the point of observation, as "floating" in the air. The refraction is due to an abnormal temperature gradient, that is, the temperature rises with the height from the ground. The cooler air has a higher density, and therefore a higher index of refraction.



The figure above to the left depicts a section of the surface of the earth, where the connection between the $\mathrm{d}s$, the radius of the Earth R and the angle $\mathrm{d}\varphi$ is $\mathrm{d}s = R \cdot \mathrm{d}\varphi$

A light ray which moves slightly upwards will move towards a slightly less (relative) index of refraction, and consequently be refracted away from the normal to the layer, that is, downwards. The next step is to establish a relation between the differential bending $\mathrm{d}\varphi$ of the beam and the change $\mathrm{d}n/\mathrm{d}y$ in the index of refraction per unit length along the normal to the layer:



The figure above shows a light ray on its way up through the atmosphere getting an infinitesimal deflection $\mathrm{d}\varphi$ at the distance $\mathrm{d}s$. Where φ is the grazing angle between the borderlines, and $\varphi=90^\circ-\theta$, where θ is the incoming angle with the normal to the layer.

We have proven just earlier above during our study of mirages (see page 4397) that:

$$\frac{\mathrm{d}\sin(\theta)}{\sin(\theta)}=\frac{\mathrm{d}n}{n(y)} \tag{10.5.156}$$

and we have:

$$\mathrm{d}\sin(\theta)=\cos(\theta)\mathrm{d}\theta \tag{10.5.157}$$

Hence:

$$\frac{\mathrm{d}\sin(\theta)}{\sin(\theta)}=\frac{\mathrm{d}n}{n}\Leftrightarrow\cos(\theta)\mathrm{d}\theta=\frac{\sin(\theta)}{n}\mathrm{d}n \tag{10.5.158}$$

And now we use $\varphi=90^\circ-\theta$ hence $\mathrm{d}\varphi=-\mathrm{d}\theta$, but also $\cos(\varphi)=\cos(90^\circ-\theta)=\sin(\theta)$ and $\sin(\varphi)=\sin(90^\circ-\theta)=\cos(\theta)$, therefore we car rewrite:

$$\cos(\theta)\mathrm{d}\theta=\frac{\sin(\theta)}{n}\mathrm{d}n\Leftrightarrow\mathrm{d}\varphi=-\frac{\cos(\varphi)}{n\sin(\varphi)}\mathrm{d}n \tag{10.5.159}$$

We then use:

$$\mathrm{d}n=\frac{\mathrm{d}n}{\mathrm{d}y}\mathrm{d}y \tag{10.5.160}$$

and since (see figure above):

$$\mathrm{d}y=\sin(\varphi)\mathrm{d}s \tag{10.5.161}$$

Then:

$$\mathrm{d}n=\frac{\mathrm{d}n}{\mathrm{d}y}\sin(\varphi)\mathrm{d}s \tag{10.5.162}$$

We finally have:

$$\mathrm{d}\varphi=-\frac{\cos(\varphi)}{n\sin(\varphi)}\sin(\varphi)\frac{\mathrm{d}n}{\mathrm{d}y}\mathrm{d}s \quad\Leftrightarrow\quad \mathrm{d}\varphi=-\frac{\cos(\varphi)}{n}\frac{\mathrm{d}n}{\mathrm{d}y}\mathrm{d}s \tag{10.5.163}$$

If a light ray should follow the curvature of the earth, we may determine the gradient of the index of refraction. Comparing this with $\mathrm{d}s=R\cdot\mathrm{d}\varphi\Leftrightarrow\mathrm{d}\varphi=1/R\mathrm{d}s$ we have:

$$\mathrm{d}\varphi=-\frac{\cos(\varphi)}{n}\frac{\mathrm{d}n}{\mathrm{d}y}\mathrm{d}s \qquad \text{and} \qquad \mathrm{d}\varphi=\frac{1}{R}\mathrm{d}s \tag{10.5.164}$$

That gives:

$$-\frac{\cos(\varphi)}{n}\frac{\mathrm{d}n}{\mathrm{d}y}=\frac{1}{R} \quad\Leftrightarrow\quad \frac{\mathrm{d}n}{\mathrm{d}y}=-\frac{n}{R\cos(\varphi)} \tag{10.5.165}$$

Ok we have here the main relations. The most important one in reality is:

$$\boxed{\Delta\varphi=-\frac{\cos(\varphi)}{n}\frac{\mathrm{d}n}{\mathrm{d}y}\Delta s} \tag{10.5.166}$$

where $\mathrm{d}n/\mathrm{d}y$ is named the "refraction rate".

✍**Example:**

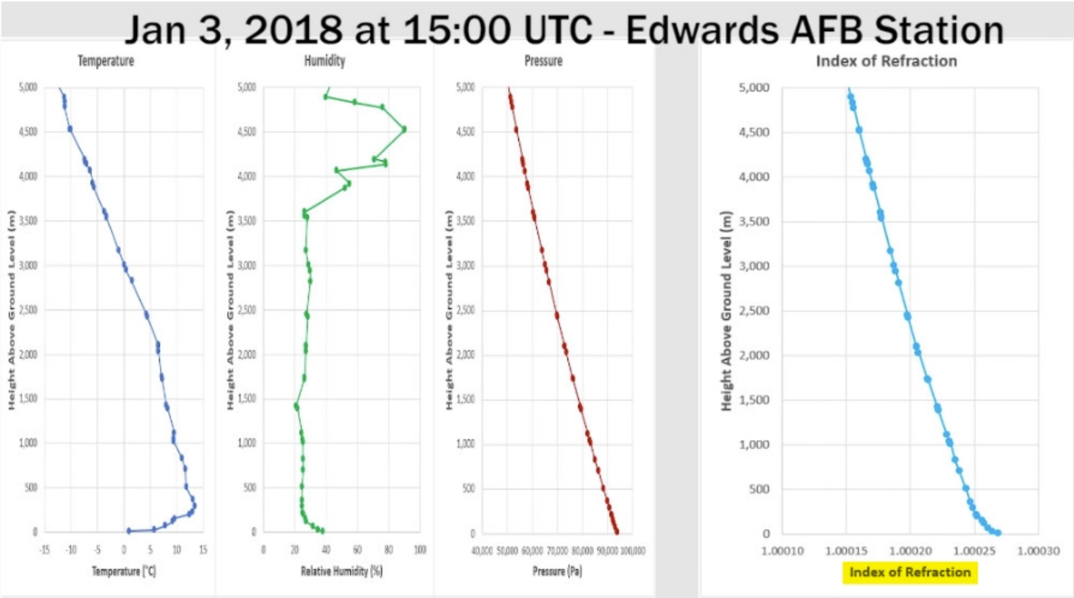
Let us consider the Monte Cinto ($2,710$ [m]) in Corsica and Mont Chauve d'Aspremont (854 [m]) near Nicea. It is measured between both of them that $\Delta s\cong 210$ [km] and we have assume to have for grazing angle $\varphi\cong 1.88^\circ$ and for Earth's radius $R\cong 6,370$ [km].

Hence, taking $n=1$ we have for the gradient of index of refraction:

$$\frac{\mathrm{d}n}{\mathrm{d}y}=\frac{n}{R\cos(\varphi)}=\frac{1}{6,370\cdot 10^3\cdot\cos(1.88^\circ)}\cong 1.57\cdot 10^{-7}\,[\mathrm{m}^{-1}]$$

According to the references the gradient will seldom have such a large value!

Indeed, see the measurement in Winter below where the index of refraction (right field below) has been calculated thanks to the Ciddor equation (source: cinnamoncontrol):



Using the rightmost chart we get (for the theoretical derivation of $\mathrm{d}n/\mathrm{d}y$ see page 4360):

$$\frac{\mathrm{d}n}{\mathrm{d}y} \cong \frac{1.00027-1.00015}{5,000} \cong 2.4\cdot 10^{-8}$$

Assuming therefore a refraction index gradient of $2.4\cdot 10^{-8}$ $[\mathrm{m}^{-1}]$, that is, approximately one tenth of the value above. Then the deviation on the distance 210 [km] from Monte Cinto to Mont Chauve d'Aspremont (near Nicea) can be calculated from:

$$\Delta\varphi = -\frac{\cos(\varphi)}{n}\frac{\mathrm{d}n}{\mathrm{d}y}\Delta s \cong -\frac{\cos(1.88^\circ)}{1}\cdot(2.4\cdot 10^{-8})\cdot(210\cdot 10^{3}) \cong -0.288^\circ$$

That means that the abnormal temperature gradient virtually brings together the to location of $(0.288^\circ = -0.00504$ [rad]) :

$$\Delta(\Delta s) = \Delta\varphi R = -0.00504\cdot 6,370\cdot 10^{3} \cong -32.1\ [\mathrm{km}]$$

This calculation thus delivers an (also quantitative) explanation of the phenomena that Monte Cinto in clear weather and winter can be viewed from Nicea!

We can therefore with the example above see that in the case of a gradient typical of that of winter, it's kinda similar as if the radius of the Earth is shrinked. That's why many of the horizon distance formulas replace the radius of the Earth R, by the "effective radius of Earth" :

$$R' = \frac{R}{1+k} \qquad (10.5.167)$$

where k is named "refraction coefficient" (not to be confused with the "refraction index" n).

10.5.4.6 Cherenkov radiation

Cherenkov radiation, also known as Vavilov–Cherenkov radiation, is electromagnetic radiation emitted when a charged particle (such as an electron) passes through a dielectric medium at a speed greater than the phase velocity of light in that medium. The characteristic blue glow of an underwater nuclear reactor is due to Cherenkov radiation. It is named after Soviet scientist Pavel Alekseyevich Cherenkov, the 11958 (holocene calendar) Nobel Prize winner who was the first to detect it experimentally. A theory of emitted corresponding spectrum was later developed within the framework of Einstein's special relativity theory by Igor Tamm and Ilya Frank, who also shared the Nobel Prize. Cherenkov radiation had been qualitatively predicted by the English polymath Oliver Heaviside in papers published in 11888–89 (holocene calendar).

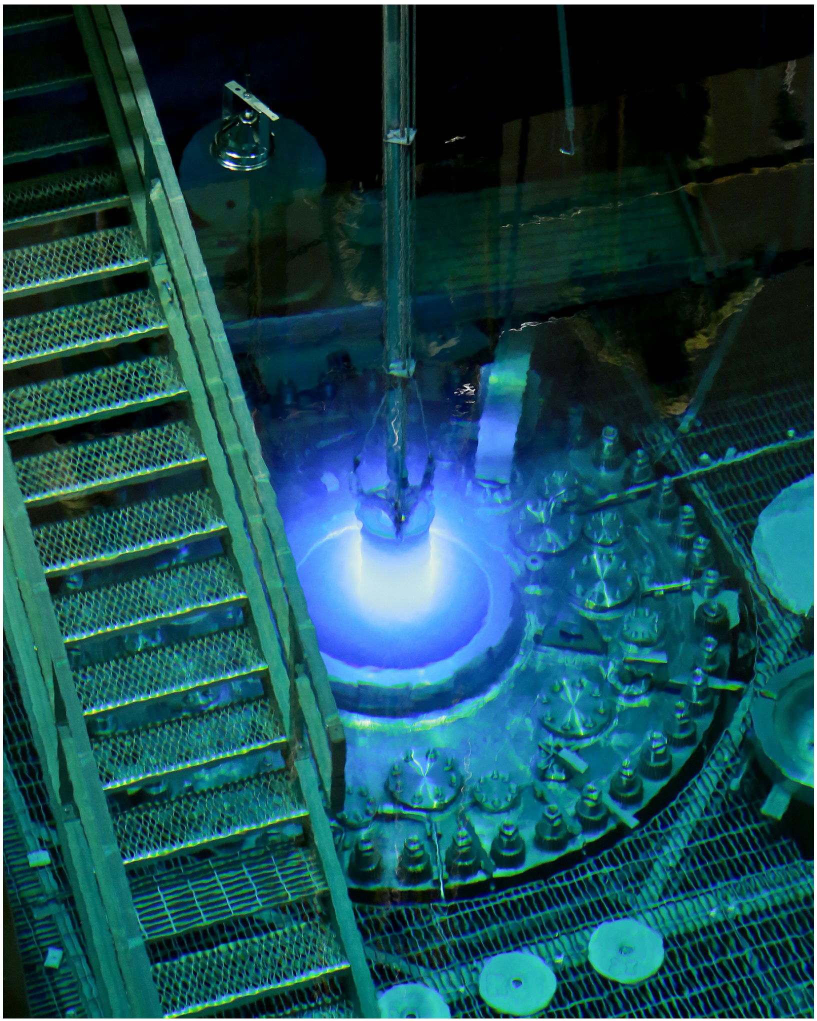


Figure 10.174: Oak Ridge National Laboratory Nuclear Reactor

Remark

Sometimes some wonder why charged particles can go faster than light in a medium other than a vacuum. It is simple to the point: even if the two particles meet roughly the same obstacles and difficulties to spread in a medium the photon cannot be accelerated by a pulse when a charged particle can be accelerated by a given phenomenon in a given medium.

We saw in the preceding paragraphs the hypothesis (relatively intuitive) than the phase propagation speed of light in an absolute refractive index medium n was not equal to c but still less by writing this:

$$v_n = \frac{c}{n} \tag{10.5.168}$$

The Cherenkov effect is (basically) a phenomenon similar to that of an (acoustic) shock wave, but producing a flash of light instead of sound, which takes place on the path of a charged particle moving in a medium with a higher phase velocity that of the speed of light in that medium (rigorous explanation is beyond the scope of study of this textbook because of its complexity treatment!).

Indeed, let us first recall that we proved in the section Electrodynamics that any moving charged particle emits electromagnetic radiation. Then we have proved in the preceding paragraphs that the speed of light in a given medium depends on the absolute refractive index n of the medium (hypothesis which is verified by the experimental accuracy of the theoretical developments arising therefrom).

So we have two basic informations:

1. The speed of the charged particle that can be written as follows with the traditional relativistic notations:

$$v = \beta c \tag{10.5.169}$$

2. The phase velocity of light in a medium with absolute refractive index given:

$$v_c = \frac{c}{n} \tag{10.5.170}$$

It is easy to see that to get $v > v_c$ we must have:

$$v > v_c \Leftrightarrow \beta c > \frac{c}{n} \tag{10.5.171}$$

Therefore:

$$\beta > \frac{1}{n} \tag{10.5.172}$$

Some authors prefer to compare the distance travelled by the light in relation to the distance travelled by the particle. It comes that as:

$$\boxed{\frac{d_{\text{light}}}{d_{\text{part}}} = \frac{\left(\dfrac{c}{n}\right)\Delta t}{\beta c \Delta t} = \frac{1}{\beta n}} \tag{10.5.173}$$

And therefore for the particle traverses distances equal to those of light at in the same time interval we must have that $\beta = 1/n$. Beyond appears the Cherenkov effect.

10.5.5 Descartes' Formulas

We have previously discussed some phenomena that occur when a wavefront passes from one medium to another in which the propagation is different. Not only have we analysed what becomes the wavefront, but we have introduced the concept of "radius" which is particularly useful for geometric constructions. We now propose to deepen the phenomena of refraction and reflection of a geometric point of view using the concept of radius as the tool to describe the processes taking place in the discontinuity surfaces of the propagation. We also assume that the process is limited to reflections and refractions, no other changes affecting the wave surfaces.

This geometry treatment is correct until surfaces and discontinuities encountered by the wave during its propagation are very large relatively to the wavelength. As long as this condition is met, the treatment applies both to light waves, sound (in particular ultrasound - very high frequency), seismic waves, etc.

We begin by considering the wave reflection on a spherical surface. For this purpose we must first given some obvious definitions: The center of curvature C (see section Differential Geometry page 2866) is the center of the spherical surface of the figure below and the top O is the pole of the spherical cap.

Definition (#10.5.493): The line passing through the pole cap O and the center of curvature C is named the "optical axis".

If we take O as coordinate origin, all measured quantities to the right of O will be taken as positive, all those on the left as negative !!!

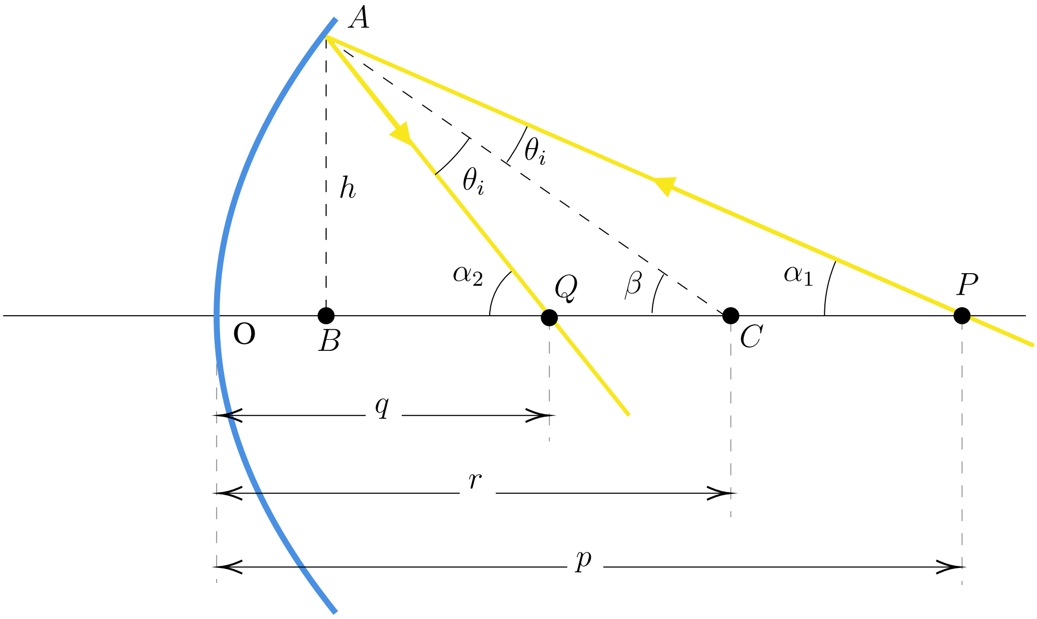

Figure 10.175: **Representation of the optical axis concept**

Let us suppose that the point P is a source of spherical waves. The radius $\overline{PA}$ gives by reflection the radius $\overline{AQ}$ and, as the angles of incidence and reflection are equal with respect to the perpendicular $\overline{AC}$ to the surface (as we have already observed it in our study of refraction), we see in the figure that:

$$\beta=\theta_i+\alpha_1 \quad \text{and} \quad \alpha_2=\beta+\theta_i \tag{10.5.174}$$

hence:

$$\alpha_1+\alpha_2=2\beta \tag{10.5.175}$$

Assuming that the angles α_1,α_2 and β are very small, that is to say, the rays are "para-axial" and the source is very far or that the sensor is very small compared to the source, we can write with a good approximation with a Maclaurin development (see section Sequences and Series page 1703) for small angles:

$$\begin{aligned}\alpha_1\cong\tan(\alpha_1) &= \frac{\overline{AB}}{\overline{BP}}\cong\frac{h}{p}\\ \alpha_2\cong\tan(\alpha_2) &= \frac{\overline{AB}}{\overline{BQ}}\cong\frac{h}{q}\\ \beta\cong\tan(\beta) &= \frac{\overline{AB}}{\overline{BC}}\cong\frac{h}{r}\end{aligned} \tag{10.5.176}$$

Substituting these approximations of α_1,α_2 and β into $\alpha_1+\alpha_2=2\beta$, we get:

$$\boxed{\frac{1}{p}+\frac{1}{q}\cong\frac{2}{r}} \tag{10.5.177}$$

which is the "Descartes formula for reflection on a concave spherical surface". It involves, in the approximation used to establish it, that for all incident rays passing through P will pass through Q after reflection on the surface. We can then say that Q is "the image of the object" P.

In the special case where the incident beam is parallel to the optical axis, that is equivalent to place the object at a great distance of the lens, we have $p=+\infty$. The Descartes formula for reflection on a concave spherical surface becomes therefore:

$$\frac{1}{q}=\frac{2}{r} \tag{10.5.178}$$

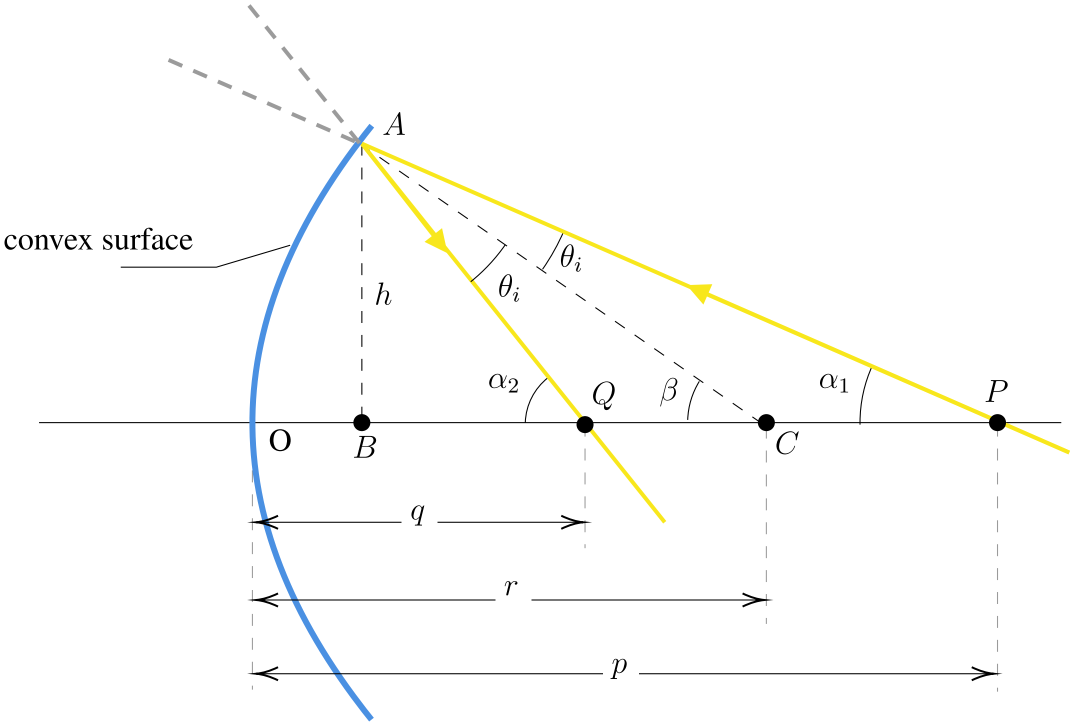
and the image is formed at the point f named the "focal" and its distance from the spherical lens is then given by:

$$\boxed{f=q\cong\frac{r}{2}} \tag{10.5.179}$$

and is named "focal length". We also get the ratio $r/2$ if we make q tend to infinity (that means the curvature radius is put to an infinite value).

So the bigger is r, the bigger is C (smaller curvature = wider angle photo) and therefore the bigger is q.

The relation obtained above is also valid for a convex surface. Indeed, we simply need pull the lines representing the light rays beyond the concave surface to see that the object of study is the same to a given symmetry:

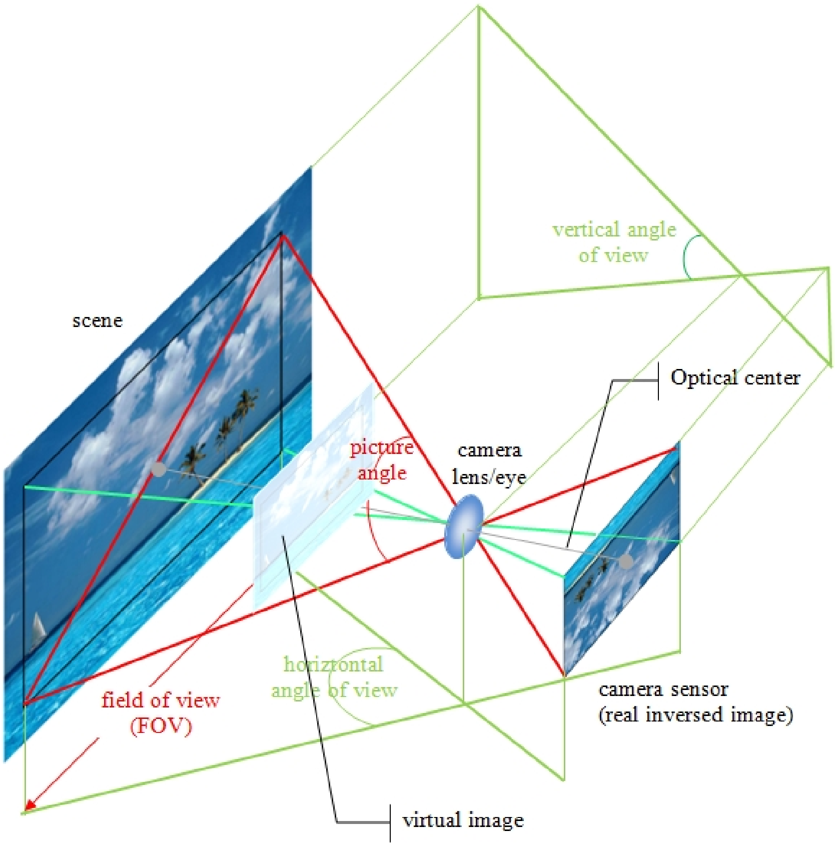


The only difference between the concave and convex surface is that in the case of the convex surface, the reflected image of the object appears as if it is behind the surface (at the equivalent of to the point P). This leads us to define the following terminology:

Definitions (#10.5.494):

D1. A "virtual image" is a term used in optics to refer to any image formed before the exit face of an optical instrument (in the direction of travel of light) and therefore will not be displayed on the projection screen. For a thin converging spherical lens an object placed between the object focus and the optical center of the lens will give a right (not inversed) virtual image. This is particularly the case of an optical system used as a magnifying glass, which provides a magnified image of the object observed through the lens.

D2. A "real picture" is a term used in optics to refer to any image formed after the exit face of an optical instrument (in the direction of travel of light). For a thin spherical converging lens an object placed against the object focus of the lens will give a real (inversed) image.



vertical angle of view
scene

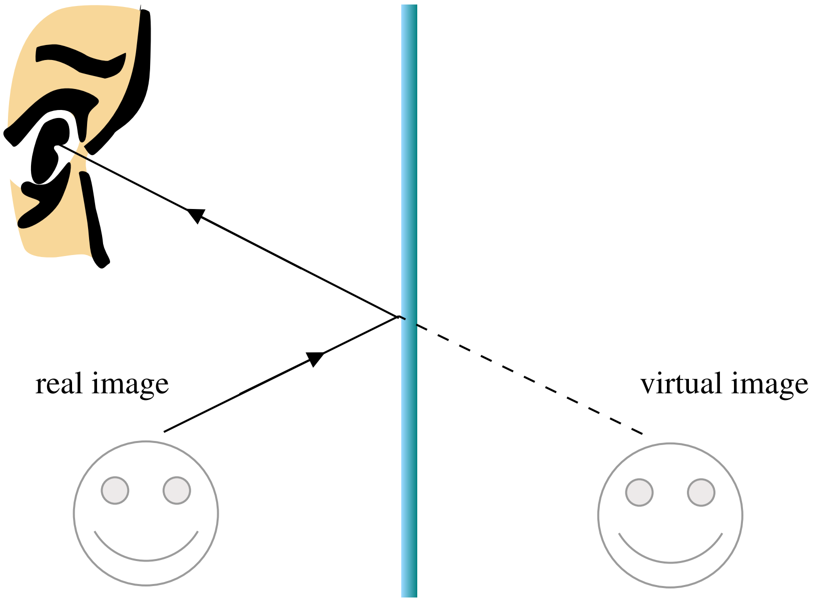
camera sensor (real inversed image)
virtual image

Figure 10.176: **Why images are reversed when passing through a thin spherical lens (for simplification purposes the focal in the drawing above is supposed to be inside the lens...)**

In the context of flat mirrors[19] the meaning is quite different:



real image
virtual image

---

[19] When we stand in front of a mirror, our mirror image flips right with left, left with right. But never top with bottom, bottom with top. The reason why is explained by the fact that this is an act of our brain! Our brain always generates a frame of reference with a vertical axis. Hence, we see things flipping vertically. This is because our brain is conditioned and trained to always flip images in the direction which demands less distortion.

obviously for flat mirrors the distance p of the real object to the mirror will have virtually the same distance q that has the "virtual object" to this same mirror so that virtually we could write $p=q$. For flat mirror the image is obviously upright and it produces and apparent left-right reversal!

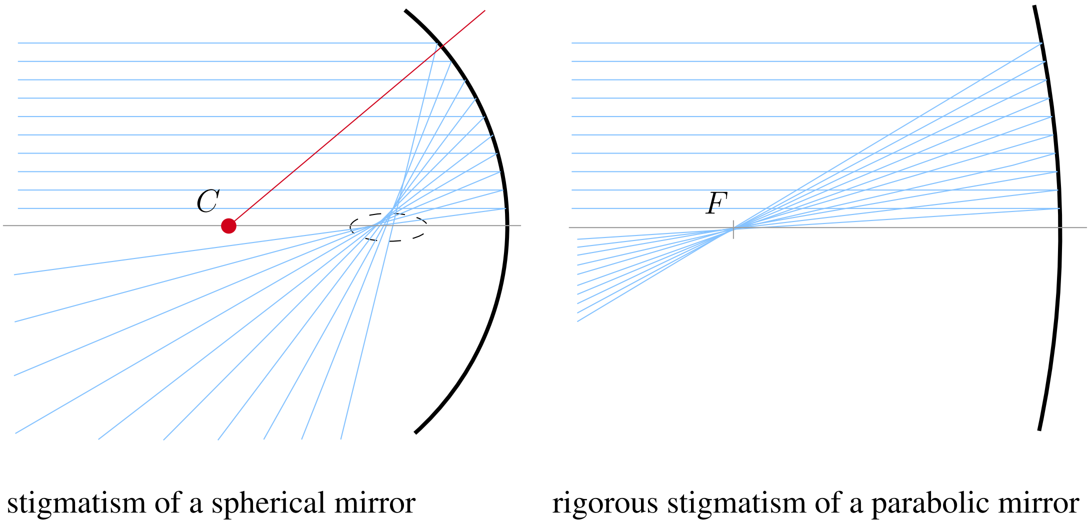
10.5.5.1 Stigmatism

If the opening (wide angle) of the mirror is large, so it receives steeply inclined rays, the above Descartes formula isn't anymore, we know it by construction, a good approximation. There is in this case no more well defined punctual image of a "point object" but an infinite number of them: consequently the image of a large object appears blurred since the images are superimposed. This effect is named "spherical aberration" and part of the optical axis which contains all the reflected images is then named the "caustic reflection". The spherical aberration can not be eliminated, but a suitable design of the surface allows to remove it for certain positions on the optical axis named "stigmatic". For example, in our previous study case, it is clear (by geometrical construction) that if we put P on C then the point C becomes the "stigmatic point". We say then that the point is "strictly stigmatic".

Remark

If we limit ourselves to the rays close to the optical axis and with a slight inclination relatively to it (these rays are said to be "paraxial"), the rays almost all intersect at the same image point: there is "approached stigmatism". This case is named the "Gaussian approximation".

By cons, for the parabolic mirror all the rays converge on the focus of the mirror where is concentrated the light energy received by the mirror. Conversely, we place the filament of a lamp at the focus of a parabolic mirror to get far-reaching headlights (typically lighthouse having no Fresnel lens). We also give a parabolic shape to antennas needing to receive radio waves. For television broadcast by satellite as it works at the centimetre waves (frequency of several GHz) a focal distance of one meter is suitable for the antenna (i.e. this applies to telescopes and radio telescopes).

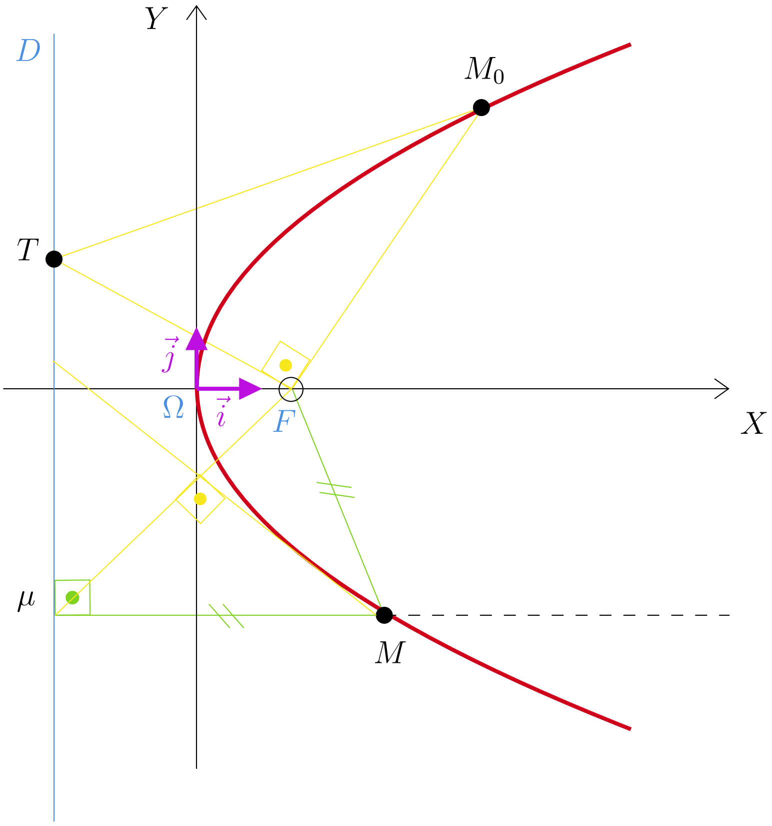


stigmatism of a spherical mirror rigorous stigmatism of a parabolic mirror

Figure 10.177: Representation of the concept of stigmatism

The idea to prove mathematically that the focus of a parabola is the rigorous stigmatic point is the following[20]:

Let us recall the following figure we used in our study of conical in the section of Analytical Geometry:



We have added on the figure the point μ that is the orthogonal projection of the point M (point of incidence of the light beam) and also the tangent to the parabola at the point M. If we can prove that the tangent to M is the mediator of segment $\overline{F\mu}$, then we also prove that the angle of incidence and reflection are equal. Therefore as we already know that incidence and reflection angles are equal, then we prove indirectly that on any point M of the parabola the incident ray comes on F.

Proof 10.2.4. Let us consider the equation of the parabola relatively to the focal as proved in the section of Analytical Geometry:

$$y^2-2hx=0 \qquad (10.5.180)$$

We have also proved in the section of Analytical Geometry that relatively to Ω the Focal is at the position $F(h/2,0)$ and the direction had for equation:

$$x+\frac{h}{2}=0 \qquad (10.5.181)$$

---

[20] That the shape of the caustic of a half-circular mirror is a "nephroid" is of minor interest so we won't do the proof in this textbook for now.

We get the equation of the tangent at $M(x_0,y_0)$ by the derivative at the same point (caution! ... remember the particular orientation of the parabola!):

$$x'_{y_0}=\frac{(x-x_0)}{(y-y_0)}=\left(\frac{y'}{2h}\right)'_{y_0}=\frac{2y_0}{2h}=\frac{y_0}{h}\Rightarrow(x-x_0)-(y-y_0)\frac{y_0}{h}=0 \tag{10.5.182}$$

Which can also be written:

$$hx-hx_0-y_0y+y_0^2=0\Leftrightarrow hx_0-hx-y_0^2+y_0y=0 \tag{10.5.183}$$

and knowing that:

$$y^2-2hx=0\Leftrightarrow y_0^2=2hx_0 \tag{10.5.184}$$

So we get the equation of the tangent:

$$hx_0-hx-y_0^2+y_0y=hx_0-hx-2hx_0+y_0y=y_0y-h(x+x_0)=0 \tag{10.5.185}$$

On of the vector of the tangent is therefore as proved in the section of Analytical Geometry during our study of the parametric equation of a the line:

$$\vec{v}=y_0\vec{i}+p\vec{j} \tag{10.5.186}$$

where in our case of the parabola, p is equal to h.

On the other hand, we have (this is easily verified by taking $x_0=0$):

$$\overrightarrow{MF}=\left(\frac{h}{2}-x_0\right)\vec{i}-y_0\vec{j}\quad\text{and}\quad\overrightarrow{M\mu}=-\left(\frac{h}{2}+x_0\right)\vec{i} \tag{10.5.187}$$

So we have the scalar product:

$$\vec{v}\circ\overrightarrow{MF}=-y_0\left(x_0+\frac{h}{2}\right)=\vec{v}\circ\overrightarrow{M\mu} \tag{10.5.188}$$

as the vectors $\overrightarrow{MF}$ and $\overrightarrow{M\mu}$ have the same norm by definition of the parabola in Analytical Geometry[21], we deduce that the vector $\vec{v}$ (giving the direction of the tangent) leads the line bisecting the angle of the $\overrightarrow{MF}$ and $\overrightarrow{M\mu}$ and therefore by extension that the tangent M is the mediator of $\overline{M\mu}$.

■ Q.E.D.

---

[21] Yes, for recall a "parabola" is the set of all points which are equidistant from a point, called the focus, and a line, named the "directrix"

Figure 10.178: **Parabolic antenna for reception or emission (source: OpenStax)**

Let us also calculate the focus position of a parabolic reflector whose equation is given by (see section Analytical Geometry page 2983):

$$\frac{x^2}{100}+\frac{y^2}{100}=\frac{z}{4} \tag{10.5.189}$$

We fix for example x to 0 then it remains:

$$\frac{y^2}{100}=\frac{z}{4} \tag{10.5.190}$$

After rearranging we get:

$$y^2=25z \tag{10.5.191}$$

As:

$$25=2h \tag{10.5.192}$$

we get immediately:

$$h=12.5 \tag{10.5.193}$$

And we have prove in the section of Analytical Geometry that:

$$F=\left(\frac{h}{2},0\right)=(6.25,0) \tag{10.5.194}$$

A circular paraboloid is theoretically unlimited in size. Any practical reflector uses just a segment of it. Often, the segment includes the vertex of the paraboloid, where its curvature is greatest, and where the axis of symmetry intersects the paraboloid. However, if the reflector is used to focus incoming energy onto a receiver, the shadow of the receiver falls onto the vertex of the paraboloid, which is part of the reflector, so part of the reflector is wasted. This can be avoided by making the reflector from a segment of the paraboloid which is offset from the vertex and the axis of symmetry:

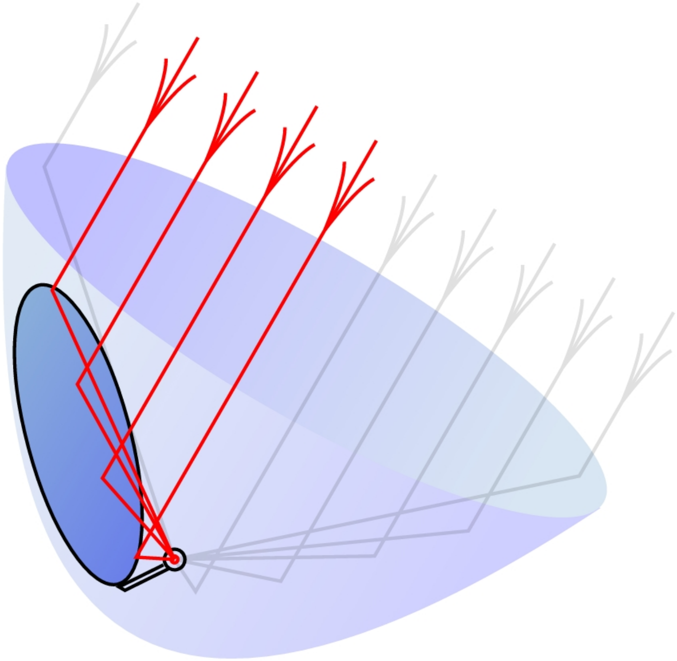


Figure 10.179: Off-axis receiver dish construction principle (source: Wikipedia)

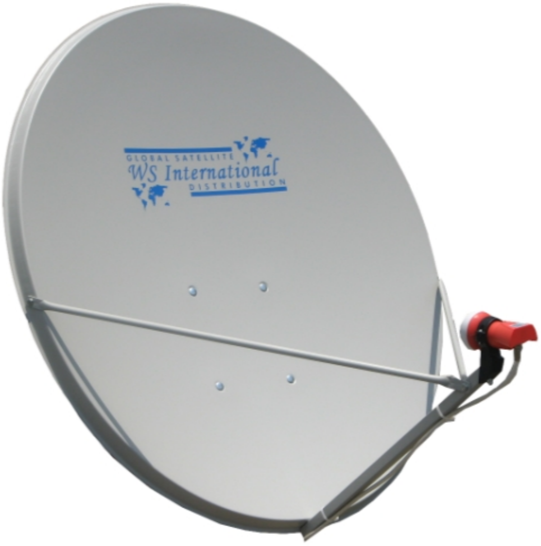
The receiver is still placed at the focus of the paraboloid, but it does not cast a shadow onto the reflector. The whole reflector receives energy, which is then focused onto the receiver. This is frequently done, for example, in satellite-TV receiving dishes, and also in some types of astronomical telescope:



GLOBAL SATELLITE
WS International
DISTRIBUTION

Figure 10.180: Off-axis satellite dish

10.5.5.2 Lenses

Let us now do a similar study to that carried out earlier, with the same properties of symmetry and defects, but the "spherical dioptres boundaries" that is a spherical boundary between to mediums (interesting results regarding the study of the eye). The results will be helpful to us before tackling the study of spherical lens (the traditional magnifying glass).

So we will now consider the refraction of the light during the passage through a spherical surface separating two medium with absolute refractive indices n_1 and n_2 (see figure below):

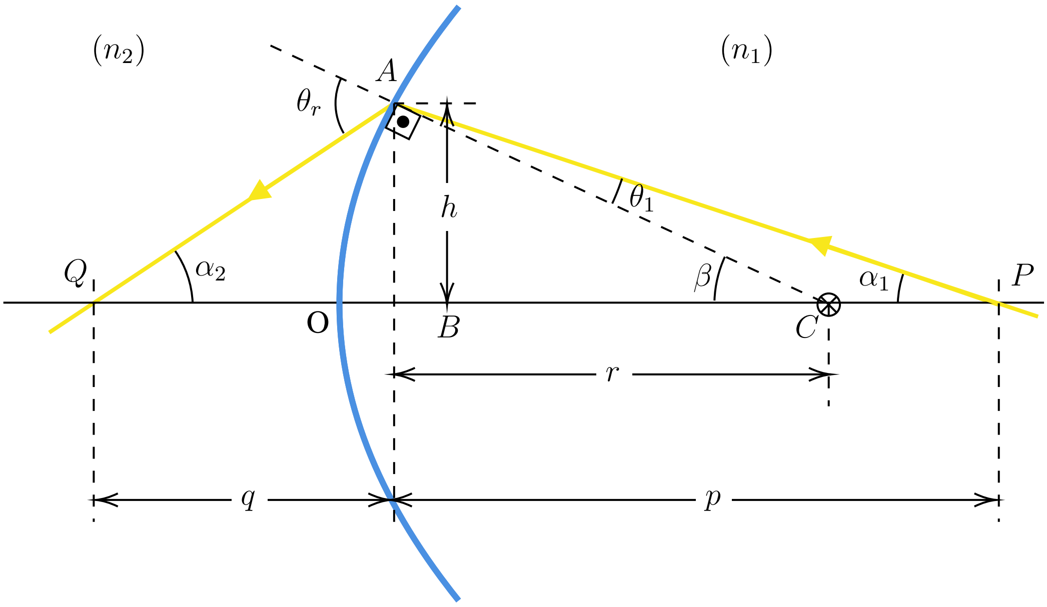


Figure 10.181: A biconvex lens in real life... (source: Wikipedia)

where for recall the center of curvature C (see section Differential Geometry page 2866) is the center of the spherical surface of the figure below and the top O is the pole of the spherical cap.

The basic geometric elements are the same as those specified for spherical surfaces. We therefore consider initially a concave refractive surface (concave dioptre) and observing that the "object distance" is located at the opposite of the other points, we must adopt a sign convention to put this observation in evidence in the equations. Thus, q will be defined as a negative value.

An incident ray such as $\overline{PA}$ is refracted as following $\overline{AQ}$ and thus cross the optical axis Q. We see from the figure that:

$$\beta=\theta_i+\alpha_i \qquad \text{and} \qquad \beta=\theta_r-\alpha_2 \tag{10.5.195}$$

We have the Snell-Descartes' law:

$$\frac{n_1}{\sin(\theta_r)}=\frac{n_2}{\sin(\theta_i)} \tag{10.5.196}$$

and we will admit as for spherical surfaces that the ray a only little bit inclined rays. Under these conditions the angles $\theta_i,\theta_r,\alpha_1,\alpha_2$ and β are very small and we can write using the Maclaurin series expansion (see section Sequences and Series page 1703):

$$\sin(\theta_i)\cong\theta_i \qquad \text{and} \qquad \sin(\theta_r)\cong\theta_r \tag{10.5.197}$$

so that the Snell-Descartes' law is now written:

$$n_1(\beta-\alpha_1)=n_2(\beta+\alpha_2) \tag{10.5.198}$$

From the figure, we can do the approximations:

$$\begin{aligned}\tan(\alpha_1)&\cong\alpha_1\cong\frac{h}{p}\\ \tan(\alpha_2)&\cong\alpha_2\cong\frac{h}{q}\\ \tan(\beta)&\cong\beta\cong\frac{h}{r}\end{aligned} \tag{10.5.199}$$

so that by substituting in the approximation of the Snell-Descartes' law we find elementary simplification:

$$n_1\left(\frac{h}{r}-\frac{h}{p}\right)=n_2\left(\frac{h}{r}+\frac{h}{q}\right)\Leftrightarrow\left(\frac{1}{r}-\frac{1}{p}\right)=n_2\left(\frac{1}{r}+\frac{1}{q}\right) \tag{10.5.200}$$

hence for a concave surface:

$$\boxed{\frac{n_1}{p}+\frac{n_2}{q}=\frac{n_1-n_2}{r}} \tag{10.5.201}$$

The "object focal F_0" also named "first focal point" of a refractive spherical surface is the position of a punctual object on the optical axis such that the refracted rays are parallel to the optical axis, which is equivalent to form the image of the point at infinity, where $q=+\infty$.

The distance of the object to the spherical surface is then named "focal distance object" and we denote it by f_0. By putting $p=f_0$ and $q=+\infty$, then we have for the concave case:

$$\frac{n_1}{f_0}=\frac{n_1-n_2}{r}\Rightarrow f_0=\left(\frac{n_1}{n_1-n_2}\right)r \tag{10.5.202}$$

The focal length f_0 is positive and the system is the convergent when the object focus is real, is placed in front of the spherical surface. When the object focus is virtual, the focal length f_0 is negative and the system is then divergent.

Similarly, if the incident rays are parallel to the optical axis, which is equivalent as to have a very distant object form the spherical surface $p=+\infty$, the refracted rays pass through a point F_i of the optical axis named "image focus" or "second focal point" (again with the same problems of stigmatims).

In this case the distance of the spherical surface to the image is named "focal image distance" and we denote it by f_i. By putting $p=+\infty$ and $q=f_i$ then we have for the concave case:

$$\frac{n_2}{f_i}=\frac{n_1-n_2}{r}\Rightarrow f_i=\left(\frac{n_1}{n_1-n_2}\right)r \tag{10.5.203}$$

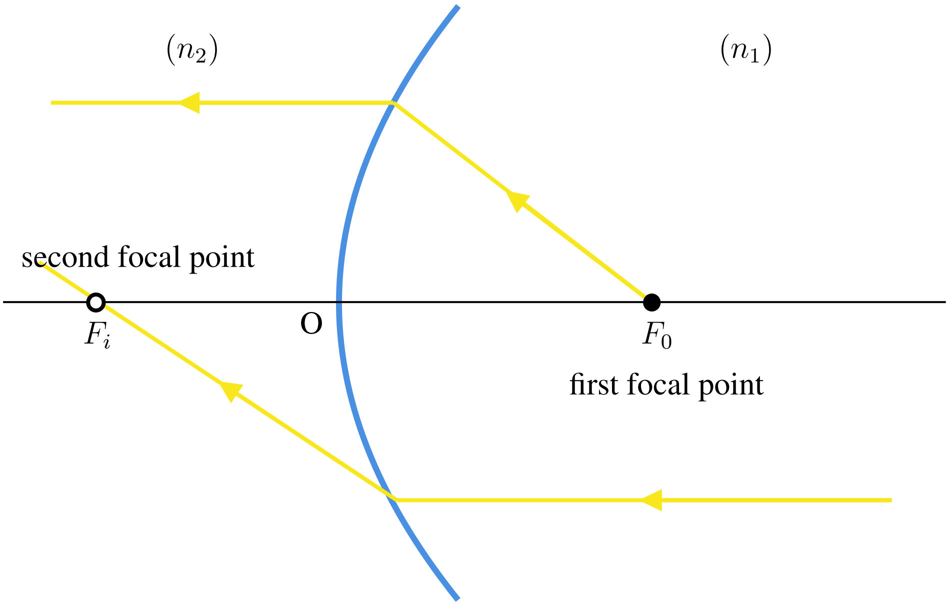

Figure 10.182: Position of first and second focal points in a dioptre

By mixing the two previous relations, we have a useful result in practice:

$$\boxed{\left.\begin{array}{l} f_0=\dfrac{n_1}{n_1-n_2}r \\ f_i=\dfrac{n_2}{n_1-n_2}r \end{array}\right\} \Rightarrow \dfrac{f_0}{f_i}=\dfrac{n_1}{n_2}=n} \tag{10.5.204}$$

So if we know the relative refractive index and one of the focal lengths, we can infer the other. Or (and we can of course make also other combinations):

$$\left.\begin{array}{l} f_0=\dfrac{n_1}{n_1-n_2}r \\ f_i=\dfrac{n_2}{n_1-n_2}r \end{array}\right\} \Rightarrow f_0-f_i=-r \tag{10.5.205}$$

Now let us take look at the type of reflective surfaces and refractions we were waiting for: the lenses!

Definition (#10.5.495): A "lens" is a transmissive optical device that focuses or disperses a light beam by means of refraction. A simple lens consists of a single piece of transparent material (generally spherical), while a compound lens consists of several simple lenses (elements), usually arranged along a common axis. Lenses are made from materials such as glass or plastic, and are ground and polished or moulded to a desired shape. A lens can focus light to form an image, unlike a prism, which refracts light without focusing. Devices that similarly focus or disperse radiation other than visible light are also named "lenses", such as microwave lenses, electron lenses or acoustic lenses.

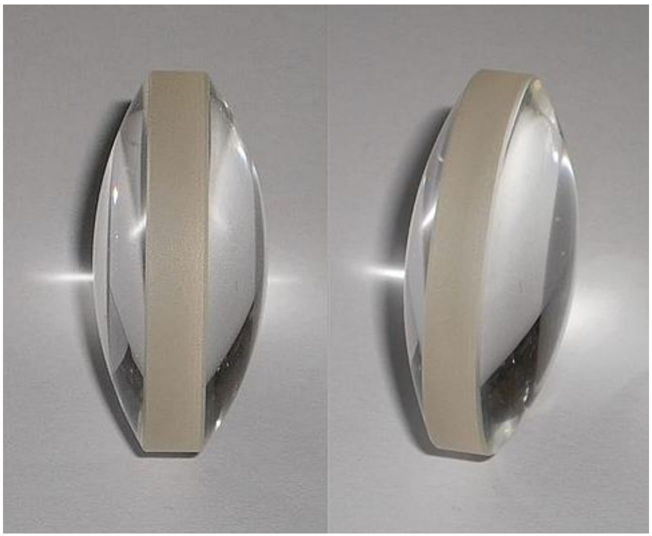

Figure 10.183: **Concept of spherical dioptre**

The study of optical lenses is a huge and subtle subject and our only purpose in this textbook is to give the mathematical basic properties of some elementary lenses shapes. As we will show it through some illustration, even traditional camera have already some huge complications to get qualitative results for the professional photographer as illustrated in the figure below:

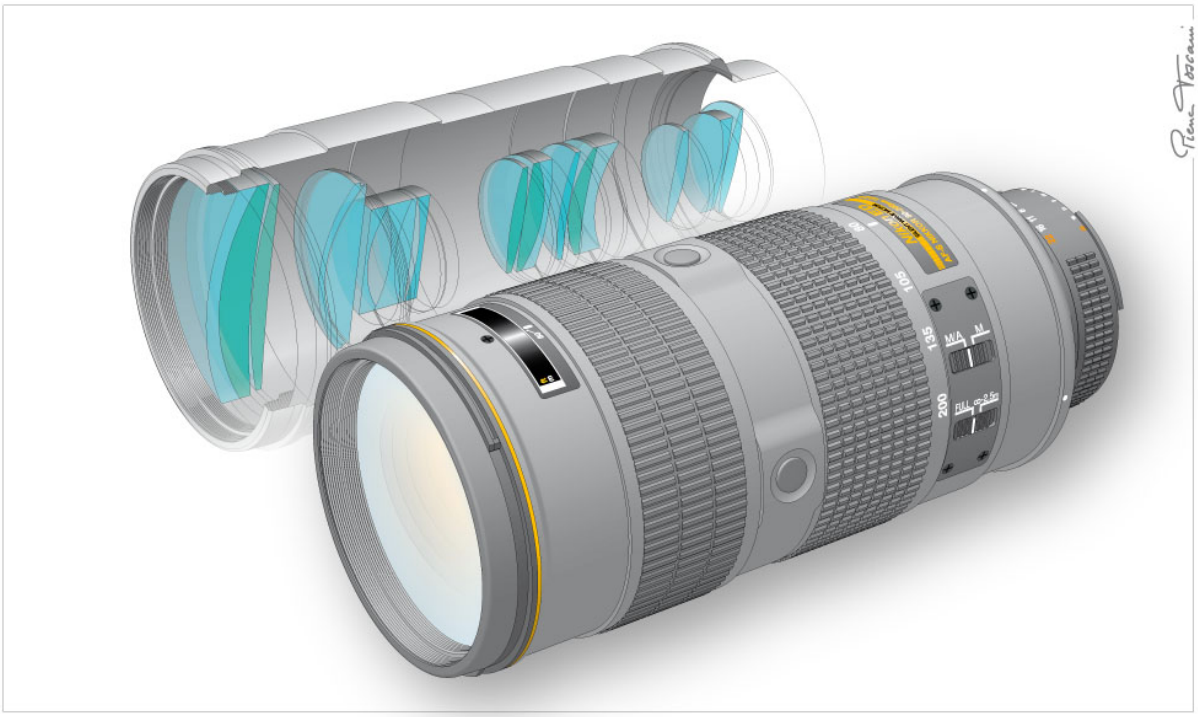

Figure 10.184: **Zoom-Nikkor AF-S 80-200 mm f/2.8D IF-ED (source: http://www.pierretoscani.com, author: Pierre Toscani)**

or even better (optical system also existing for smartphones!):

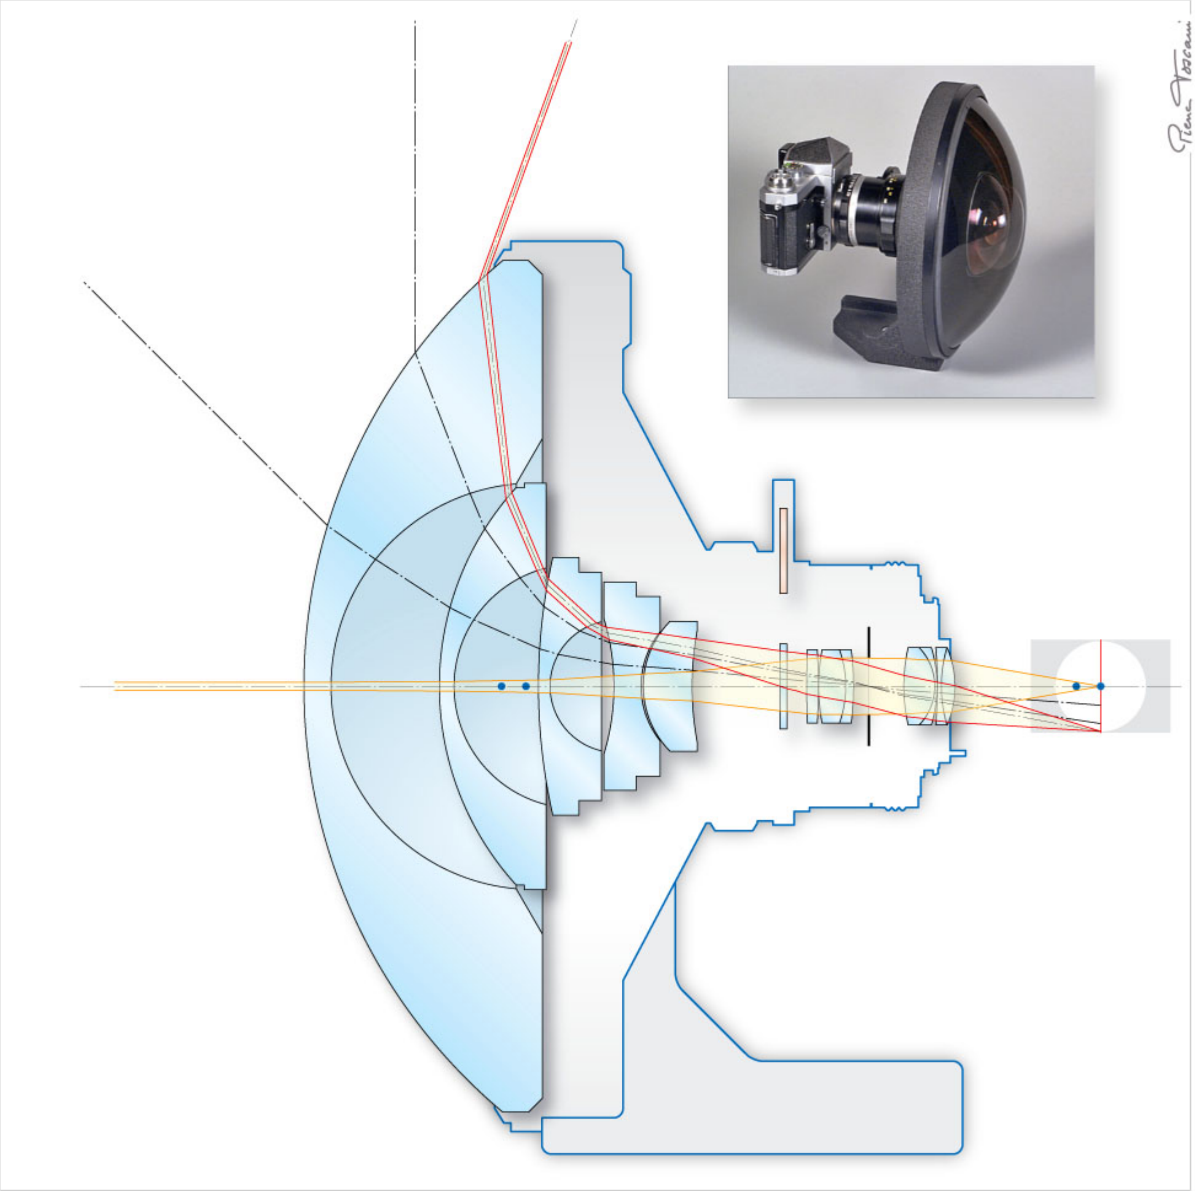

Figure 10.185: Fisheye-Nikkon 6 mm f/2.8 simplified cut (source: http://www.pierretoscani.com, author: Pierre Toscani,)

An incident ray thus undergoes two refractions at the crossing of the lens. Assume for simplicity that the media of both sides of the lens are identical and their absolute refraction index equal to 1 (air or vacuum for example). We will also consider only thin lenses in this textbook, that is to say whose thickness is very small compared to the radii of curvature:

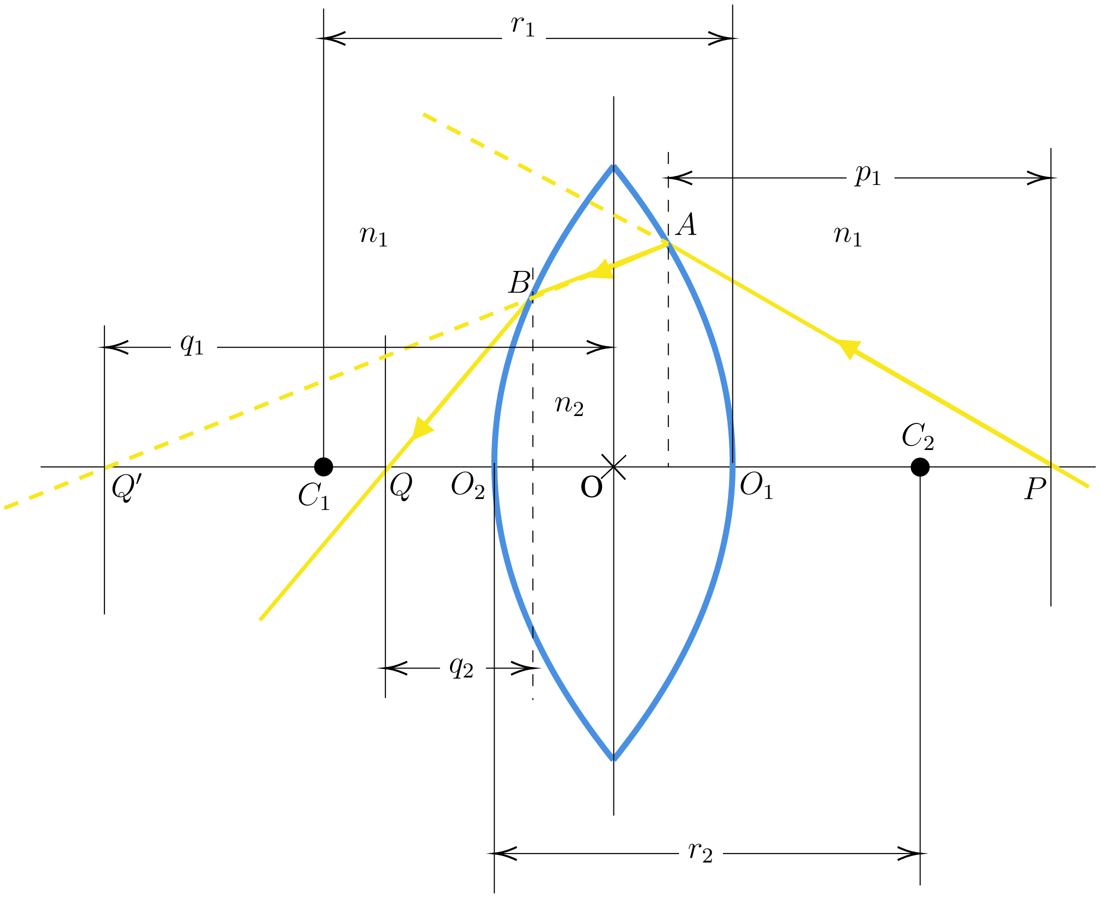

Figure 10.186: Technical representation of a lens

The optical axis is the line determined by the two centers $\overline{C_1C_2}$. We seek to establish a relation between the position of P and Q from easily measured physical parameters!

We will consider for the analysis that the image formed after the refraction on the first surface is the object for the refraction on the second surface.

Let us consider the incident ray $\overline{PA}$ through P. When passing the first surface, the incident ray is refracted following the radius $\overline{AB}$ and continues virtually to Q' according to the behaviour of a convex spherical surface. So we apply the relation proved just earlier above for the convex diopter:

$$\frac{n_1}{p_1}+\frac{n_2}{q_1}=\frac{n_2-n_1}{r_1} \qquad (10.5.206)$$

In B the ray undergoes a second refraction and becomes the radius $\overline{BQ}$ according to the behaviour of a concave spherical surface. We can imagine that the incident beam in B come from a virtual point P' (not show in the figure above) that is on the optical axis and immersed in the material virtually extended to the right of the lens (that is the difficult side of this proof ... you have to imagine that!).

So we have to apply the relation proved earlier above for the concave refractive surface (dioptre) but by being careful this time to the order of absolute refractive indices (subtle trap!) and by imagining that the point:

$$\frac{n_2}{p_2}+\frac{n_1}{q_2}=\frac{n_1-n_2}{r_2} \tag{10.5.207}$$

As we consider the lens is surrounded by air (unitary refractive index), then we have:

$$\frac{1}{p_1}+\frac{n}{q_1}=\frac{n-1}{r_1} \qquad \frac{n}{p_2}+\frac{1}{q_2}=\frac{1-n}{r_2} \tag{10.5.208}$$

We will now assume that the thickness of the lens tends to zero. In other words his two radii tend to infinity. Then we have:

$$\left.\begin{array}{l} \dfrac{1}{p_1}+\dfrac{n}{q_1}=\dfrac{n-1}{r_1}=_{r_1\rightarrow+\infty}0 \\ \dfrac{n}{p_2}+\dfrac{1}{q_2}=\dfrac{1-n}{r_2}=_{r_1\rightarrow+\infty}0 \end{array}\right\} \Rightarrow \frac{1}{p_1}+\frac{1}{q_1}=\frac{n}{p_2}+\frac{1}{q_2} \tag{10.5.209}$$

By identifying term to term and remembering that what is left from the origin O is negative, then we have:

$$p_2\cong -q_1 \tag{10.5.210}$$

while subtly ignoring the other two terms ... (we understand now easily why this proof is often omitted in the literature ...).

Therefore, both prior previous relations become:

$$\frac{1}{p_1}+\frac{n}{q_1}=\frac{n_1}{r_1} \qquad \frac{n}{-q_1}+\frac{1}{q_2}\cong\frac{1-n}{r_2} \tag{10.5.211}$$

Summing it comes finally:

$$\frac{1}{p_1}+\frac{1}{q_2}\cong(n-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right) \tag{10.5.212}$$

and that is often denoted in the following form, name "Descartes's first formula for thin lenses" or simply "thin lens equation":

$$\boxed{\frac{1}{p}+\frac{1}{q}\cong(n-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right)} \tag{10.5.213}$$

While being careful to rehabilitate the figure above such that it becomes:

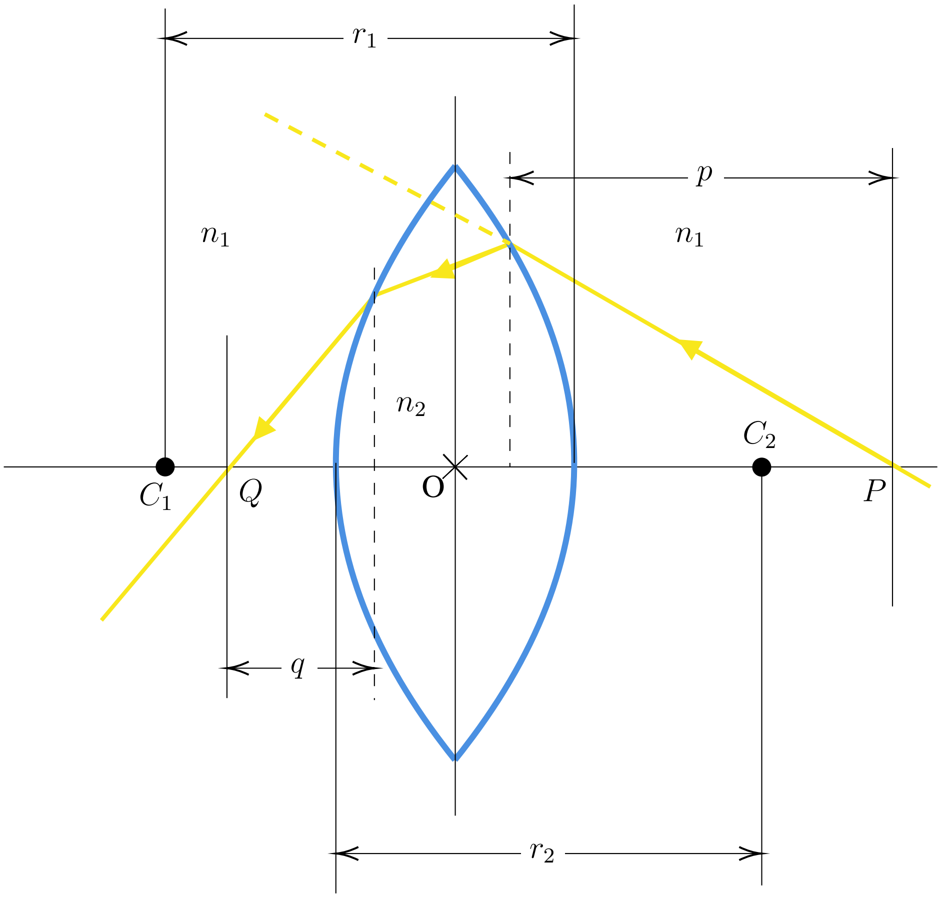

Figure 10.187: **Thin lens equation corresponding technical figure**

By writing this formula it should be applied to r_1, r_2 the sign convention we have set, that is to say, the rays are positive for a concave surface and negative for a convex surface, as seen from the side on which the light hits the lens. Thus, if the two radii are the same, we have:

$$\frac{1}{p}+\frac{1}{q}\cong(n-1)\left(\frac{1}{r}-\frac{1}{(-r)}\right)=(n-1)\frac{2}{r} \tag{10.5.214}$$

The right term of the thin lens equation is only a constant depending on the physical characteristics of the lens and it customary to name it "refractive power" or "dioptric power" and whose unity is the "diopter" and denoted:

$$\frac{1}{p}+\frac{1}{q}\cong\mathcal{D} \tag{10.5.215}$$

Converging lenses have positive optical power, while diverging lenses have negative power. When a lens is immersed in a refractive medium, its optical power and focal length change.

Notice that if we put the source at infinity such that $p=+\infty$ then all light rays will focus on the same point q, therefore denoted f_0 as we have:

$$\frac{1}{f_0}\cong(n-1)\left(\frac{1}{r}-\frac{1}{(-r)}\right)=(n-1)\frac{2}{r} \tag{10.5.216}$$

Hence:

$$\boxed{f_0=\frac{r}{2}(n-1)} \tag{10.5.217}$$

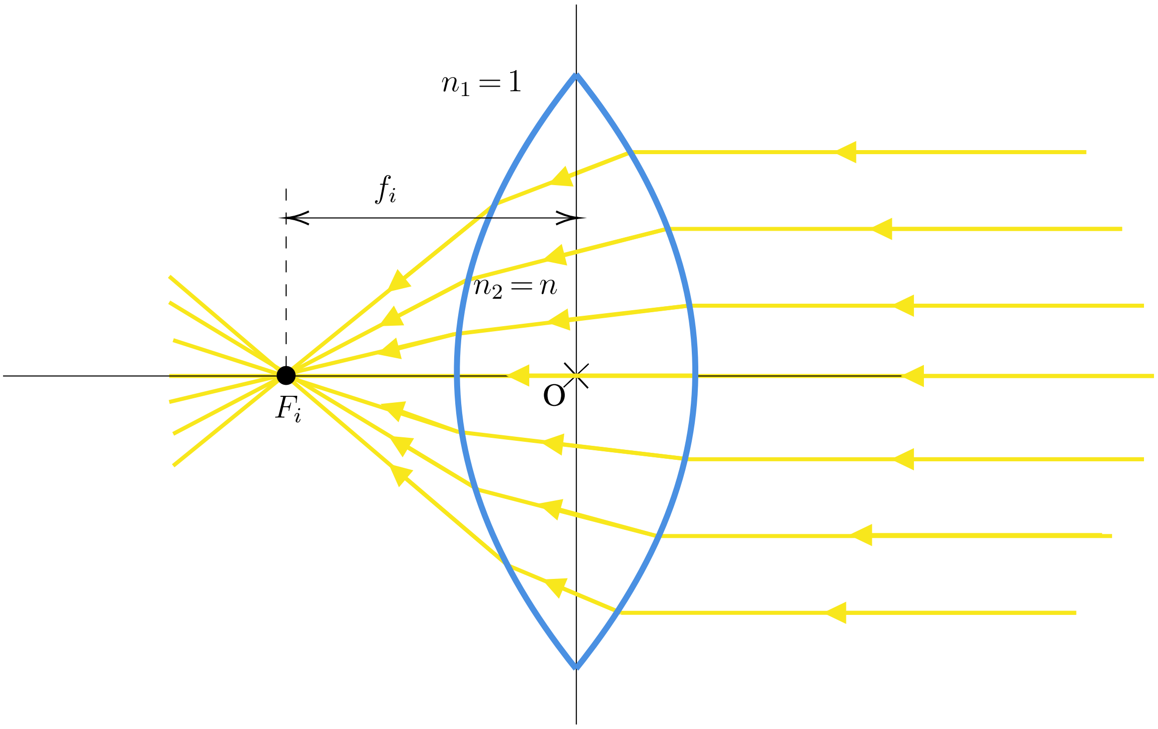

Figure 10.188: **Focal of a thin lens with parallel entering light rays**

Now it's interesting to see that the concept is reversible. That means if you consider the source as being the focus, i.e. such that (by symmetry) $q = f_0$, the by using the previous relation, we get:

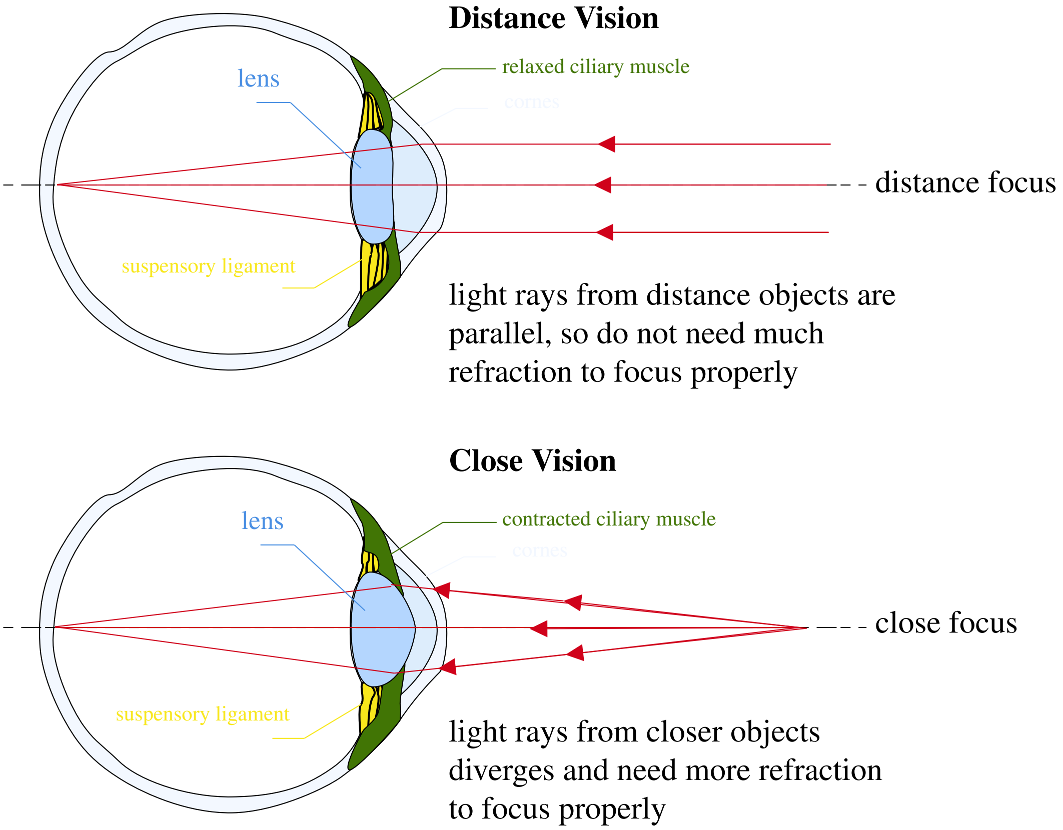
$$\frac{1}{p}+\frac{1}{q}=(n-1)\frac{2}{r}\Rightarrow\frac{1}{f_0}+\frac{1}{q}=(n-1)\frac{2}{r} \tag{10.5.218}$$

Therefore:

$$\frac{1}{q}=(n-1)\frac{2}{r}-\frac{1}{f_0}=(n-1)\frac{2}{r}-(n-1)\frac{2}{r}=0 \tag{10.5.219}$$

Hence $q = +\infty$ and the target is at infinity. So ray tracing is invertible because if the source is a the focus, the all rays go out of the lens parallel at infinity!

The following figure can help to understand (play with the values of q, p, r in the previous relations to understand it completely):



Distance Vision
lens
relaxed ciliary muscle
cornea
distance focus
suspensory ligament
light rays from distance objects are parallel, so do not need much refraction to focus properly
Close Vision
lens
contracted ciliary muscle
cornea
close focus
suspensory ligament
light rays from closer objects diverges and need more refraction to focus properly

Figure 10.189: Human eye adaptative refractive power mechanism

Remark

An eye that has too much or too little refractive power to focus light onto the retina has a refractive error. A myopic eye has too much power so light is focused in front of the retina. Conversely, a hyperopic eye has too little power so when the eye is relaxed, light is focused behind the retina. An eye with a refractive power in one meridian that is different from the refractive power of the other meridians has astigmatism. Anisometropia is the condition in which one eye has a different refractive power than the other eye.

The point O in the previous figure, is selected to coincide with the "optical center" of the lens. As we know, the optical center has the property of being such that any ray passing through it exit parallel to the direction of the incident ray !! This is an important property because any point of an object lying on one side of a lens (whatever which one because of the symmetry of the lens) will emit light from which some rays will pass through the optical center. Thus allowing to have similar triangles on the left and right of the symmetry axis of the lens and apply Thales' theorem (see section Euclidean Geometry page 2610) to calculate the concept of "magnification" (see further below).

To prove that such a point exists let us consider in the lens below (with horizontal and vertical symmetry):

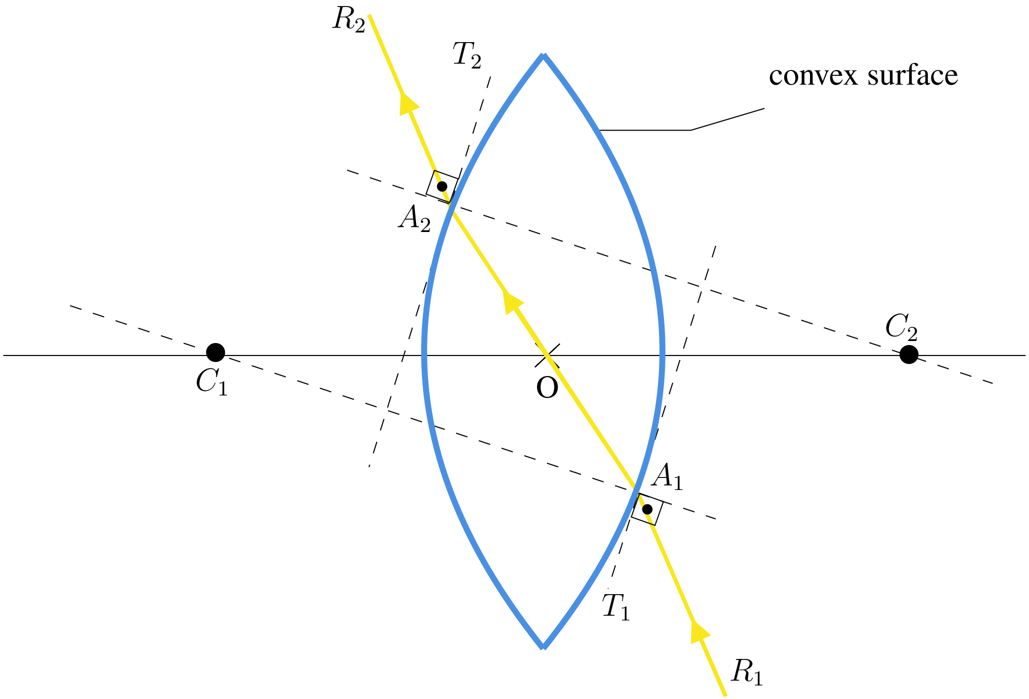


Figure 10.190: **Representation of the property of the optical center of a lens**

Let us consider two parallel curvatures radius:

$$\overline{C_1A_1}=r_1 \qquad \overline{A_2C_2}=-r \tag{10.5.220}$$

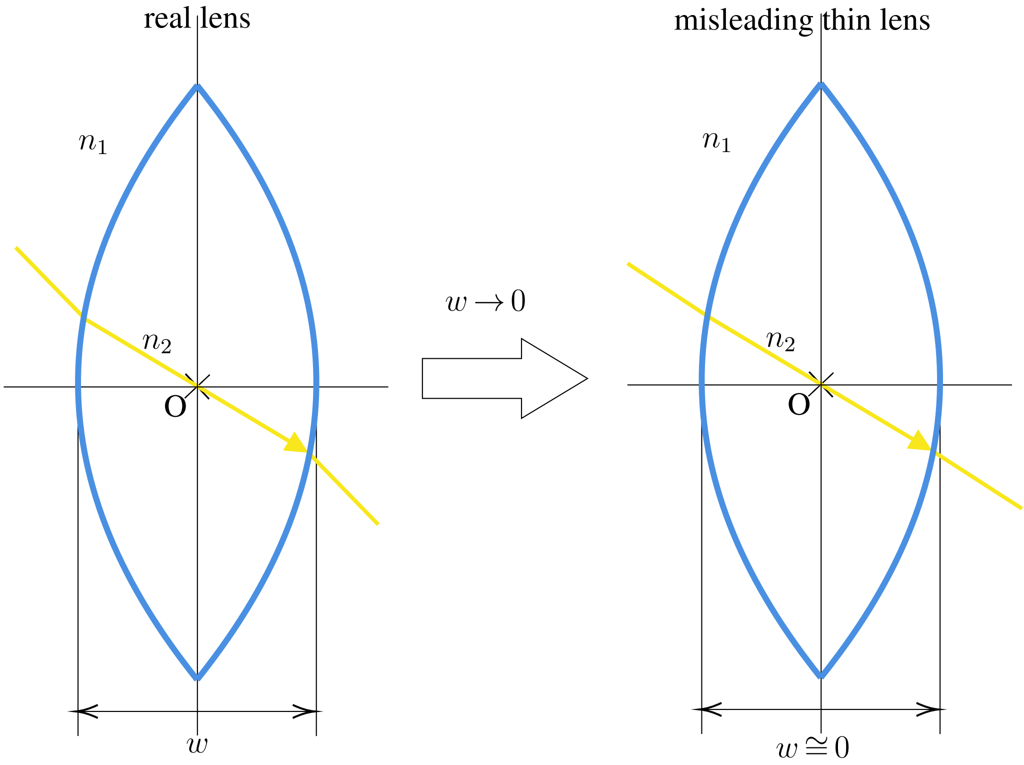
generators of the diopters (elements of the thin spherical lens for recall...) chosen such that the corresponding tangent planes T_1 and T_2 are also parallel.

For the radius $\overline{R_1A_1}$, which direction is such that it is refracted following $\overline{A_1A_2}$, the emerging ray $\overline{A_2R_2}$ is parallel to $\overline{A_1R_1}$ by the horizontal symmetry of the lens. Thus the triangles $C_1A_1\text{O}$ and $C_2A_2\text{O}$ are similar regardless of the "generators radius", thus we see that the position of the optical center O is satisfied by the relation:

$$\frac{\overline{C_1\text{O}}}{\overline{\text{O}C_2}}=\frac{\overline{C_1A_1}}{\overline{A_2C_2}}=-\frac{r_1}{r_2} \tag{10.5.221}$$

and therefore exists independently of the generating radii.

Notice that in the "thin lens" assumption the width is assumed to tend to zero. This is why in many textbook the reader can see the following quite abusive and misleading representation on the right of the figure below:



As in the case of a single diopter, the "focal object" F_0, or "first focal point of a lens" is the position of the object for which the rays emerge parallel to the optical axis ($q = +\infty$) after have passed through the lens. The distance from the lens to the object focus is named the "focal distance object" and we designate it in practice often by the simple letter f for thin lenses.

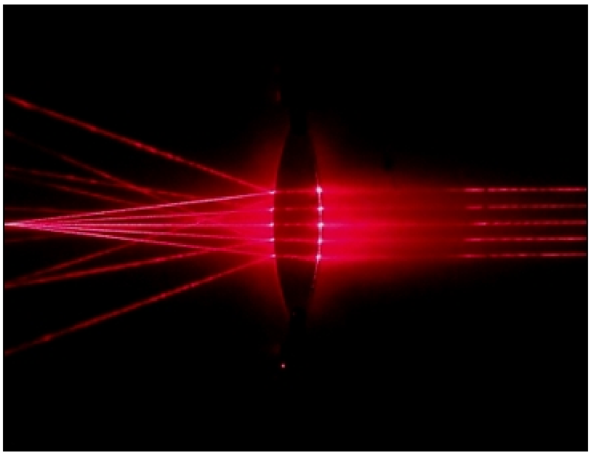


Figure 10.191: **First focal point (source) is here on the left of the thin lens**

Or for those who cannot see well the figure above, there is another more explicit illustration of what happen with the first focal point of a bi-convex lens:

Convergent emerging rays
F_0
Divergent emerging rays
Pierre Toscani

Figure 10.192: **First focal point with bi-convex lens behaviour (source: http://www.pierretoscani.com, author: Pierre Toscani)**

Then by putting $p = f$ and $q = +\infty$ in the equation of spherical thin lenses we get:

$$\frac{1}{p}+\frac{1}{q}=(n-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right) \tag{10.5.222}$$

We then get the following focal distance object in the form named "focal length of the lens":

$$\boxed{\frac{1}{f}=(n-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right)} \tag{10.5.223}$$

Similarly in the case of a simple diopter, the "focal image" F_i, or "second focal point of a lens" is where converge the light rays after passing through the lens, but that were before the lens parallel between them and to the optical axis ($p = +\infty$). Thus, given the central spherical symmetry of thin lenses it is simple enough to reverse in our imagination the previous picture to get the concept:

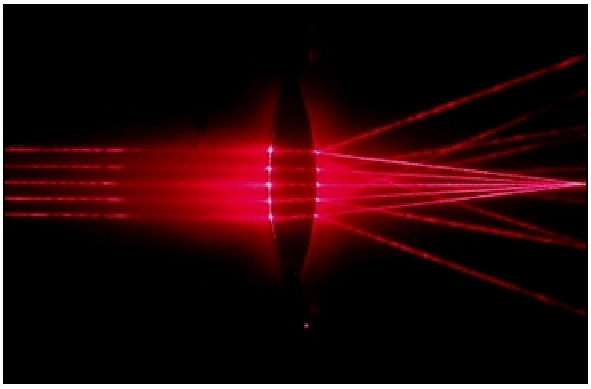

Figure 10.193: **Second focal point (target) is here on the right of the thin lens**

Or for those who cannot see well the figure above, there is another more explicit illustration of what happen with the second focal point of a bi-convex lens:

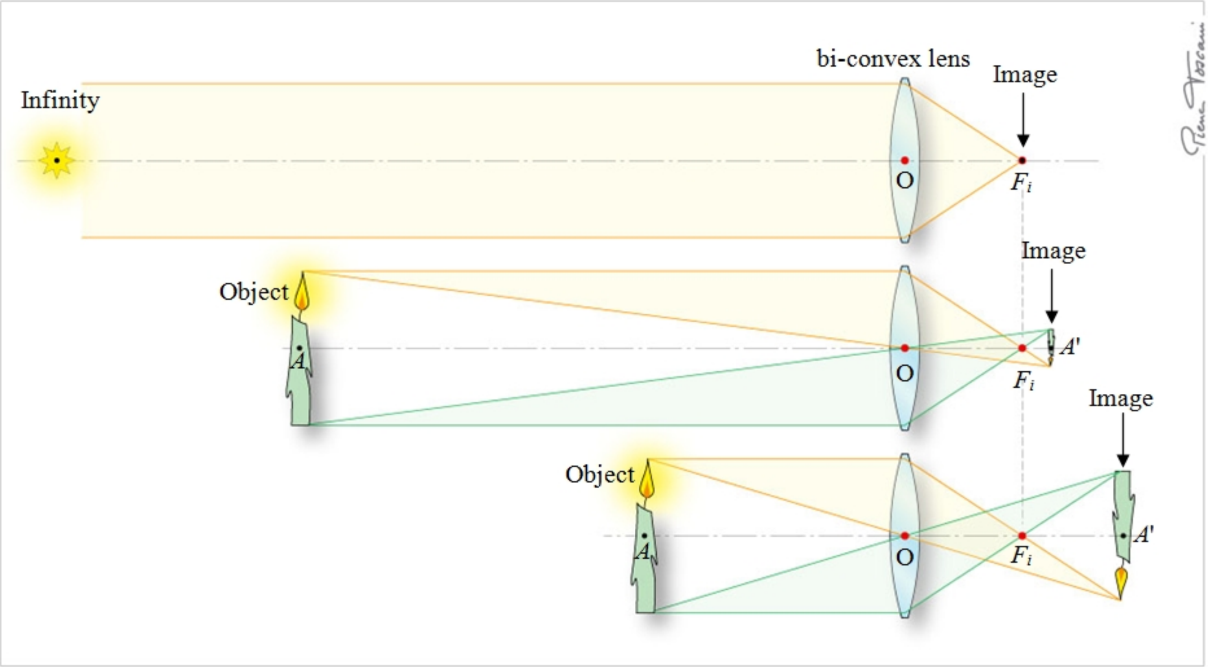

Figure 10.194: **Second focal point with bi-convex lens behaviour (source: `http://www.pierretoscani.com`, author: Pierre Toscani)**

The distance from the lens to the image focus is then named the "focal image distance" and we denote it in practice with the same letter f as by symmetry of the thin lens, by putting $q=f$ and $p=+\infty$ we have:

$$\frac{1}{f}=(n-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right) \tag{10.5.224}$$

Therefore, in a thin lens the two foci are located symmetrically on each side of the vertical axes of symmetry of the lens.

So as in both the inverse of the focal length is equal to the refractive power nothing prevents us to write the equation of thin lenses as we often found in textbooks:

$$\boxed{\frac{1}{p}+\frac{1}{q}=\frac{1}{f}=(n-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right)=\mathcal{D}} \tag{10.5.225}$$

In this form it is then named the "equation of Opticians" or "eyewear equation" or "Lens maker equation"... In the following simple form that does not make appear the physical properties of the lens (which is often the relation shown in high-school classes and could be the reason why it seems that it has a different name):

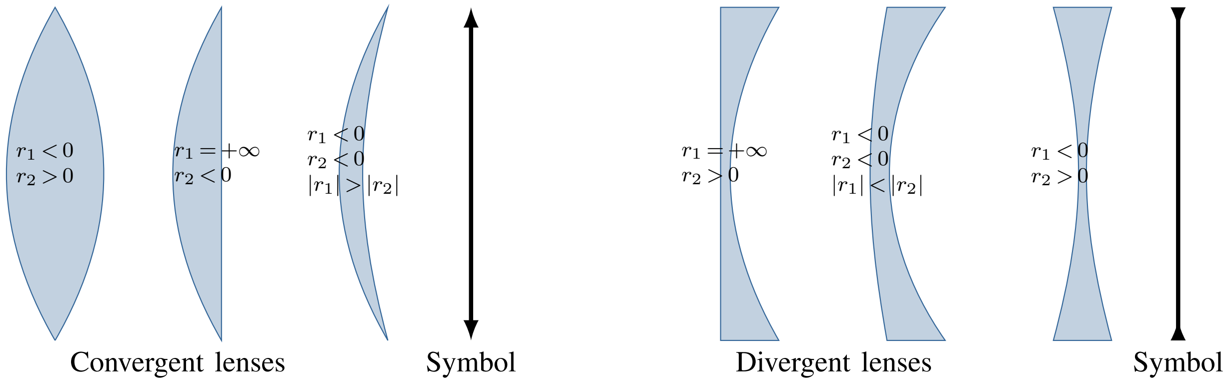
$$\frac{1}{p}+\frac{1}{q}=\frac{1}{f} \tag{10.5.226}$$

or more explicitly:

$$\frac{1}{\text{object distance}}+\frac{1}{\text{image distance}}=\frac{1}{\text{focal length}} \tag{10.5.227}$$

we name it "conjugation equation" or "second Descartes formula for thin lenses" or "spherical mirror equation".

Furthermore, if the focal distance is positive, and thus respectively the dioptric power as well, then the lens is say to be (obviously) a "convergent lens" and if the focal length is negative, and thus the refractive power respectively also, the lens is say to be a "diverging lens" (notice also the traditional symbolic representations of lenses for example in the E-draw software):



$r_1 < 0$
$r_2 > 0$
$r_1 = +\infty$
$r_2 < 0$
$r_1 < 0$
$r_2 < 0$
$|r_1| > |r_2|$
$r_1 = +\infty$
$r_2 > 0$
$r_1 < 0$
$r_2 < 0$
$|r_1| < |r_2|$
$r_1 < 0$
$r_2 > 0$

Figure 10.196: Convergent and divergent lens concepts (author: Jimmy Roussel)

✍**Example:**

We want to find the radius of a biconcave lens symmetrically ground from a glass with index of refractive 1.55 so that its focal length in air is 20 [cm] (for a biconcave lens, both surfaces have the same radius of curvature). To found the answer we use the thin-lens form of the lens maker's equation:

$$\frac{1}{f} = (n-1)\left(\frac{1}{r_1} - \frac{1}{r_2}\right) = \left(\frac{n_2}{n_1} - 1\right)\left(\frac{1}{r_1} - \frac{1}{r_2}\right) \tag{10.5.228}$$

where $r_1 < 0$ and $r_2 > 0$. Since we are making a symmetric biconcave lens, we have

$|r_1| = |r_2| = r$. Therefore:

$$\frac{1}{f} = \left(\frac{n_2}{n_1} - 1\right)\left(-\frac{2}{R}\right) \tag{10.5.229}$$

Solving for R and inserting $f = -20$ [cm], $n_2 = 1.55$, and $n_1 = 1.00$ gives:

$$R = -2f\left(\frac{n_2}{n_1} - 1\right) = -2(-20)\left(\frac{1.55}{1.00}\right) = 22\,[\text{cm}] \tag{10.5.230}$$

10.5.5.2.1 Optical Magnification (zoom)

Magnification is the process of enlarging something only in appearance, not in physical size. This enlargement is quantified by a calculated number also named "magnification". When this number is less than one, it refers to a reduction in size, sometimes named "minification" or "de-magnification".

Typically, magnification is related to scaling up visuals or images to be able to see more detail, increasing resolution, using microscope, printing techniques, or digital processing. In all cases, the magnification of the image does not change the perspective of the image.

Figure 10.197: **The stamp appears larger with the use of a magnifying glass (source: Wikipedia)**

Before studying the magnification of spherical convex lenses, let us focus on the general definition of a magnification. For this purpose, consider the following figure:

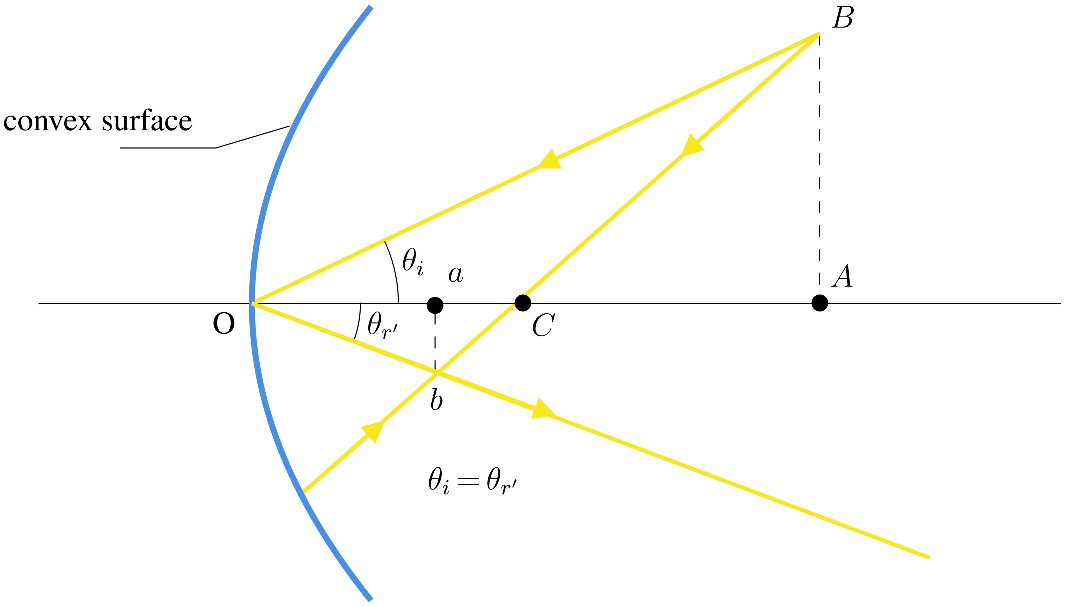

Figure 10.198: **Magnification basic principle**

where for recall the center of curvature C (see section Differential Geometry page 2866) is the center of curvature of the spherical surface of the figure above and the top O is the pole of the spherical cap.

Thus, the "magnification M" of any optical system is defined as the ratio of the size of the image $\overline{ab}$ to that of the real object $\overline{AB}$, that is to say:

$$\boxed{M = \frac{\overline{ab}}{\overline{AB}}} \qquad (10.5.231)$$

We see from the figure above that:

$$\begin{aligned} \tan(\theta_i) &= \frac{\overline{AB}}{\overline{\mathrm{O}A}} = \frac{\overline{AB}}{p} \\ \tan(\theta'_r) &= \frac{\overline{ab}}{\overline{\mathrm{O}a}} = \frac{\overline{ab}}{q} \end{aligned} \qquad (10.5.232)$$

We therefore get, taking into account that $\theta_i = \theta'_r$:

$$\frac{\tan(\theta'_r)}{\tan(\theta_i)} = 1 = \frac{\overline{ab}}{q}\frac{p}{\overline{AB}} \qquad (10.5.233)$$

Hence the "magnification equation":

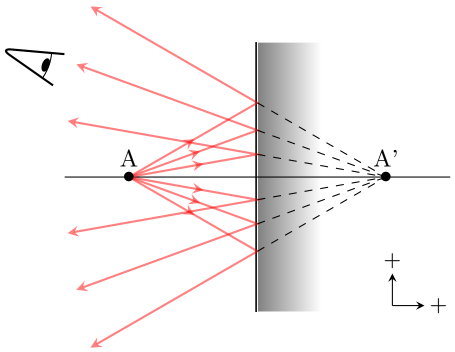
$$\boxed{M = \frac{\overline{ab}}{\overline{AB}} = \frac{q}{p}} \qquad (10.5.234)$$

So in the case of a thin symmetrical spherical lens whose rays pass through the optical center we obtain rays which are describe similar triangles on each side of the axis of symmetry of the spherical thin lens then applying Thales' theorem we also get:

$$M = \frac{\overline{ab}}{\overline{AB}} = \frac{q}{p} \qquad (10.5.235)$$

That's the same result as that obtained already above.

Notice that for a flat mirror we have $\overline{ab}=\overline{AB}$, hence for $p\neq 0$, we always have $M=1$. So whatever the distance $d\neq 0$ from a flat mirror, an object looks like always the same size!!! The reason why many people think that the reflection gets smaller is that most often they see mirrors sitting above the bathroom sink; when they back away the see more of themselves (but the know the mirror is of the same size!), so they think the reflection has shrunk. It's hard to remember that half the mirror start out full of the reflected image of the sink...



Example:

Two sides of a convex lens have a radius of 3 [cm]. The index of the lens material is 1.52. An object of 1.80 [m] height is set to 14 [m] distance of the lens (no matter that it is left or right of the lens because it is assumed as biconvex and therefore symmetrical). Then the dioptric power of the lens is first:

$$\mathcal{D}=(n-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right)=\frac{1}{f}=(1.52-1)\frac{2}{r}=0.52\frac{2}{0.3}\cong 3.47\,[\text{m}^{-1}] \tag{10.5.236}$$

Which is indeed a positive value and thus gives a focal length (image or object focal regardless because of symmetry of the spherical thin lens!) of $f\cong 28.84\,[\text{cm}]$ so it is better to have a camera with a telephoto lens in the present case... We notice by the value of the focal length, that the subject is obviously beyond the focus. The position of the image is given by:

$$\frac{1}{p}+\frac{1}{q}=\frac{1}{14}+\frac{1}{q}\cong 3.47 \tag{10.5.237}$$

Therefore:

$$q\cong 0.2942\,[\text{m}] \tag{10.5.238}$$

So the picture is about 29.42 centimetres beyond the focus and will by definition be named the "real (reversed) image". The magnification value is then:

$$M=\frac{q}{p}=\frac{0.2942}{14}\cong 0.021 \tag{10.5.239}$$

The size of the inverted real image will be in q:

$$h\cong 0.021\cdot 1.8=0.0378=3.78\,[\text{cm}] \tag{10.5.240}$$

Therefore we have:

$$\boxed{M=\frac{q}{p}=\frac{\left(\mathcal{D}-\dfrac{1}{p}\right)^{-1}}{p}=\frac{\left(\dfrac{1}{f}-\dfrac{1}{p}\right)^{-1}}{p}=\frac{\left(\dfrac{2}{r}-\dfrac{1}{p}\right)^{-1}}{p}} \tag{10.5.241}$$

If we want a magnification (zoom), we must have:

$$M=\frac{1}{p\left(\dfrac{2}{r}-\dfrac{1}{p}\right)}=\frac{1}{\dfrac{2p}{r}-1}\geq 1 \tag{10.5.242}$$

Therefore:

$$\frac{2p}{r}-1\leq 1 \tag{10.5.243}$$

Is trivially:

$$\frac{2p}{r}\leq 2 \tag{10.5.244}$$

Finally:

$$p\leq r \tag{10.5.245}$$

So to do that there is magnification (zoom) it is necessary that the real object is between the center of curvature and the vertical axis of symmetry of the lens.

Remark

The study of this model will allow us to understand partially how the prism works and also of goniometer in astronomy for spectrum analysis as well as X-ray diffraction by a network of atoms (the importance of the latter being quite significant!).

We must be careful with how the human brain process the world! Many configurations of objects are misleading for the way our internal machine process images. For example in the image below both Moons have the same size but our internal processing machine (brain) has the tendency to interpret the above Moon as being bigger than the lower Moon... :

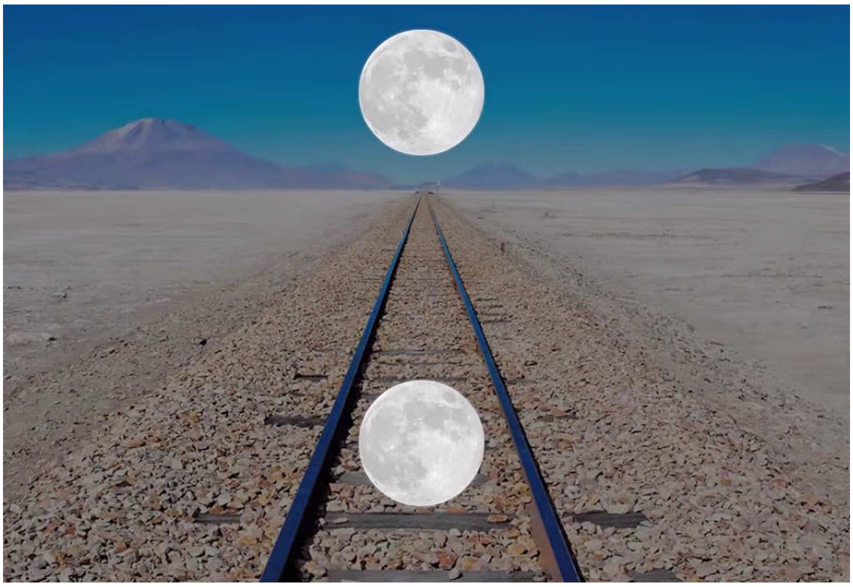


Figure 10.199: **Magnification optical illusion (source: NASA)**

We haven't so far studied all possibles configuration of biconvex lenses (mainly because I'm not a fan of the subject...) but here is very good summary founded on Instagram of all main configurations:

Object distance (u)	**Ray diagram**	**Type of image**	**Image distance** (v)	**Uses**
$u = +\infty$	parallel rays from a distant object 	- inverted - real - diminished	$v = F$ - oposite side of the lens	- object lens of a telescope
$u > 2F$	 object $2F$ F O F $2F$ image u v	- inverted - real - diminished	$F < v < 2F$ - oposite side of the lens	- camera - eye
$u = 2F$	 object $2F$ F O F $2F$ image u v	- inverted - real - same size	$v = 2F$ - oposite side of the lens	- photocopier making same-sized copy
$F < u < 2F$	 object $2F$ F O F $2F$ image u v	- inverted - real - magnified	$v > 2F$ - oposite side of the lens	- projector - photograph enlarger
$u = F$	image at infinity  object F O F u parallel rays	- upright - virtual - magnified	- image at infinity - same side of the lens	- to produce a parallel beam of light, e.g. a spotlight
$u < F$	 image object F O F u v	- upright - virtual - magnified	- image is behind the object - same side of the lens	- magnifying glass

Figure 10.200: **Biconvex lenses typical configurations and applications**

The concave mirror bends light inwards, towards ourselves. If we imagine the mirror as a part of a larger sphere, then if we view the mirror from a point closer than the center of this sphere, we see an enlarged (magnified) upright image. If look further away fro the center we will see reversed image as illustrated by the photo below:

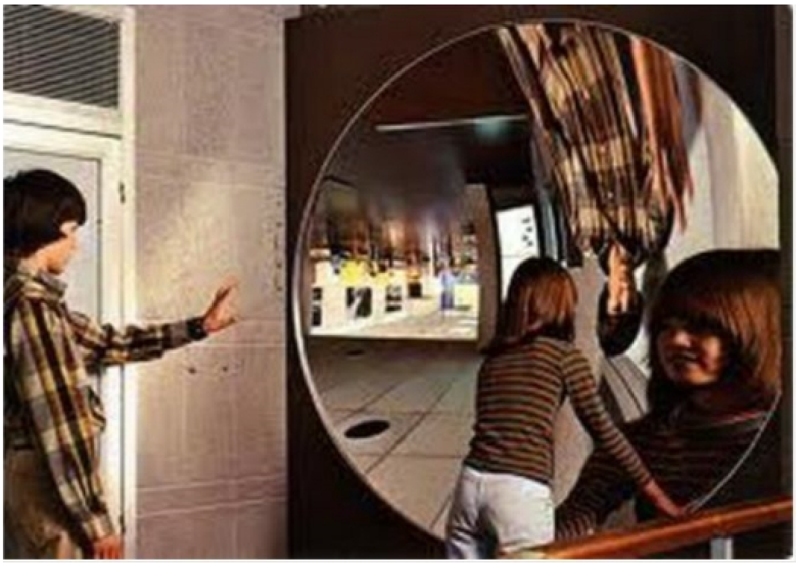

Figure 10.201: **Concave mirror (source: ?)**

Notice above now the image of the girl with the striped shirt is right side up and magnified. She is inside the focal point. The person in the plaid shirt is outside the focal point, so it is upside down and about the same size. But the image from the back of the room is both upside down and smaller than normal, because it is much further away from the focal point!

The same rules applies with a famous case know by all young children:

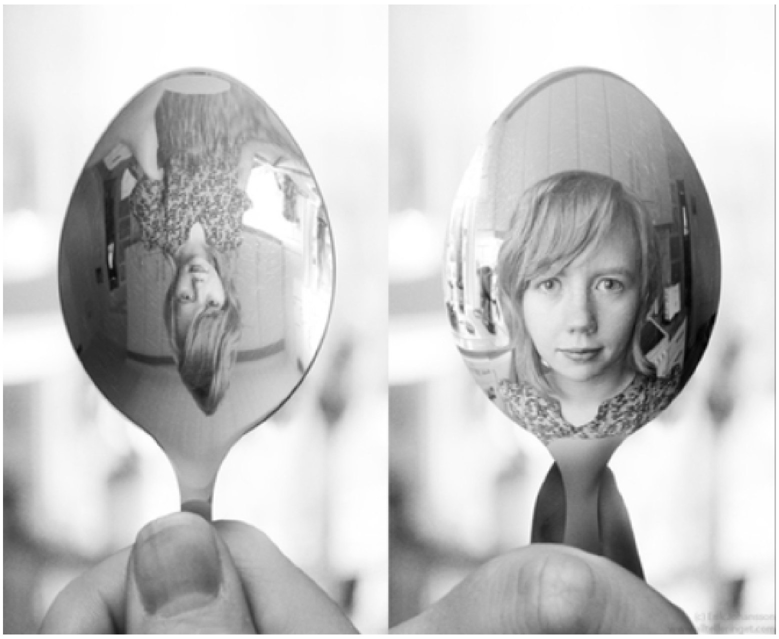

Figure 10.202: **Left concave spoon-mirror, Right convex spoon-mirror (source: ?)**

Remark

Depending on the manufacturer a makeup mirror is concave or convex as they have the same structure as a spoon but at the difference that they have a very polish surface. But most of time the visible part is a concave mirror build in such a way that a person at 25 [cm] away from the surface see its image doubled.

For practical purposes, let us indicate the following figure (left global view, right zoom on the curve part):

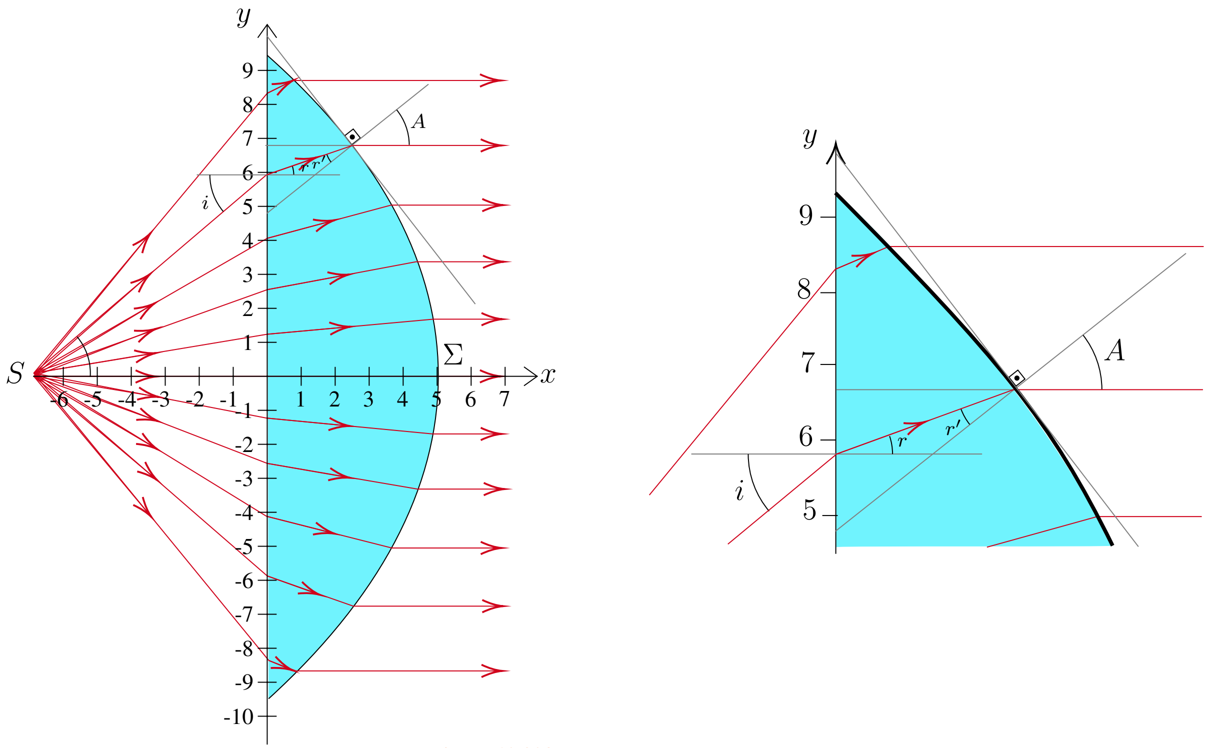

Figure 10.203: **Full plane-curved lens**

and therefore a full plane-curved lens, as a parabolic mirror, has the property of making parallel the rays having for source its focal. It produced by refraction the effect that the parabolic mirror produced by reflection...!

Fresnel invented a quite clever lens that is seen in many lighthouses and that achieves the same result with less material and therefore with less intensity loss:

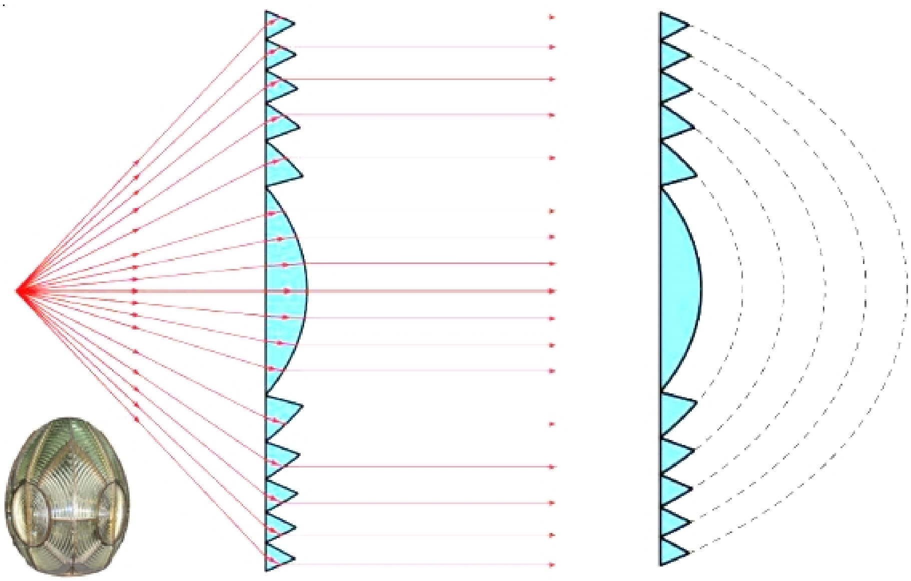

Figure 10.204: Fresnel lens with lighthouse example in the left bottom corner (source: ?)

So far it could be important to make a summary of the sign convention for the equation of opticians (or "mirror equation") and the magnification equation:

$$\begin{gathered}\frac{1}{p}+\frac{1}{q}=\frac{1}{f}\cong\frac{2}{r}\\ M=\frac{q}{p}\end{gathered} \tag{10.5.246}$$

therefore:

- Focal length f:
  - Positive for concave mirrors or concave lenses
  - Negative for convex mirrors or convex lenses
- Magnification M:
  - Positive for upright images
  - Negative for inverted images
  - Enlarged when $|M|>1$
  - Reduced when $|M|<1$
- Image distance q:
  - Positive for real images
  - Negative for virtual images

Remark

Fun fact! A mirror doubles the perceived distance of any object! If you are at 50 [cm] away from the mirror, your reflection will appear to be at 100 [cm] away (since you reflection appears to be 50 [cm] behind the mirror). At 20 [cm] you will appear 40 [cm] away. At 10 [cm] you will appear 20 [cm] away. At 0.5 [cm] you will appear 1 [cm] away. At 0 [cm] you will appear to be 0 [cm] away. The relation is according to the mirror equation $r=2d$, where r is an object's reflection perceived distance and d is the object's actual distance from the mirror.

✍**Example:**

Consider that the Sun (actually a G2V-type star, aka yellow dwarf) is the object, so the object distance is essentially infinity: $q=+\infty$. The desired image distance is $q=40.0$ [cm]. We use the mirror equation to find the focal length of the mirror:

$$f=\left(\frac{1}{p}+\frac{1}{q}\right)^{-1}=\left(\frac{1}{+\infty}+\frac{1}{0.4}\right)^{-1}=0.4\,[\text{m}] \tag{10.5.247}$$

But we have proved earlier that in the approximation of small angles:

$$\frac{1}{p}+\frac{1}{q}\cong\frac{2}{r} \tag{10.5.248}$$

Thus, the radius of the mirror if considered as spheric, will be equal to:

$$r\cong 2f=0.8\,[\text{m}] \tag{10.5.249}$$

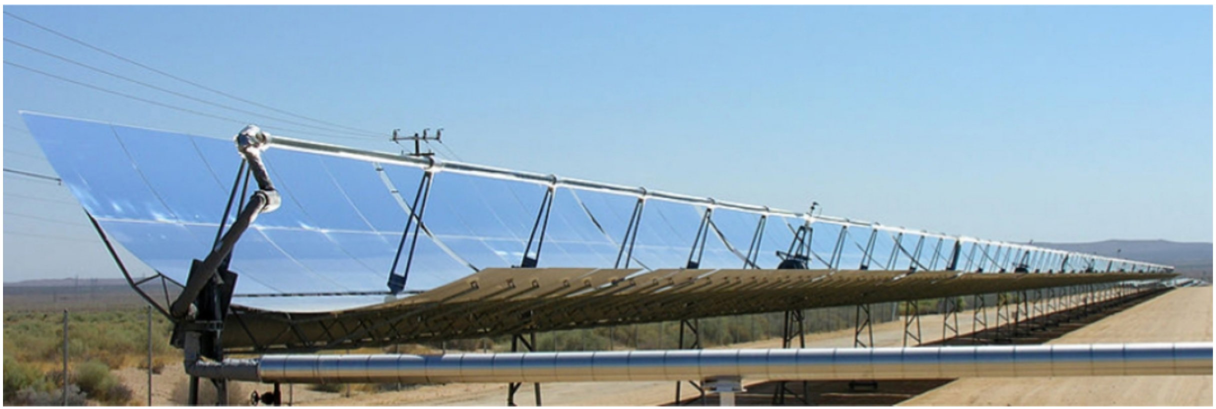

Figure 10.205: Parabolic trough collectors are used to generate electricity in southern California (source: Wikipedia)

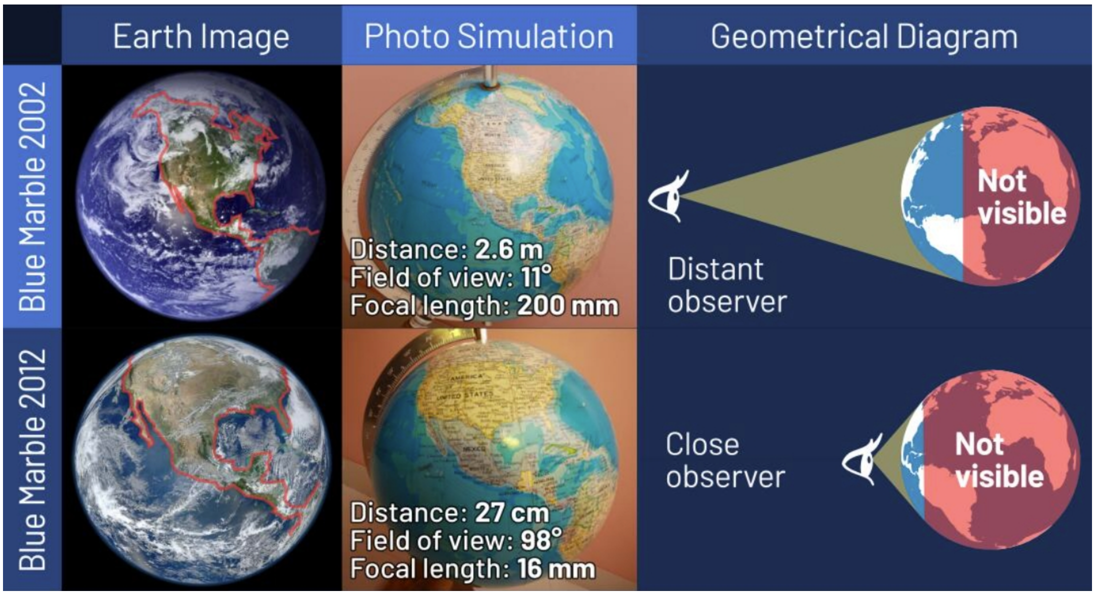
10.5.5.2.2 Angle of View

In photography, the "angle of view" (AOV) describes the angular extent of a given scene that is imaged by a camera. It is used interchangeably with the more general term "field of view" (FOV).

What we will see further below should help the reader to understand what happens in both following figures made of real photos:



Earth Image
Photo Simulation
Geometrical Diagram
Blue Marble 2002
Distance: 2.6 m
Field of view: 11°
Focal length: 200 mm
Not visible
Distant observer
Blue Marble 2012
Distance: 27 cm
Field of view: 98°
Focal length: 16 mm
Close observer
Not visible

Figure 10.206: Field of view real case with Earth's photo (source: FleatEarth.ws)

The narrower the field of view, the larger they appear in a photo.

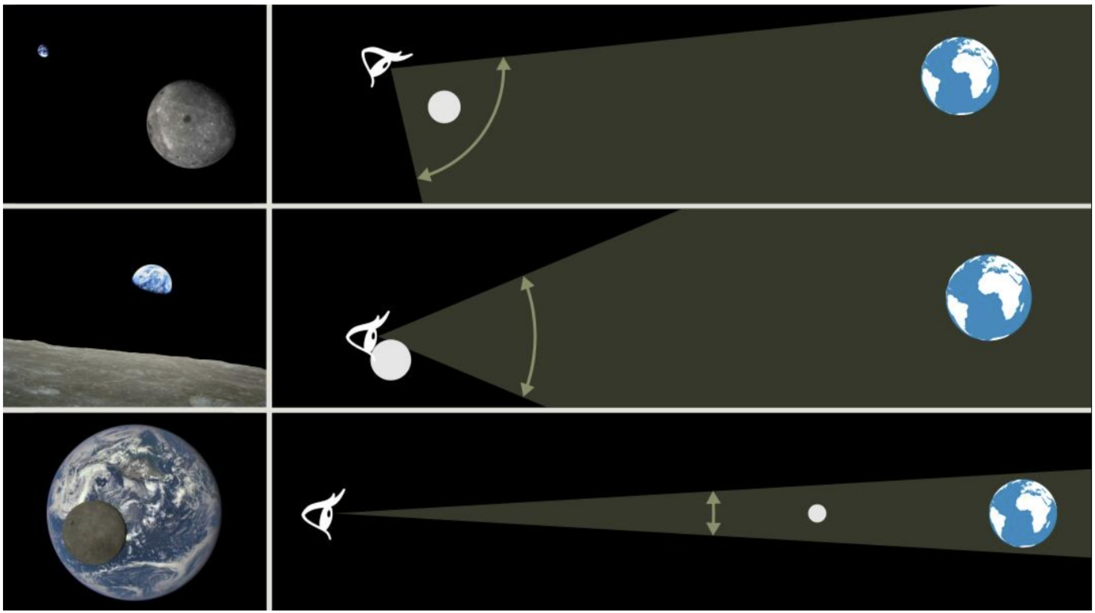


Figure 10.207: Field of view real case Earth and Moon (source: FleatEarth.ws)

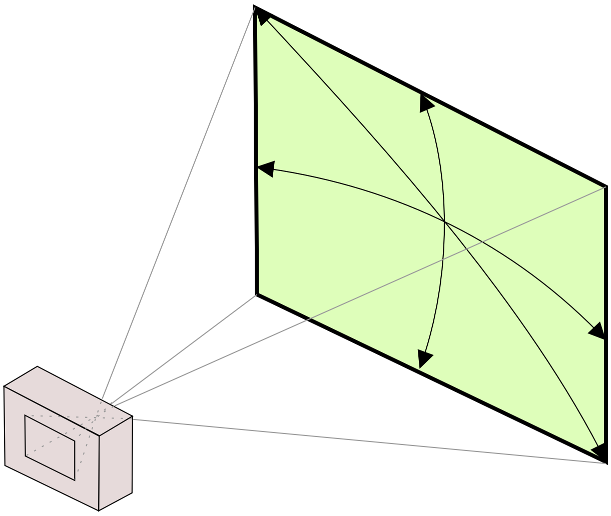
A camera's angle of view can be measured horizontally, vertically, or diagonally:



As mentioned above, a camera's angle of view depends not only on the lens, but also on the image sensor or film. Digital sensors are usually smaller than 35 [mm] film, and this causes the lens to have a narrower angle of view than with 35 [mm] film, by a constant factor for each sensor (named the "crop factor"). In everyday digital cameras, the crop factor can range from around 1, called full frame (professional digital SLRs where the sensor size is similar to the 35 [mm] film), to 1.6 (consumer SLR), to 2 (Micro Four Thirds ILC), and to 6 (most compact cameras).

For lenses projecting rectilinear (non-spatially distorted) images of distant objects, the effective focal length and the image format dimensions completely define the angle of view.

For a lens projecting a rectilinear image (focused at infinity, see proof below), the angle of view (α) can be calculated from the chosen dimension (d), and effective focal length (f) (f will be defined here as the distance of the lens with respect to the image plane. For a thick lens, it is the distance of the rear principal plane of the lens with respect to the image plane) as follows:

$$\alpha = 2\arctan\left(\frac{d}{2f}\right) \tag{10.5.250}$$

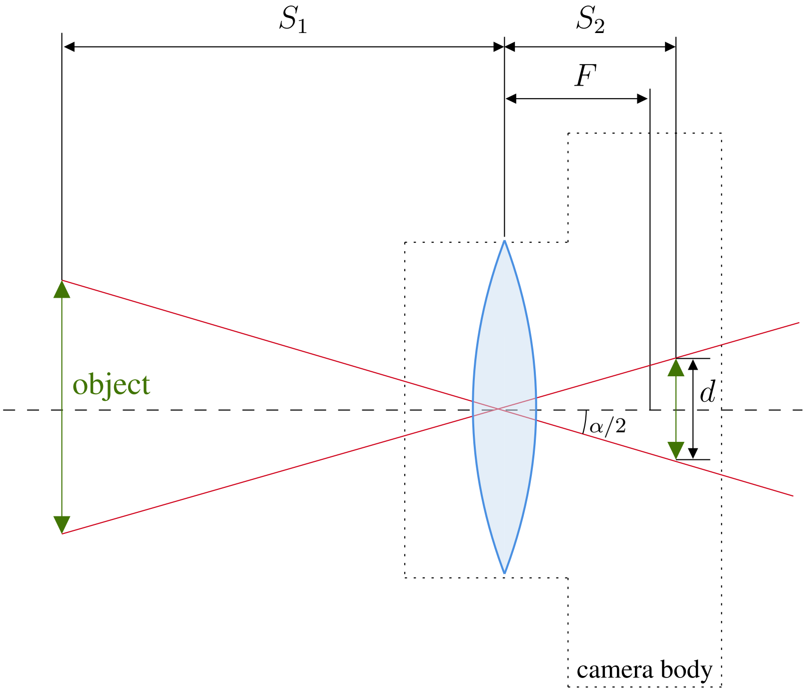
d represents the size of the film (or sensor) in the direction measured. For example, for 35 [mm] film which is 36 [mm] wide and 24 [mm] high, $d = 36$ [mm] would be used to obtain the horizontal angle of view and $d = 24$ [mm] for the vertical angle.

Because this is a trigonometric function, the angle of view does not vary quite linearly with the reciprocal of the focal length. However, except for wide-angle lenses, it is reasonable to approximate:

$$\alpha \cong \frac{d}{f} \tag{10.5.251}$$

or $180d/(\pi F)$ degrees.

Proof 10.2.5. Consider a rectilinear lens in a camera used to photograph an object at a distance S_1, and forming an image that just barely fits in the dimension, d, of the frame (the film or image sensor). Treat the lens as if it were a pinhole at distance S_2 from the image plane (technically, the center of perspective of a rectilinear lens is at the center of its entrance pupil where chief rays meet):



Now $\alpha/2$ is the angle between the optical axis of the lens and the ray joining its optical center to the edge of the film. Here α is defined to be the angle-of-view, since it is the angle enclosing the largest object whose image can fit on the film. We want to find the relationship between:

- the angle α
- the "opposite" side of the right triangle, $d/2$ (half the film-format dimension)
- the "adjacent" side, S_2 (distance from the lens to the image plane)

Using basic trigonometry, we find:

$$\tan(\alpha/2)=\frac{d/2}{S_2} \tag{10.5.252}$$

which we can solve for α, giving:

$$\alpha=2\arctan\left(\frac{d}{2S_2}\right) \tag{10.5.253}$$

To project a sharp image of distant objects, S_2 needs to be equal to the focal length, that we will denote here F, which is attained by setting the lens for infinity focus. Then the angle of view is given by:

$$\boxed{\text{FOV}=\alpha=2\arctan\left(\frac{d}{2F}\right)} \tag{10.5.254}$$

■ Q.E.D.

For macro photography, we cannot neglect the difference between S_2 and F. From the conjugation equation (see page 4440):

$$\frac{1}{F}=\frac{1}{S_1}+\frac{1}{S_2} \tag{10.5.255}$$

The absolute transverse magnification (the absolute ratio of the image height to the object height) can be expressed as we have seen earlier above by the magnification equation (see 4442):

$$M=\frac{S_2}{S_1} \tag{10.5.256}$$

we can substitute S_1 and with some algebra find:

$$S_2=F\cdot(1+M) \tag{10.5.257}$$

Therefore:

$$\alpha=2\arctan\left(\frac{d}{2S_2}\right) \tag{10.5.258}$$

can be rewritten:

$$\boxed{\text{FOV}_{\text{macro}}=\alpha=2\arctan\left(\frac{d}{2F\cdot(1+M)}\right)} \tag{10.5.259}$$

✍**Example:**

Consider a 35 [mm] camera with a lens having a focal length of $F=50$ [mm]. The dimensions of the 35 [mm] image format are 24 [mm] (vertically) $\times 36$ [mm] (horizontal), giving a diagonal of about 43.3 [mm].

At infinity focus, $f=F$, the angles of view are:

- Horizontally:

$$\alpha_h=2\arctan\left(\frac{h}{2f}\right)=2\arctan\left(\frac{36}{2\cdot 50}\right)\cong 39.6^\circ \tag{10.5.260}$$

- Vertically:

$$\alpha_v=2\arctan\left(\frac{v}{2f}\right)=2\arctan\left(\frac{24}{2\cdot 50}\right)\cong 27.0^\circ \tag{10.5.261}$$

- Diagonally:

$$\alpha_d=2\arctan\left(\frac{d}{2f}\right)=2\arctan\left(\frac{43.3}{2\cdot 50}\right)\cong 46.8^\circ \tag{10.5.262}$$

In the mosaic below the angle of view and distance of the camera while keeping the object in frame results in vastly differing images. At distances approaching infinity, the light rays are nearly parallel to each other, resulting in a "flattened" image. At low distances and high angles of view objects appear "foreshortened"

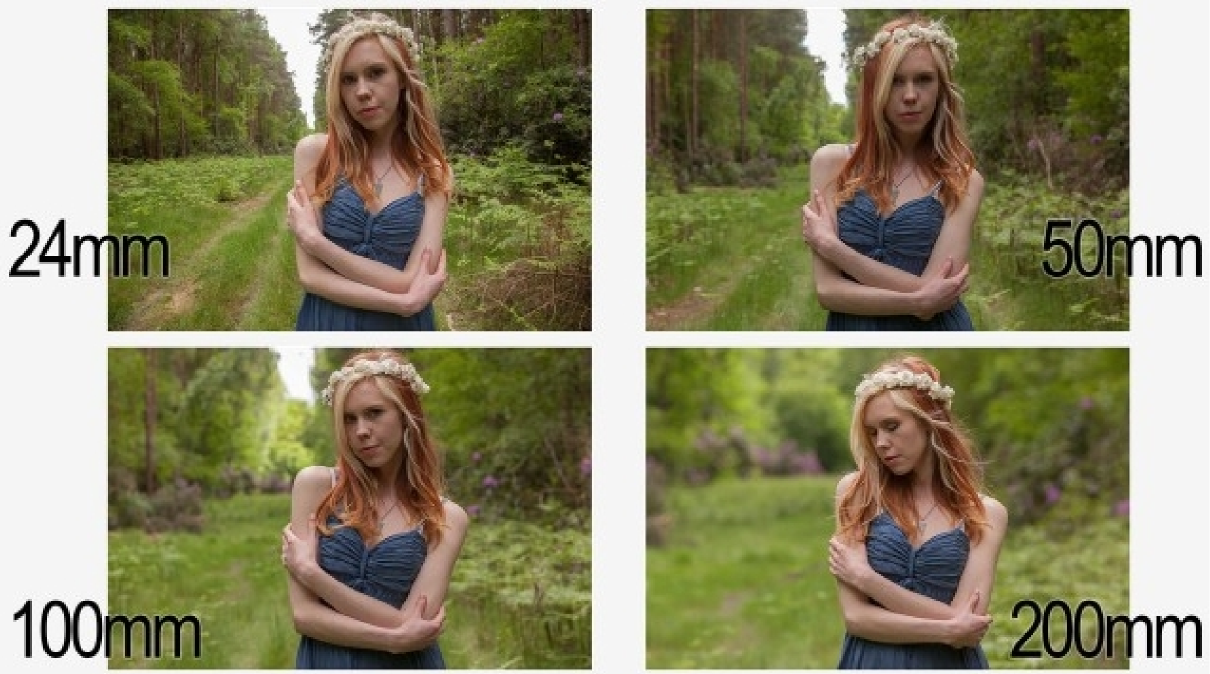
This explains the famous effect of "background compression" also well represented below by Gavin Hoey (the model is Fern Meave for information...):



24mm
50mm
100mm
200mm

Figure 10.209: **Illustration of background compression at difference focal lengths for different distance by keeping the model size on the screen (author: Gavin Hoey, source:** `https://www.gavtrain.com/`**)**

The reader must really keep in mind that in order to keep the model the same size, the photogrpaher had to increase his shooting distance as then zoomed in and that increase in distance that causes the background to compress. Not the focal length change!

10.5.5.2.3 Human eyes

Let us do some human biology to close this topic about lenses...

The lens of the eye which can be deformed under the effect of certain muscles, constitutes a variable focus lens to accommodate variable distance vision of objects. The distance from the optical center to the retina r being fixed (see figure below), the only way to clearly see objects at different distances d is to change the focal length f. In its normal state, the lens has a relatively flat configuration, with a large radius of curvature.

Figure 10.210: Human eye optics (simplified, not to scale and in a special configuration case)

The human eye has the function of focusing light from an object at infinity on the retina. But all eyes are not doing this correctly and the far point (maximum distance of distinct vision without accommodation) or "punctum remotum" is sometimes at a finite distance, sometimes even less than 5 meters (probably causing eyestrain) as practitioners consider 6 meters already as infinity relatively to the retina modification over this distance being most of time not significant.

If the object approaches the eye, the muscles of the retina contract, the lens swells and its focal length decreases so that the image is always formed on the retina. The nearest point which can be seen clearly with maximum accommodation is named the "near point" or "punctum proximum". This distance is changing significantly with age: it is ten centimetres for a ten years old child, a hundred centimetres for a person of sixty years old (that is "presbyopia").

The reader must keep in mind that the image projected onto the back of our eyes is upside down. Our brain software decodes this image so that we perceive it the right way up (at least by the huge majority of people as a few case well known by the scientific community are born with a defective brain visual software). Those little ray diagrams as above for non-optical specialists are very misleading and deceptively simple. In a real system, even a simple lens, there a rays going everywhere. In most textbooks - as the present one - they sometimes only draw two. Feynman liked to say that these textbooks cheated you because they never really explained the ray diagrams or how they switched from one kind to another when they talked about different things.

Remark

Cones in the retina are sensitive to single photons. However, such tiny signals are filtered out during the image processing in the human optic nerve and brain. It takes 7 to 30 photons to "see" an event. In comparison the company Photon Force™ manufactures single-photon sensitive cameras! For standard mainstream cameras the sensitivity depends on many factors: aperture, focal, sensitivity of the sensor/tape, signal to noise ratio of the sensor/tape. So there is no general answer to the sensitiveness of a camera as the technologies are veeery diversified.

10.5.5.2.3.1 Eye magnification

When we want to examine the details of an object, we approach it to our eye. By doing so, we get a bigger picture on the retina. Indeed, the distance from the focal point O of the eye to the retina can be considered to be 15 [mm], $\overline{ab}$ image of $\overline{AB}$ is the intersection of the rays $\overline{AO}$ and $\overline{AB}$ with the retina (the rays being considered as a first approximation in a straight line):

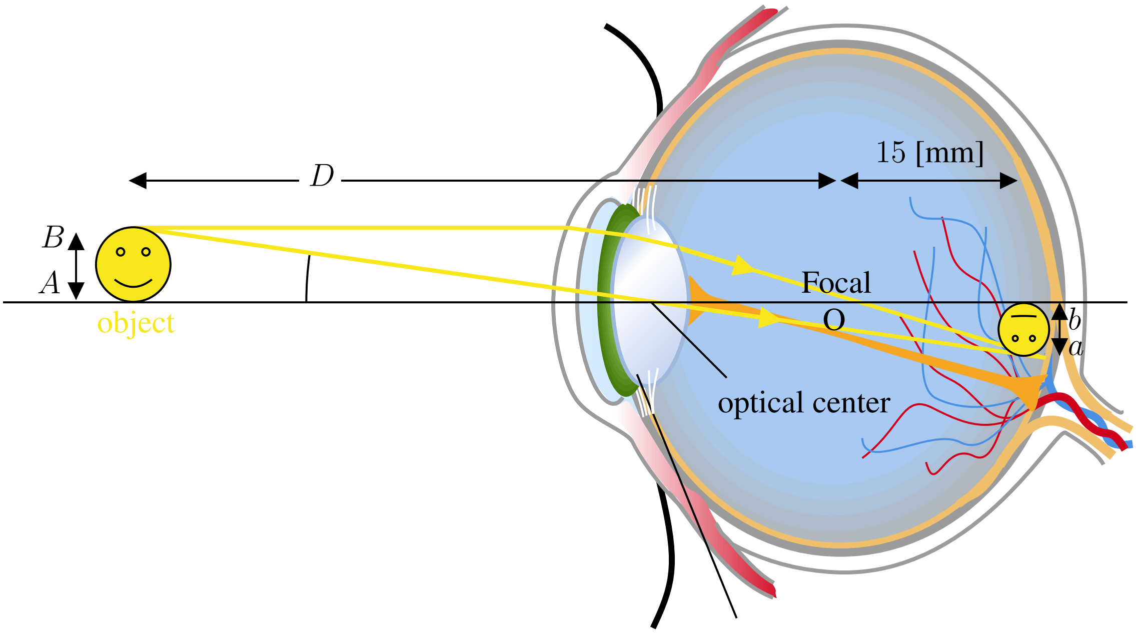

Figure 10.211: **Eye as magnifier tool**

We then use Thales theorem (i.e. intercept theorem) once again and assuming that everything is measured in millimetres (and not forgetting that we consider the rays as a first approximation in a straight line from the focus to the original object):

$$\frac{\overline{ab}}{\overline{AB}}\cong\frac{15}{D} \tag{10.5.263}$$

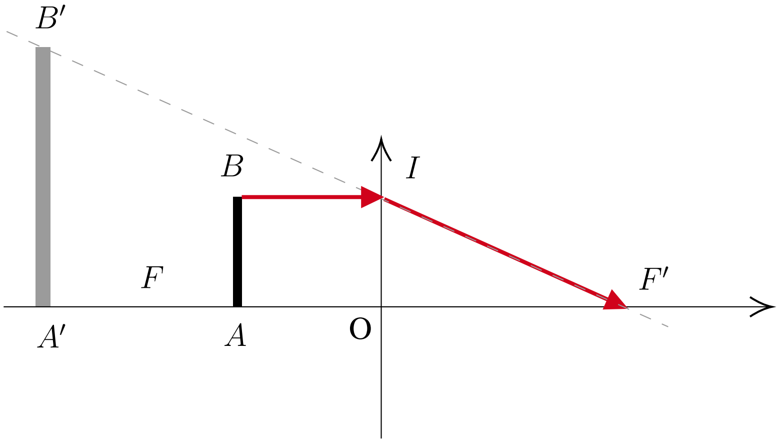
or:

$$\overline{ab}\cong 15\frac{\overline{AB}}{D} \tag{10.5.264}$$

However, the distance D cannot become smaller than that for which the accommodation is maximum. This minimum distinct vision distance can be considered to be 250 [mm]; it allows the fairly prolonged examination of objects without too much "exhaustion" of the eye.

We have shown that a converging lens gives an enlarged virtual image of a real object provided that the object is placed between the center of curvature and the vertical axis of symmetry of the converging lens. So let's look under what configuration this device is really advantageous for human vision (considering that I is a symbolic 1D representation of converging lens).

Let us place the eye at the focal point F'; instead of the object $\overline{AB}$, it sees the image $\overline{A'B'}$ which is at distance $\overline{A'F'}$:



The size of the corresponding retinal image is then according to the previous image:

$$\overline{a'b'}\cong 15\frac{\overline{A'B'}}{\overline{A'F'}} \tag{10.5.265}$$

Then from the similarity of the triangles, we can write (application of Thales theorem again):

$$\frac{\overline{A'B'}}{\overline{A'F'}}=\frac{\overline{\mathrm{O}I}}{\overline{\mathrm{O}F'}}=\frac{\overline{AB}}{f} \tag{10.5.266}$$

since the distance $\overline{\mathrm{O}F'}$ corresponds to the focal length f of the converging lens. We then have:

$$\overline{a'b'}\cong 15\frac{\overline{A'B'}}{\overline{A'F'}}=15\frac{\overline{AB}}{f} \tag{10.5.267}$$

However, as we mentioned, if the object were seen with the naked eye, the retinal image would have under the aforementioned hypotheses an optimum of:

$$\overline{ab} \cong 15\frac{\overline{AB}}{250} \tag{10.5.268}$$

So that we have an advantage to observe through a covering lens, which in this case we name a "magnifying glass", $\overline{a'b'}$ must be larger than $\overline{ab}$. Either mathematically:

$$\overline{a'b'} > \overline{ab} \Leftrightarrow 15\frac{\overline{AB}}{f} > 15\frac{\overline{AB}}{250} \tag{10.5.269}$$

which give the fundamental condition of the converging lens:

$$f < 250\,[\text{mm}] \tag{10.5.270}$$

Thus, a converging lens can only be used as a magnifying glass if its focal length is less than 250 [mm] under the aforementioned assumptions. By definition, we named "magnification" of the magnifying glass the ratio:

$$M = \frac{\overline{a'b'}}{\overline{ab}} = \frac{250}{f} \tag{10.5.271}$$

of the retinal images obtained through the magnifying glass and with the naked eye in the best conditions.

Remark

The horizontal field of view for a human is approximately 200 degrees, while the vertical field is about 135 degrees.

10.5.5.3 Triangular Prism

a prism is a transparent optical element with flat, polished surfaces that refract light. At least two of the flat surfaces must have an angle between them. The exact angles between the surfaces depend on the application. The traditional geometrical shape is that of a triangular prism with a triangular base and rectangular sides, and in colloquial use "prism" usually refers to this type. Some types of optical prism are not in fact in the shape of geometric prisms. Prisms can be made from any material that is transparent to the wavelengths for which they are designed. Typical materials include glass, plastic and fluorite.

A dispersive prism can be used to break light up into its constituent spectral colors (the colors of the rainbow). Furthermore, prisms can be used to reflect light, or to split light into components with different polarizations.

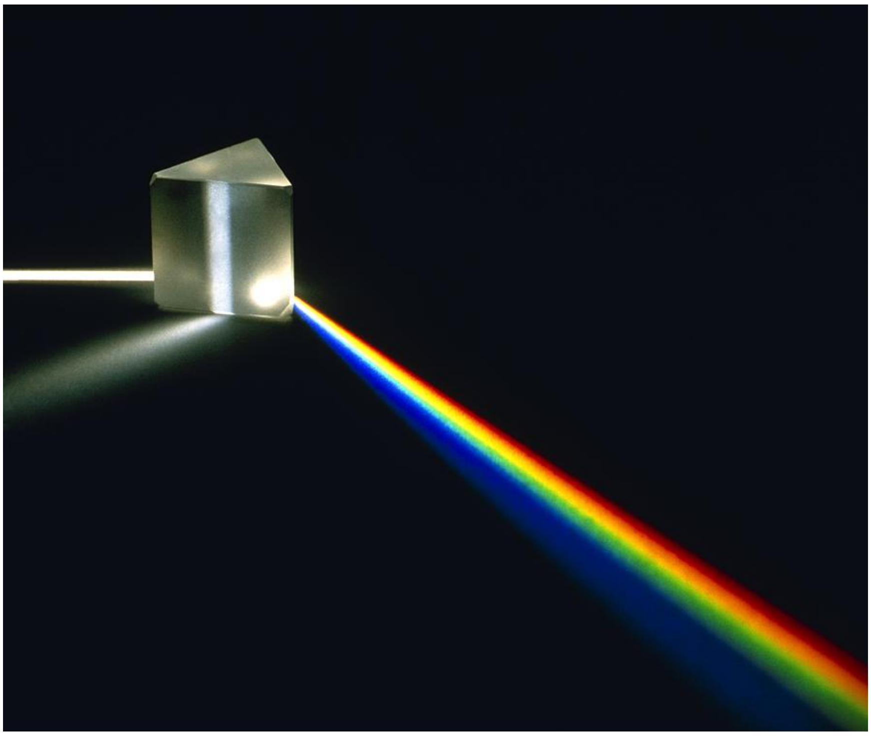


Figure 10.212: **Triangular prism dispersing white light ray (source: Wikipedia, David Parker)**

In optics, the triangular prism is one of the most important components of optics. It can be found in chemistry, condensed matter physics, astrophysics, optoelectronics and still many other popular devices of everyday life (such as lentils). This is probably the first tool shaped by human to make "spectroscopy" (spectrum analysis) after the rainbow sky obviously... which is a natural phenomenon spectroscopy.

We will in the following paragraphs identify the most important relations in relation to know about triangular prisms and useful to the engineer and physicist.

We will focus on light rays entering through one side and exiting by another having undergone two refractions (we do not study the internal reflections).

Here is the typical schematic representation of a triangular prism in optical geometry with the incident light ray S and outgoing one S' and the two normals N, N', to the edges of the top of opening angle α. More the different angles of incidence and refraction:

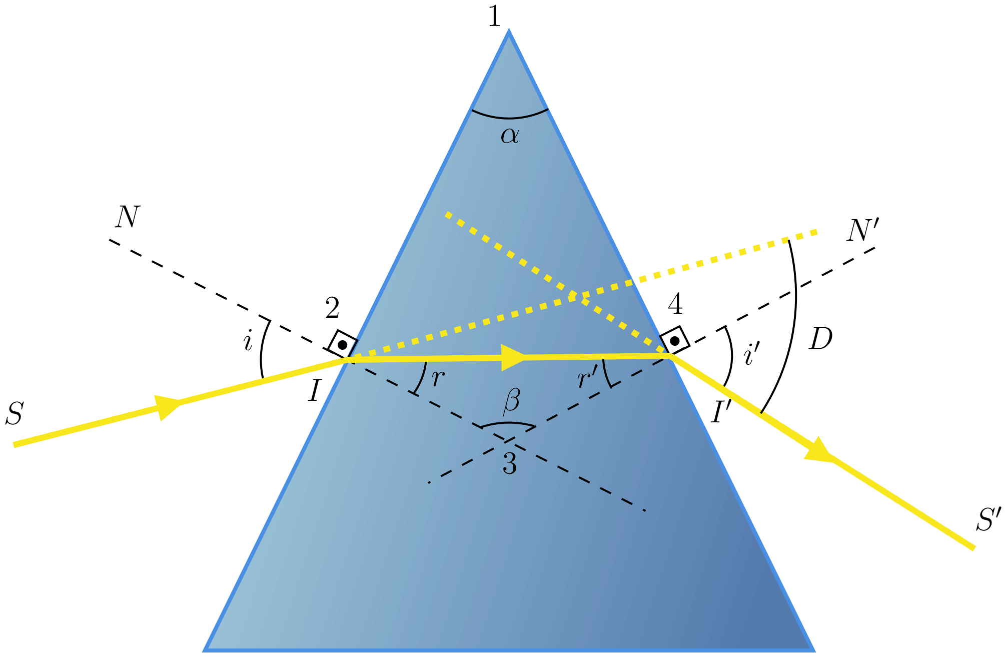

Figure 10.213: **Schematic triangular prism**

We know that the sum of the angles of a quadrilateral (always decomposable into two triangles whose the sum of the angles is π) is equals 2π (see section Geometric Shapes page 2593). So in the quadrilateral defined by the nodes 1234. We have the sum of:

$$\alpha+2\frac{\pi}{2}+\beta=2\pi \Rightarrow \beta=\pi-\alpha \quad (10.5.272)$$

Now that the situation has know let us focus on the optical part ...

We have 4 fundamental relations to prove for to the triangular prism.

First, we have at the point of incidence I and I' the Descartes' law that allows us to write:

$$\sin(i)=\frac{m}{n}\sin(r)=n_{21}\sin(r) \quad (10.5.273)$$

As the absolute refractive index of air is 1 we simply have in I:

$$\sin(i)=m\sin(r) \quad (10.5.274)$$

In the same idea in I' we have:

$$\sin(r')=\frac{n}{m}\sin(i')=\frac{1}{m}\sin(i') \quad (10.5.275)$$

and therefore:

$$\sin(i')=m\sin(r') \quad (10.5.276)$$

We also have the relation:

$$\pi=r+r'+\beta=r+r'+\pi-\alpha \quad (10.5.277)$$

Therefore:

$$\alpha = r + r' \tag{10.5.278}$$

The deflection angle D is easy to determine. We just have to take the central quadrilateral:

$$2\pi = i + i' + \beta + (\pi - D) \Rightarrow D = -\pi + i + i' + \beta = -\pi + i + i' + (\pi - \alpha) \tag{10.5.279}$$

Therefore:

$$D = i + i' - \alpha \tag{10.5.280}$$

So we have the 4 fundamental relations of the triangular prism:

$$\boxed{\begin{aligned} &\sin(i) = m\sin(r) \\ &\sin(i') = m\sin(r') \\ &\alpha = r + r' \\ &D = i + i' - \alpha \end{aligned}} \tag{10.5.281}$$

Knowing i and i' and the relative refractive index m then we can determine all parameters.

The ideal would still be able to get rid of the experimental knowledge of i'.

So we have:

$$i' = \arcsin(m\sin(r')) \tag{10.5.282}$$

But as:

$$r' = \pi - \beta - r = \pi - (\pi - \alpha) - r = \alpha - r = \alpha - \arcsin\left(\frac{\sin(i)}{m}\right) \tag{10.5.283}$$

Therefore it comes:

$$i' = \arcsin(m\sin(r')) = \arcsin\left\{m\sin\left[\alpha - \arcsin\left(\frac{\sin(i)}{m}\right)\right]\right\} \tag{10.5.284}$$

Therefore:

$$\boxed{D = i + \arcsin\left\{m\sin\left[\alpha - \arcsin\left(\frac{\sin(i)}{m}\right)\right]\right\}} \tag{10.5.285}$$

Since it is obvious that the index n of a material varies with the wavelength according to Cauchy law introduce at the beginning of this section, it is easy to understand that the triangular prism is capable of dispersing white light.

Finally if i is small:

$$D \cong \arcsin\left\{m\sin\left[\alpha - \arcsin\left(\frac{\sin(i)}{m}\right)\right]\right\} - \alpha \tag{10.5.286}$$

and if i and α are small, we have to first order in Maclaurin development (see section Sequences and Series 1703):

$$D\cong\arcsin\left\{m\sin\left[\alpha-\frac{i}{m}\right]\right\}-\alpha\cong\arcsin(m\alpha-i)-\alpha\cong\arcsin(m\alpha)-\alpha\cong m\alpha-\alpha=\alpha(m-1) \tag{10.5.287}$$

Therefore:

$$\boxed{D\cong\alpha(m-1)} \tag{10.5.288}$$

either by explicitly introducing Cauchy's law as introduced earlier in this section:

$$\boxed{D\cong\alpha(m_\lambda-1)=\alpha\left(\left(A+\frac{B}{\lambda^2}\right)-1\right)} \tag{10.5.289}$$

The fact that the index of refraction in glass depends on wavelength (Cauchy's law) is then the reason that prisms can spread the colors of the rainbow!

10.5.5.4 Pentaprism

The pentaprism roof that is enclosed in most viewfinder of single-lens reflex cameras is an adaptation of the pentaprism, or "optical square", invented in 11864 (holocene calendar) by Charles Moÿse Goulier.

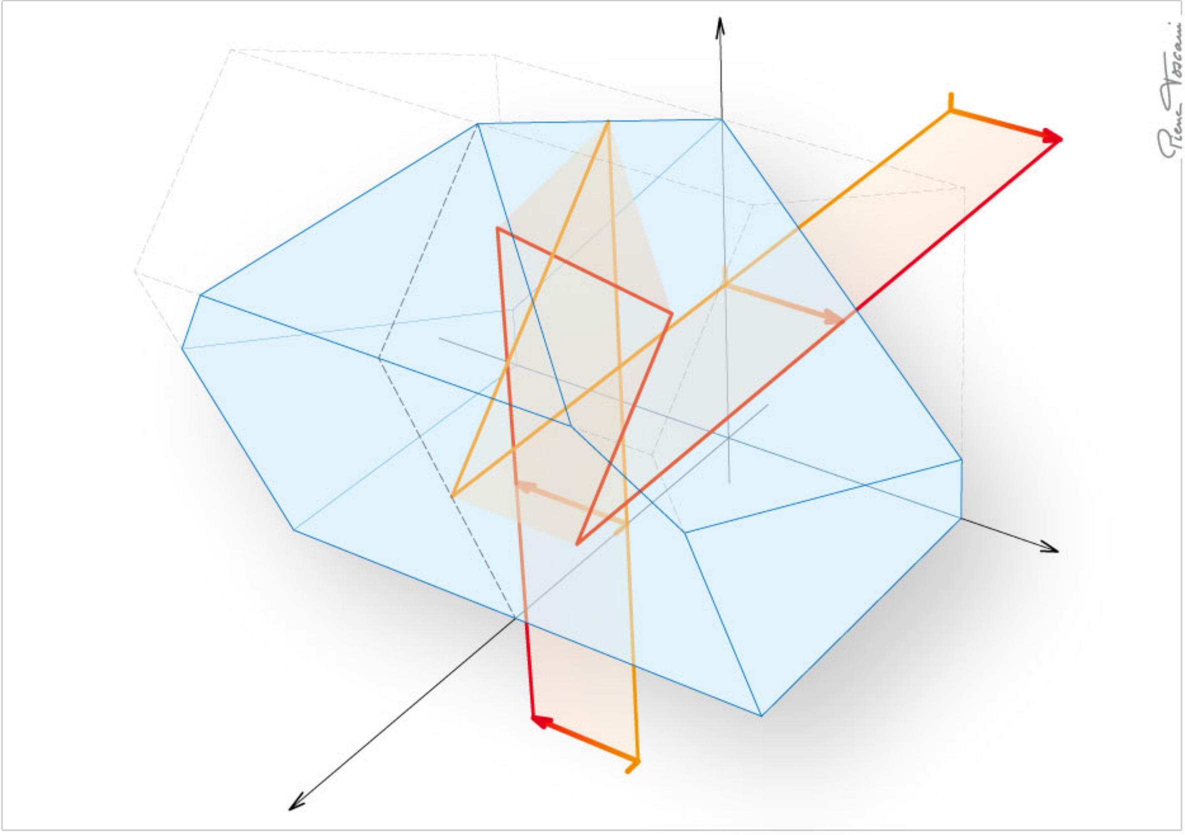

Figure 10.214: **Pentaprism roof (source: http://www.pierretoscani.com, author: Pierre Toscani)**

A pentaprism is a five-sided reflecting prism used to deviate a beam of light by a constant 90°, even if the entry beam is not at 90° to the prism (see proof below). The beam reflects inside the prism twice, allowing the transmission of an image through a right angle without inverting it vertically (that is, without changing the image's handedness) as an ordinary right-angle prism or mirror would.

The reflections inside the prism are not caused by total internal reflection, since the beams are incident at an angle less than the critical angle (the minimum angle for total internal reflection). Instead, the two faces are coated to provide mirror surfaces. The two opposite transmitting faces are often coated with an anti-reflection coating to reduce spurious reflections. The fifth face of the prism is not used optically but truncates what would otherwise be an awkward angle joining the two mirrored faces.

As we have show it, the camera lens renders an image that is both vertically and laterally reversed, and the reflex mirror re-inverts it leaving an image laterally reversed. In this case, the image needs to be reflected left-to-right as the prism transmits the image formed on the camera's focusing screen. This lateral inversion is done by replacing one of the reflective faces of a normal pentaprism with a "roof" section, with two additional surfaces angled towards each other and meeting at 90°, which laterally reverses the image back to normal.

In a precision optical device, when the path of a light beam must be deflected at 90°, the simplest solution is to use a plane mirror oriented at 45° relatively the direction of the incident beam (see figure below). The mirror must be accurately positioned and stable because any angular positioning error induces a double error in the direction of the reflected beam: the reflected beam rotates twice as fast as the mirror (this is obvious as when the mirror in oriented at $\alpha = 45^\circ$ the output beam is at an output angle of $2\alpha = 90^\circ$ and therefore in general any modification δ implies a deflection of 2δ):

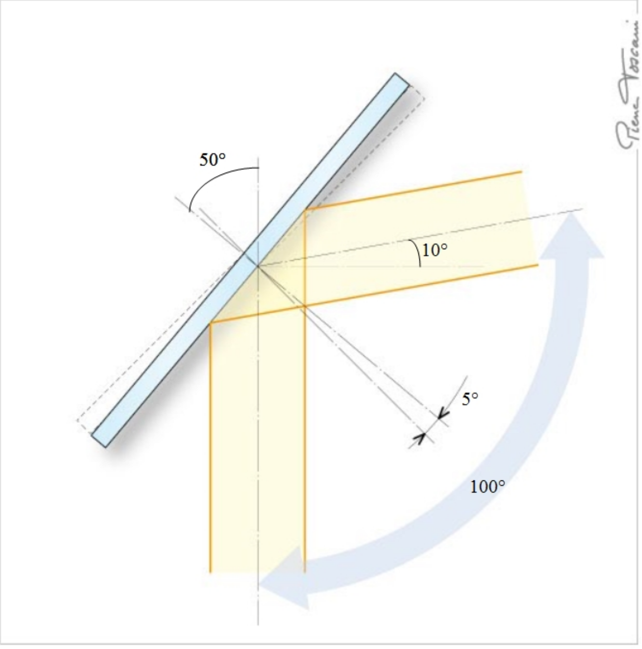

Figure 10.215: **Mirror double deflection property**
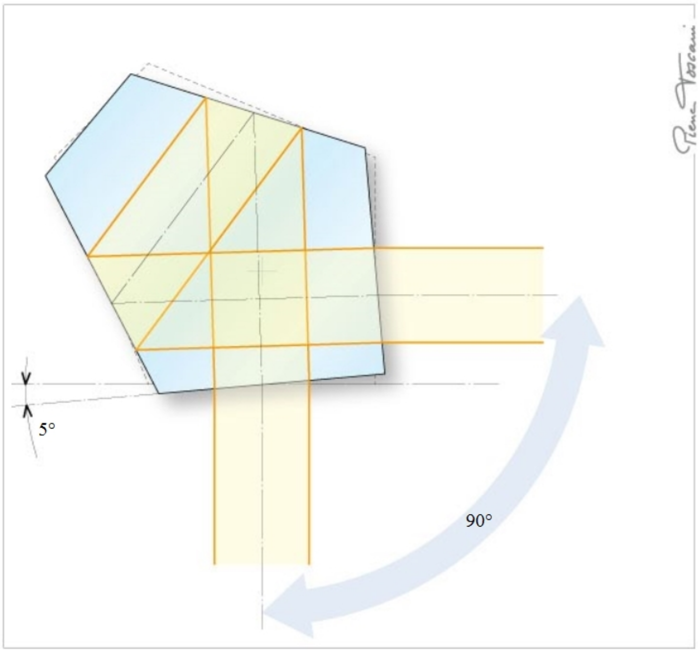
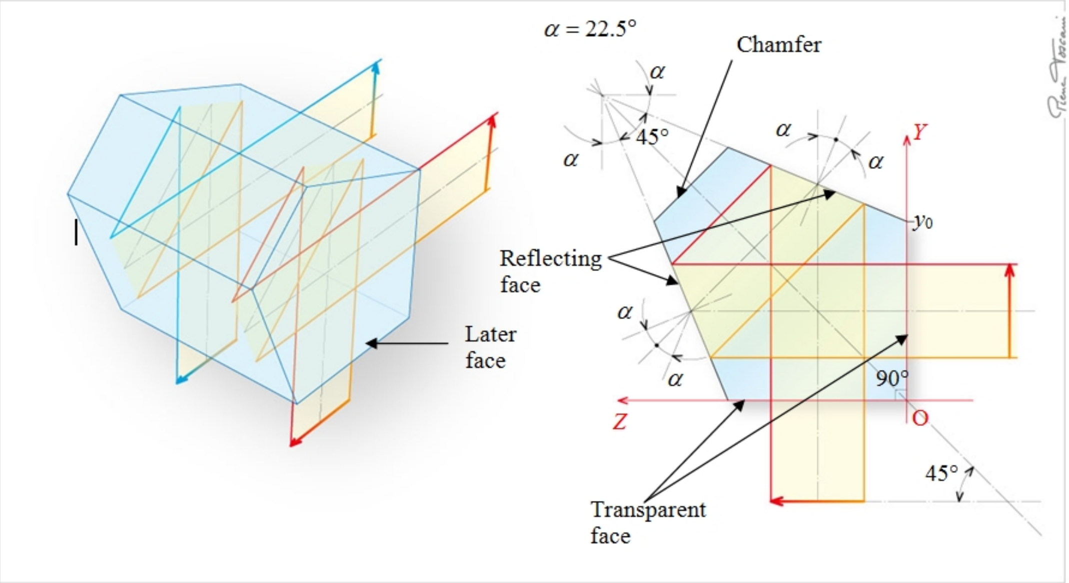
(source: http://www.pierretoscani.com, author: Pierre Toscani)

But for the pentaprism it is different... It behaves like a set square:



Before we deal with the maths, the reader should be aware that this pentaprism has the following properties:

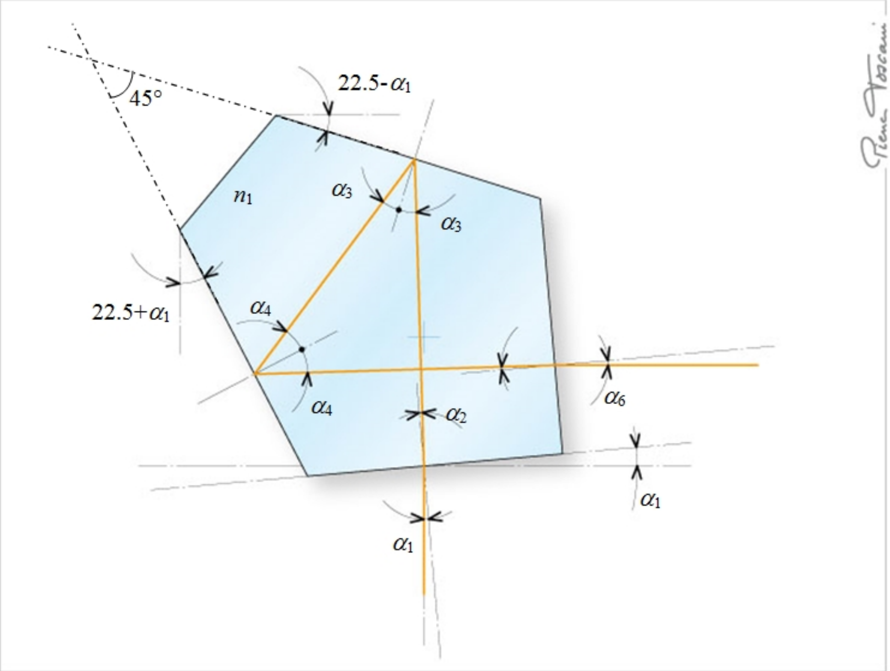
- Two transparent faces (input or output) forming an angle of $90°$
- Two reflecting faces forming an angle of $45°$, separated by a chamfer (fifth face, no function)
- The both reflective surfaces have to be metallized to provide good reflection coefficient.



$\alpha = 22.5°$
Chamfer
α
45°
α
α
α
Y
y_0
Reflecting face
α
Later face
α
90°
Z
O
45°
Transparent face

Figure 10.216: **Pentaprism detailed design (source: http://www.pierretoscani.com, author: Pierre Toscani)**

Now to prove that property consider the following figure:



45°
22.5-α_1
n_1
α_3
α_3
22.5+α_1
α_4
α_4
α_2
α_6
α_1
α_1

We have then looking this figure:

$$n\sin(\alpha_1)=m\sin(\alpha_2) \tag{10.5.290}$$

That we will rearrange and write:

$$\sin(\alpha_1)=\frac{m}{n}\sin(\alpha_2)=n_r\sin(\alpha_2) \tag{10.5.291}$$

Now in the above triangle we have:

$$\alpha_3=(22.5^\circ-\alpha_1)+\alpha_1-\alpha_2 \tag{10.5.292}$$

Therefore:

$$\alpha_3=22.5^\circ-\alpha_2 \tag{10.5.293}$$

On the left triangle we have:

$$\alpha_4=90^\circ-(22.5^\circ+\alpha_1)-(22.5^\circ-\alpha_1)-\alpha_3 \tag{10.5.294}$$

Therefore:

$$\alpha_4=45^\circ-\alpha_3 \tag{10.5.295}$$

That is:

$$\alpha_4=22.5^\circ+\alpha_2 \tag{10.5.296}$$

Finally in the last triangle we have:

$$\alpha_5=\alpha_1-(22.5^\circ+\alpha_1)+\alpha_4 \tag{10.5.297}$$

And therefore:

$$\alpha_5=\alpha_4-22.5^\circ \tag{10.5.298}$$

That is:

$$\alpha_5=\alpha_4-22.5^\circ \tag{10.5.299}$$

Finally:

$$\alpha_5=\alpha_2 \tag{10.5.300}$$

And now at the exit of the pentaprism we have:

$$\sin(\alpha_6)=n_r\sin(\alpha_5) \tag{10.5.301}$$

But as $\alpha_5=\alpha_2$ we have:

$$\sin(\alpha_6)=n_r\sin(\alpha_5)=n_r\sin(\alpha_2) \tag{10.5.302}$$

Therefore it follows that:

$$\alpha_6=\alpha_1 \tag{10.5.303}$$

And this finish our proof!

10.6. Wave Optics

In this section will study some elements that led to the development of quantum mechanics. Indeed, quantum mechanics was born, first, by a careful study of the nature of light. Although this new science was developed in the early 120th century (holocene calendar), the considerations which have guided to it are undoubtedly the result of 25 centuries of maturation. Basically, it is a long history of the light full of controversies to which quantum mechanics in the 120th century finally brings a masterful conclusion.

Electron microscopes can make images of individual atoms, but why will a visible-light microscope never be able to? Stereo speakers create the illusion of music that comes from a band arranged in your living room, but why doesn't the stereo illusion work with bass notes? Why are computer chip manufacturers investing billions of dollars in equipment to etch chips with X-rays instead of visible light?

The answers to all of these questions have to do with the subject of wave optics. So far this textbook has discussed the interaction of light waves with matter, and its practical applications to optical devices like mirrors, but we have used the ray model of light almost exclusively. Hardly ever have we explicitly made use of the fact that light is an electromagnetic wave. We were able to get away with the simple ray model because the chunks of matter we were discussing, such as lenses and mirrors, were thousands of times larger than a wavelength of light. We now turn to phenomena and devices that can only be understood using the wave model of light.

10.6.1 Huygens' principle

Huygens visualized the propagation of light as a result of the process of a generation of spherical wavelets in each point reached by a wavefront, wavelet whose sum gave the propagation field. By drawing the tangent to the wavefronts of the wavelet at a given time, one obtained the wavefront of the total wave at the same moment.

Caution! As we have already mentioned it earlier, the Fermat's principle doesn't explain anything, even if it's accurate that light follow the shortest path! That's why most textbooks introducing refraction as we did above geometrically (named sometimes the "marching soldier analogy", but wrong as nothing explain why the solders don't continue you walk straight) or using the variational principal (i.e. "Fermat's principle") are quite misleading. Using Huygens principle as we will do it now isn't also accurate as we will explain it (even if we fall back on the same result as using Fermat's principle or the marching soldier analogy)! In fact we should use Maxwell equation to understand better what happens physically!

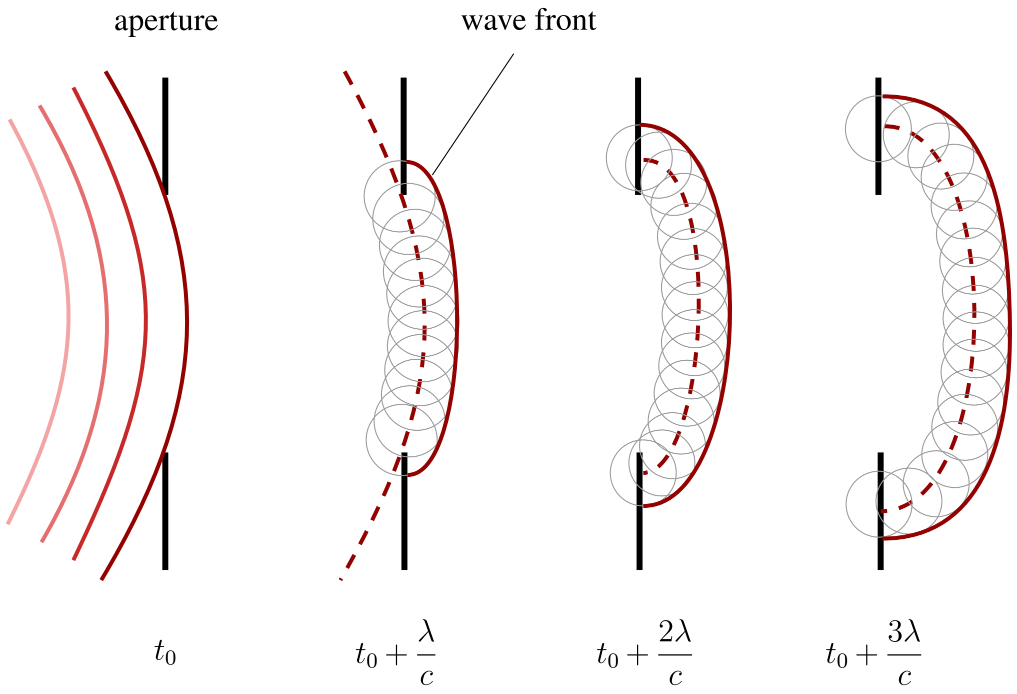

Figure 10.217: **Illustration of Huygen's construction of a propagating wave**

Definition (#10.6.496): A "wavefront surface" is the localization of points of the medium reach by the wave motion at the same instant. The disturbance has therefore the same phase at any point of a wavefront. For a plane wave, for example, the disturbance is expressed by (we have prove this in the section of Wave Mechanics):

$$f(kx-vt) \tag{10.6.1}$$

or in a more general way:

$$f(\vec{k}\circ\vec{r}-vt) \tag{10.6.2}$$

which therefore gives the expression of the propagation of the disturbance for which the "wavefront" is the locus of points where the phase $\vec{k}\circ\vec{r}-vt$ has the same value at a given instant. The wave surface is given accordingly by the equation:

$$\vec{k}\circ\vec{r}-vt=c^{te} \tag{10.6.3}$$

Huygens gave a pictorial representation method of the passage of a wave surface to another in the case where the wave is assumed to result from the movement of the particles constituting the material medium. Thus, if we consider the wave surface S below:

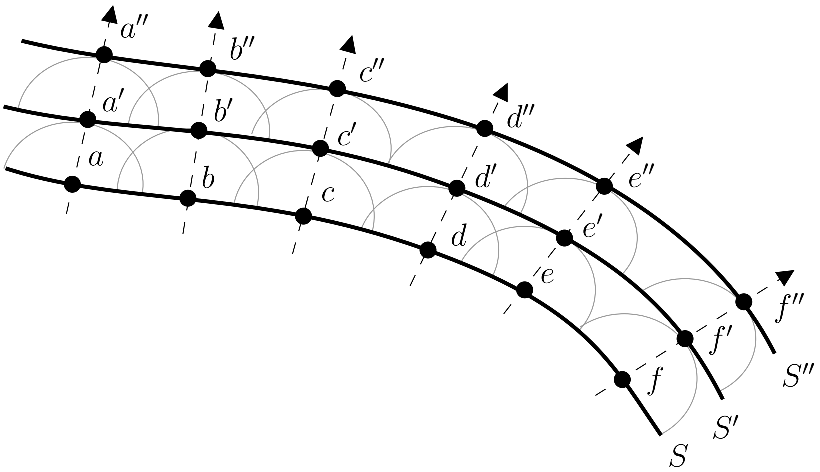

Figure 10.218: **Representation of a wavefront according to Huygens**

When the wave motion reaches this surface, each particle $a, b, c, \ldots$ of the surface becomes in turn a wave source, emitting secondary waves (indicated by the small half-circles in the figure above) that reach the next layer of particles of the medium. These particles are put in motion and form the new wave surface S' and so on... So, Huygens had a wave conception of light, but he did not consider the periodic nature of the wave, which not allow him to introduce the concept of light of color (frequency); moreover, according to its principle, a wave propagating in the opposite direction to that of the incident wave should also occur, which is not the case in a homogeneous material...

Figure 10.219: **Crepuscular rays as a real life example of Huygens-Fresnel secondary source effect**

The intuition of Huygens is however close to reality as will show if Fresnel in its diffraction theory (see further below). However, it was Kirchhoff, which will introduce a tilt factor (obliquity) in the theory, to gen an explanation of the absence of wave propagating backward (when the time will come we will write related mathematical developments).

As on the previous figure all the "corresponding points" $(a,b,c,\ldots),(a',b',c',\ldots)$ are equidistant, by Huygens' principle, the time interval between corresponding points of two wavefronts is the same for any two corresponding points!

The consequences are (refer simultaneously to the figure below):

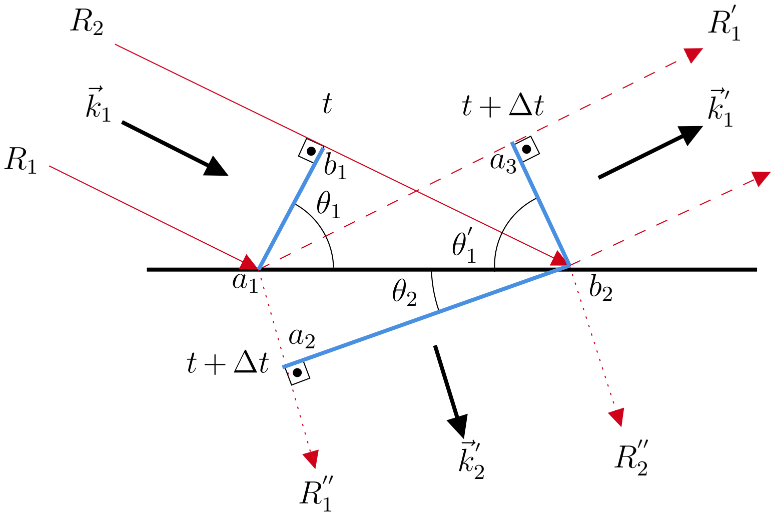

Figure 10.220: **Schematic diagram**

If we denote the propagation velocities of the incident rays R_1, R_2 by v_1 and v_2 respectively, we have:

$$\overline{b_1b_2}=v_1\Delta t \qquad \overline{a_1a_3}=v_1\Delta t \qquad \overline{a_1a_2}=v_2\Delta t \tag{10.6.4}$$

- When the wave propagates in a homogeneous medium, the light rays must be straight and the wave surfaces remain parallel.
- When the wave change of medium, the distance between two pairs of corresponding points vary from one medium to another, if the propagation velocities are different.

Theorem 10.3. Let us prove that this principle allows to find the Descartes-Snellius law that we have already proven in the section of Geometric Optics, which ensures a priori that the Huygens principle is still valid in the context of Geometric Optics.

Proof 10.3.1. Following the figure above, we have:

$$\Delta t=\frac{\overline{b_1b_2}}{v_1}=\frac{\overline{a_1a_3}}{v_1}=\frac{\overline{a_1a_2}}{v_2} \tag{10.6.5}$$

by dividing each term by $\overline{a_1b_2}$, we get:

$$\frac{\sin(\theta_1)}{v_1}=\frac{\sin(\theta'_1)}{v_1}=\frac{\sin(\theta_2)}{v_2} \tag{10.6.6}$$

so we fall back well on the Descartes-Snellius law as we had obtained it in the section of Geometric Optics:

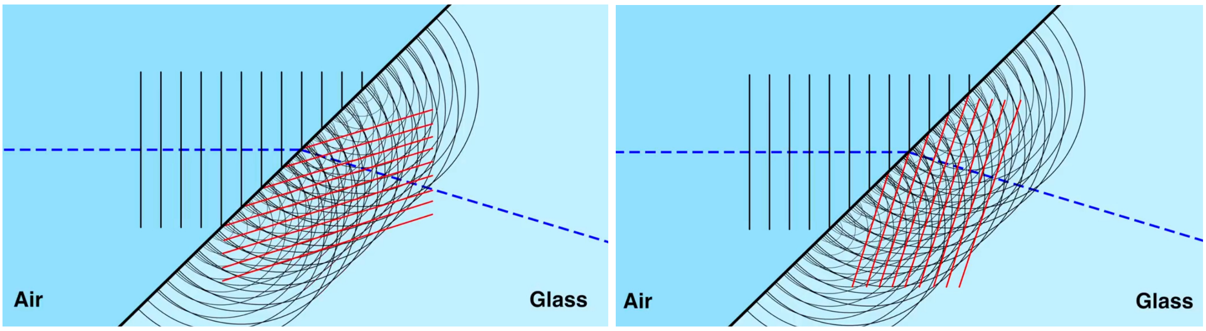
$$\frac{\sin(\theta_1)}{\sin(\theta_2)}=\frac{v_1}{v_2}=n_{12} \tag{10.6.7}$$

noting on the way that on the diagram, we also have $\theta_1=\theta'_1$.

■ Q.E.D.

So to derive Snell's law we have seen so far three commonly suggested explanations that are wrong, or at least incomplete. They are for Fermat's principle, the analogy of soldiers marching and Huygens' principle. Fermat's principle says that light will travel from one point to the other, taking the minimum amount of time. It's often explained in terms of a lifeguard in a drowning swimmer in order to maximize the chances that the swimmer will be saved, the lifeguard needs to get to them as soon as possible. But while that's true for light, it doesn't explain anything. It just says what it does, not why it does it. So that's not an explanation and we need to come up with a proper reason. Let's look at the second option on the list. A very common explanation used to teach why light bends involves soldiers marching over firm ground, but then who encounter a wall, although not all soldiers hit mud at the same time. The idea is simple. The first soldier who encounters the mud cannot move as quickly as the rest of the soldiers, so he slows down. Each soldier hits the mud and turn, resulting in a direction change. Eventually the lines of soldiers are moving in a different direction at a different speed. This is how it's often taught. The problem is that this doesn't work. In fact, the soldiers will slow down, but their direction doesn't change. They will continue to walk in the same direction, but with marching lines that are slanted compared to how they started. This explanation gets the angle of the lines of soldiers right but not the direction of travel. In fact, the only way that this explanation can be right is if the lines of soldiers are rigid, then the first soldier hitting the mud puts a torque on the entire line and that would work. The problem is that this torque means that the soldiers on the top of the screen move faster, which is to say that if they were light, this part of the beam of light would have to move faster than light, so this explanation doesn't work either.

What about Huygens' principle? Remember in the figure on the left below that the lines denote the top of the peaks of the waves. We can see that there are many places where the peaks line up. We can overlay a couple of lines that show the direction that the wave is travelling and then remove the circular waves and we see that this explanation seems to be doing a good job of predicting what happens when light goes from air to glass. Looks good, right? But not so fast! What happens when we look at all of the waves coming through the glass? Things get a lot more complicated. We do see that the waves add together to predict the direction that light moves in glass. On the other hand, that's not the only alignment! For instance, we see other geometry's where the waves line up a visible in the figure on the right below.



(a) What most textbooks show (b) What only a few textbooks admit...

Figure 10.221: **Failure of Huygens' principle**

So it seems that this approach doesn't give a unique prediction. OK, we've ruled out Fermat's principle, the soldier analogy, and Huygens' principle!

These are all often seen as explanations of the cause of refraction given by people who really do know some physics. So what's the real answer? It turns out that the only way to really answer the question of why light bends when it goes from air to glass is to get serious about the nature of light and to embrace the fact that it is made of oscillating electromagnetic fields, and that means we need Maxwell's equations!

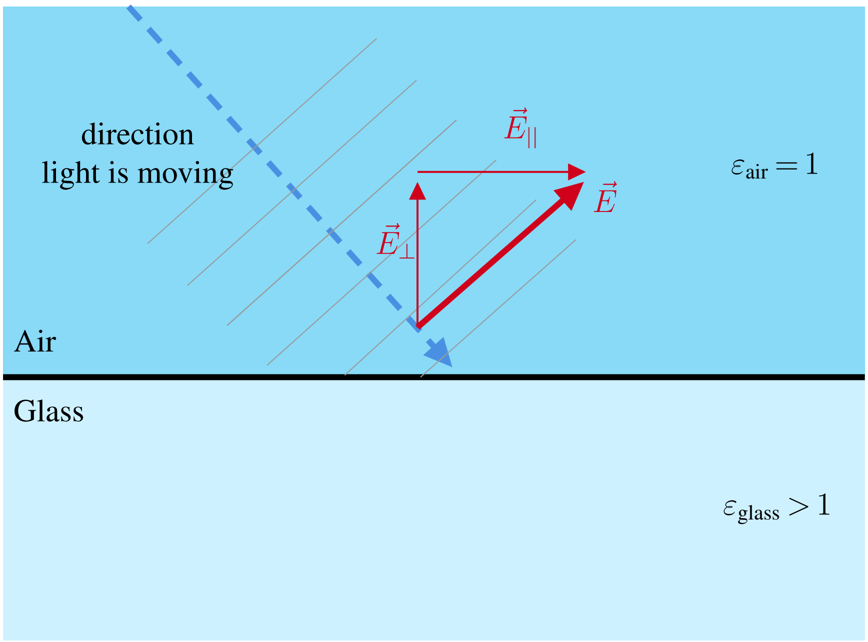
We will focus here only on the electric fields. So we start with Maxwell's equations:

$$\begin{aligned} \vec{\nabla}\circ\vec{E} &= \frac{\rho_Q}{\varepsilon} & \vec{\nabla}\circ\vec{B} &= 0 \\ \vec{\nabla}\times\vec{E} &= -\frac{\partial\vec{B}}{\partial t} & \vec{\nabla}\times\vec{B} &= \mu\vec{j}+\mu\varepsilon\frac{\partial\vec{E}}{\partial t} \end{aligned} \tag{10.6.8}$$

In fact, we're going to need only the bottom two equations:

$$\varepsilon\vec{\nabla}\circ\vec{E} = \rho_Q \qquad \vec{\nabla}\times\vec{E} = -\frac{\partial\vec{B}}{\partial t} \tag{10.6.9}$$

So let's see what's going on. We start with light going from air to glass, hitting the surface at an angle. In our figure, we can replace the waves with the direction of motion. Now it turns out that the electric field of light is perpendicular to the direction that light is travelling, and we can add that field direction to the diagram. And it's very important to remember that this field has components. One parallel to the surface of the glass and one that is perpendicular to the glass:



direction
light is moving
$\vec{E}_{||}$
$\vec{E}$
$\vec{E}_{\perp}$
$\varepsilon_{\text{air}} = 1$
Air
Glass
$\varepsilon_{\text{glass}} > 1$

And here is where Maxwell's equations come into play!

Two copies of the equations are written here, one that covers when light is travelling in air:

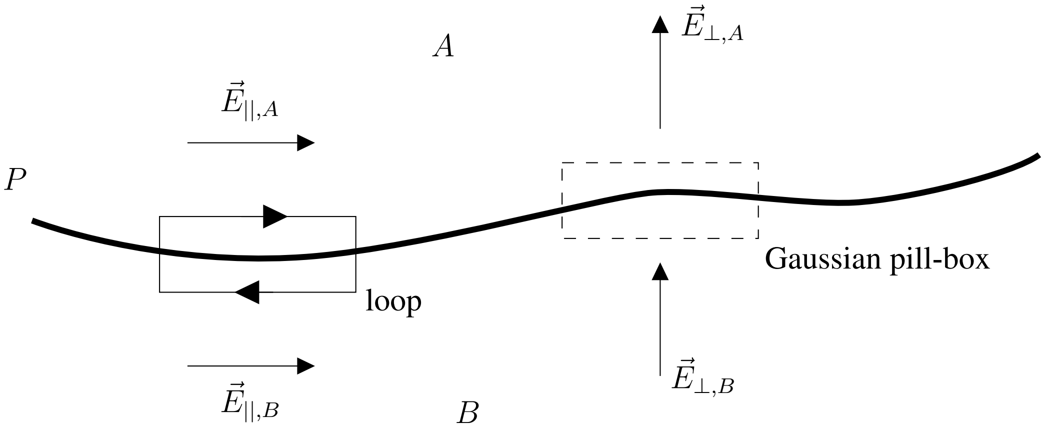
$$\varepsilon_{\text{air}}\vec{\nabla}\circ\vec{E}_{\text{air}} = \rho_Q \qquad \vec{\nabla}\times\vec{E}_{\text{air}} = -\frac{\partial\vec{B}}{\partial t} \tag{10.6.10}$$

and one where it is travelling in glass:

$$\varepsilon_{\text{glass}}\vec{\nabla}\circ\vec{E}_{\text{glass}} = \rho_Q \qquad \vec{\nabla}\times\vec{E}_{\text{glass}} = -\frac{\partial\vec{B}}{\partial t} \tag{10.6.11}$$

So here's the key point! The surface belongs to both the air region and the glass region. This means that at the surface, the equations on the top and the equations on the bottom have to apply, and with that little bit of calculus we can find two important restrictions. Let us see which are these restrictions?

For that purpose let us see what are the most general boundary conditions satisfied by the electric field at the interface between two media: e.g., the interface between a vacuum and a conductor? Consider an interface P between two media A (for example "air") and B (for example "glass"):



A
$\vec{E}_{\perp,A}$
$\vec{E}_{||,A}$
P
Gaussian pill-box
loop
$\vec{E}_{||,B}$
$\vec{E}_{\perp,B}$
B

Let us, first of all, apply Gauss' law (see section Electrodynamics page 4095):

$$\oint_S \vec{E}\circ\mathrm{d}\vec{S}=\frac{1}{\varepsilon_0}\int_V \rho\mathrm{d}V \tag{10.6.12}$$

to a Gaussian pill-box S of cross-sectional area A whose two ends are locally parallel to the interface (see figure above). The ends of the box can be made arbitrarily close together. In this limit, the flux of the electric field out of the sides of the box is obviously negligible. The only contribution to the flux comes from the two ends. In fact:

$$\oint_S \vec{E}\circ\mathrm{d}\vec{S}=(E_{\perp A}-E_{\perp B})A \tag{10.6.13}$$

where $E_{\perp A}$ is the perpendicular (to the interface) electric field in medium A at the interface, etc. The charge enclosed by the pill-box is simply σ_A, where σ is the sheet charge density on the interface. Note that any volume distribution of charge gives rise to a negligible contribution to the right-hand side of the above equation, in the limit where the two ends of the pill-box are very closely spaced. Thus, Gauss' law yields:

$$E_{\perp A}-E_{\perp B}=\frac{\sigma}{\varepsilon_0} \tag{10.6.14}$$

at the interface: i.e., the presence of a charge sheet on an interface causes a discontinuity in the perpendicular component of the electric field.

The way electric permittivity works is that it lets us use Gauss' law as if there is no charge, provided we integrate $\vec{D}=\varepsilon\vec{E}$ over the surface rather than $\vec{E}$. Therefore the boundary condition is $D_{\perp A}=D_{\perp B}$, which implies:

$$\varepsilon_A E_{\perp A}=\varepsilon_B E_{\perp B} \tag{10.6.15}$$

What about the parallel electric field? Let us apply Faraday's law (see section Electrokinetics page 4259) to a rectangular loop C whose long sides, length l, run parallel to the interface:

$$\oint_C \vec{E}\circ\mathrm{d}\vec{l}=-\frac{\partial}{\partial t}\int_S \vec{B}\circ\mathrm{d}\vec{S} \tag{10.6.16}$$

(see figure above). The length of the short sides is assumed to be arbitrarily small. The dominant contribution to the loop integral comes from the long sides:

$$\oint_C \vec{E}\circ\mathrm{d}\vec{l}=(E_{\parallel A}-E_{\parallel B})l \tag{10.6.17}$$

where $E_{\parallel A}$ is the parallel (to the interface) electric field in medium A at the interface, etc. The flux of the magnetic field through the loop is approximately $B_{\perp A}$, where $B_\perp$ is the component of the magnetic field which is normal to the loop, and A is the area of the loop. But, $A\rightarrow 0$ as the short sides of the loop are shrunk to zero. So, unless the magnetic field becomes infinite (we shall assume that it does not), the flux also tends to zero. Thus:

$$E_{\parallel A}-E_{\parallel B}=0 \tag{10.6.18}$$

i.e., there can be no discontinuity in the parallel component of the electric field across an interface.

So, coming back to our glass and air case, this leads us to:

$$E_\parallel^{\text{glass}}=E_\parallel^{\text{air}}\quad\text{and}\quad\varepsilon_{\text{glass}}E_\perp^{\text{glass}}=\varepsilon_{\text{air}}E_\perp^{\text{air}} \tag{10.6.19}$$

Remark

For the magnetic field, the boundary conditions will be affected due to the magnetic moment of the charges in the medium, as encoded in the permeability μ. Since a magnetic field induces in a material a current perpendicular to the field, only $B_{\parallel}$ will be affected (because of the change of material perpendicular to the surface in the plane where the induced current should happen), not $B_{\perp}$.

Thus:

$$B_{\perp A} = B_{\perp B} \tag{10.6.20}$$

Since the part of the magnetic field which is sensitive to an accumulated current in a material is treated using $\vec{H} = \vec{B}/\mu$ the condition is then that:

$$\frac{1}{\mu_A} B_{\parallel A} = \frac{1}{\mu_B} B_{\parallel B} \tag{10.6.21}$$

In transparent materials, the electric permittivity can vary significantly in comparison to air, but so does not the magnetic permeability. So some textbooks assume that $\mu_A \cong \mu_B$. In this case, the four boundary conditions:

$$E_{\parallel}^{\text{glass}} = E_{\parallel}^{\text{air}} \quad \text{and} \quad \varepsilon_{\text{glass}} E_{\perp}^{\text{glass}} = \varepsilon_{\text{air}} E_{\perp}^{\text{air}} \tag{10.6.22}$$

$$\frac{1}{\mu_{\text{glass}}} B_{\parallel}^{\text{glass}} = \frac{1}{\mu_{\text{air}}} B_{\parallel}^{\text{air}} \quad \text{and} \quad B_{\perp}^{\text{glass}} = B_{\perp}^{\text{air}} \tag{10.6.23}$$

reduce to:

$$E_{\parallel}^{\text{glass}} = E_{\parallel}^{\text{air}} \quad \text{and} \quad \varepsilon_{\text{glass}} E_{\perp}^{\text{glass}} = \varepsilon_{\text{air}} E_{\perp}^{\text{air}} \tag{10.6.24}$$

$$\vec{B}_{\text{glass}} = \vec{B}_{\text{air}} \tag{10.6.25}$$

The first is that the electric field parallel to the surface of the glass has to be the same in the air in the glass and similarly perpendicular to the surface:

$$\varepsilon_{\text{glass}} \vec{\nabla} \circ \vec{E}_{\text{air}} = \rho_Q = \varepsilon_{\text{air}} \vec{\nabla} \circ \vec{E}_{\text{air}} \tag{10.6.26}$$

$$\vec{\nabla} \times \vec{E}_{\text{air}} = -\frac{\partial \vec{B}}{\partial t} = \vec{\nabla} \times \vec{E}_{\text{glass}} \tag{10.6.27}$$

Therefore:

$$\varepsilon_{\text{glass}} \vec{\nabla} \circ \vec{E}_{\text{air}} = \varepsilon_{\text{air}} \vec{\nabla} \circ \vec{E}_{\text{air}} \tag{10.6.28}$$

$$\vec{\nabla} \times \vec{E}_{\text{air}} = \vec{\nabla} \times \vec{E}_{\text{glass}} \tag{10.6.29}$$

Because ε is bigger in glass than in air, that means that the perpendicular electric field in glass has to be smaller than it is in air.

Now we remember that the direction the late travels is perpendicular to the electric field, so we can put in an arrow to show the direction light must travel in the glass. And finally, we can see what light does when it enters glass or water or any transparent medium, it bends. And the reason that it bends is because the epsilon in glass is bigger than an air.

OK, what we just seen is an equation thing. The reader may probably asking himself what that epsilon actually physically means. It's there because how the electric fields from the light interacts with the matter in the glass. We start out with glass with no electric field in it. The glasses charges in it, but they're arranged in a random way. But when we send light in, we impose an electric field on it. That field makes the charges move around, which sets up a counterbalancing electric field from the charges. The result is that the electric field in the glass is lower than it is in air because of how the electric field from the glass is in the opposite direction. And this is the reason that the perpendicular electric field is lower in glass, and that is why light bends when it goes from here to glass. It's not because of many of the ordinary explanations, it's because of how light interacts with glass and changes the glasses properties, and it's because the electric field inside the glass is affected by the arrangements of atoms and molecules in the glass when light hits it. It's the same reason why. Light slows down in matter inside matter. The electric field due to the light and the electric field due to the matter both have to be taken into account. Outside they don't. And now you know some serious physics! We imagine that some of you will may ask about the quantum explanation, which is similar to the one we just told you here using Maxwell equations except using energy and momentum of the photons instead.

10.6.1.1 Normal refraction

Let us start with the case of normal incidence (perpendicular to the interface). To find out how much light is reflected, we need to work out the impedance, which determines the reflection and transmission coefficients.

For normal incidence the incident angle to the normal is $\theta_1=0$ (see the figure 10.223 below). Thus $E_\perp=B_\perp=0$. That is, the electric and magnetic fields are both polarized in the plane of the interface so there simply is no $\perp$ component.

Without loss of generality, let's take a plane wave of frequency ω moving in the z direction with $\vec{E}$ in the y direction. Then since (see page 4145):

$$\vec{B}=\frac{1}{ck}\vec{k}\times\vec{E} \tag{10.6.30}$$

the magnetic field points in the x direction. So the incident fields are:

$$\vec{E}_I=E_I\vec{u}_y e^{\mathrm{i}\omega\left(t-\frac{1}{v_1}z\right)} \qquad \vec{B}_I=B_I\vec{u}_x e^{\mathrm{i}\omega\left(t-\frac{1}{v_1}z\right)} \tag{10.6.31}$$

The transmitted and reflected waves are also moving normal to the surface (by Snell's law), so we can write:

$$\begin{aligned}\vec{E}_T&=E_T\vec{u}_y e^{\mathrm{i}\omega\left(t-\frac{1}{v_1}z\right)} & \vec{B}_T&=B_T\vec{u}_x e^{\mathrm{i}\omega\left(t-\frac{1}{v_1}z\right)}\\ \vec{E}_R&=E_R\vec{u}_y e^{\mathrm{i}\omega\left(t+\frac{1}{v_1}z\right)} & \vec{B}_R&=-B_R\vec{u}_x e^{\mathrm{i}\omega\left(t+\frac{1}{v_1}z\right)}\end{aligned} \tag{10.6.32}$$

with E_T,E_R,B_T and B_R the transmission and reflection coefficients to be determined. Note that we have flipped the sign on the z term in the phase since the reflected wave is moving in the $-\vec{u}_z$ direction (that is, $\vec{k}$ flips).

Since $\omega\vec{B}=\vec{k}\times\vec{E}$, this means that $\vec{B}$ flips sign too, which explains the minus sign in $\vec{B}_R$.

Since there is no $\perp$ component and that we have the boundary condition $E_{\parallel}^{(1)}=E_{\parallel}^{(2)}$, we will assume that this implies:

$$E_I+E_R=E_T \tag{10.6.33}$$

Similarly we will assume that:

$$\frac{1}{\mu_1}B_{\parallel}^{(1)}=\frac{1}{\mu_2}B_{\parallel}^{(2)} \tag{10.6.34}$$

implies:

$$\frac{1}{\mu_1}B_I-\frac{1}{\mu_1}B_R=\frac{1}{\mu_2}B_T \tag{10.6.35}$$

Since $||\vec{B}||=\frac{1}{v}||\vec{E}||$ for any plane wave, we have obviously:

$$B_I=\frac{1}{v_1}E_I \qquad B_T=\frac{1}{v_2}E_T \tag{10.6.36}$$

and the above relation becomes:

$$\frac{1}{\mu_1 v_1}(E_I-E_R)=\frac{1}{\mu_2 v_2}E_T \tag{10.6.37}$$

Combining:

$$\begin{gathered}E_I+E_R=E_T\\ \frac{1}{\mu_1 v_1}(E_I-E_R)=\frac{1}{\mu_2 v_2}E_T\end{gathered} \tag{10.6.38}$$

and solving gives:

$$E_R=E_I\frac{Z_2-Z_1}{Z_2+Z_1} \qquad E_T=E_I\frac{2Z_2}{Z_2+Z_1} \tag{10.6.39}$$

where:

$$Z_i=\mu_i v_i=\mu_i\frac{c}{n_i}=\sqrt{\frac{\mu_i}{\varepsilon_i}} \tag{10.6.40}$$

For most materials, μ_i is pretty constant, so the form $Z=\mu_i c/n_i$, which says $Z\propto n_i^{-1}$, is most useful.

What is the power reflected and transmitted assuming the above assumptions correct? The incident power in a medium is given by the Poynting vector (see page 4156):

$$\vec{S}=\frac{1}{\mu}\vec{E}\times\vec{B} \tag{10.6.41}$$

times area A. So:

$$P_I=\frac{1}{\mu v}||\vec{E}_I||^2A=\frac{1}{Z}||\vec{E}_I||^2A \tag{10.6.42}$$

Thus the reflected power is:

$$P_R = \frac{E_R^2}{Z_1}A = \left(\frac{Z_2 - Z_1}{Z_2 + Z_1}\right)^2 \frac{E_I^2}{Z_1}A = \left(\frac{Z_1 - Z_2}{Z_1 + Z_2}\right)^2 P_I \qquad (10.6.43)$$

and the transmitted power is:

$$P_T = \frac{E_T^2}{Z_2}A = \left(\frac{2Z_2}{Z_2 + Z_1}\right)^2 \frac{E_I^2}{Z_2}A = \frac{4Z_1Z_2}{(Z_1+Z_2)^2}\frac{E_I^2}{Z_1}A = \frac{4Z_1Z_2}{(Z_1+Z_2)^2}P_I \qquad (10.6.44)$$

These satisfy $P_T + P_R = P_I$ as expected. Note that these equations hold for normal incidence only and the others assumptions!

10.6.1.2 Thin film interference

Using the relations we get from the above developments:

$$E_R = E_I\frac{Z_2 - Z_1}{Z_2 + Z_1} \qquad E_T = E_I\frac{2Z_2}{Z_2 + Z_1} \qquad (10.6.45)$$

and that since $Z \propto n^{-1}$, the first relation becomes:

$$\frac{E_R}{E_I} \propto \frac{n_1 - n_2}{n_1 + n_2} \qquad (10.6.46)$$

Thus for $n_2 > n_1$ the reflected electric field has a phase flip compared to the incoming field, and for $n_1 < n_2$ there is no phase flip.

So what happens when light hits a thin film?

The film will generally have $n_2 = n_{\text{film}} > n_{\text{air}} = n_1$. Thus we get a phase flip at the top surface, but no phase flip at the bottom surface. The picture looks like this:

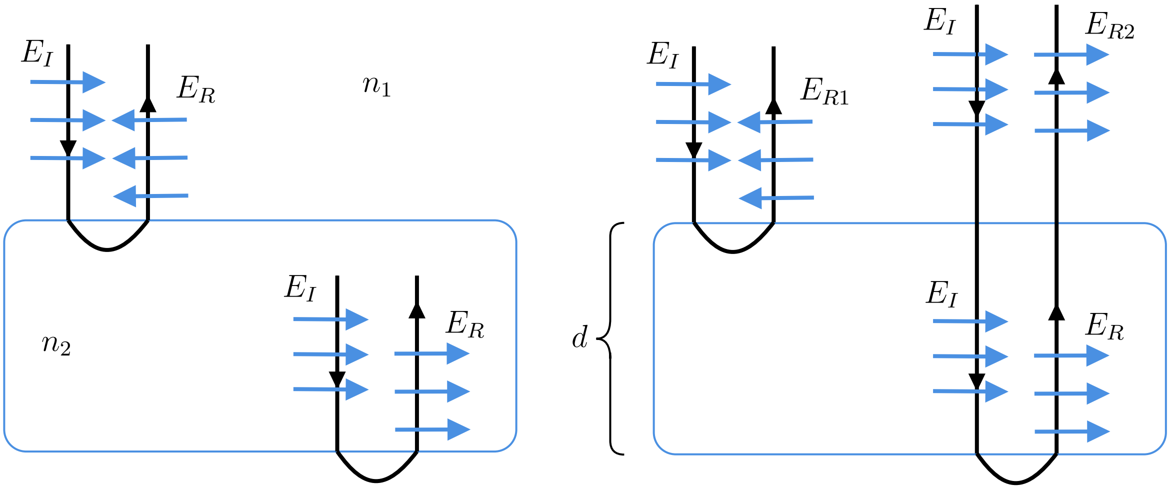


Figure 10.222: **There is a π phase flip from reflections off the top surface, where $n_2 > n_1$, but not off the bottom surface, where $n_2 < n_1$.**

So what happens if light of wavelength λ hits a film of thickness d?

There will be two reflected waves, one off the top surface (A) of the film and one off the bottom (B) of the film which will interfere!

Say the incoming electric field on (A) is:

$$E_{I,(A\to A)} = E_{I,(A)}\cos(kz-\omega t) \tag{10.6.47}$$

pointing to the right. Then the wave which reflects off the top surface $(z=0)$ will be:

$$E_{R1,(A\to A)} = RE_{I,(A)}\cos(-\omega t-\pi) = -RE_{I,(A)}\cos(-\omega t) \tag{10.6.48}$$

with R being the reflection coefficient. This now points to the left!

The wave which gets through the surface (A) from the film will be:

$$E_{I,(A\to B)}T\cos\left(kz-\omega t\right) \tag{10.6.49}$$

with T the transmission coefficient. This wave then goes to the bottom surface, reflects with no phase flip, and comes back and exits with no more phase flips. So when it exits, it is back to $z=0$ after having traversed a distance $\Delta z = 2d$. Thus it is:

$$E_{T,(B\to A)} = E_{I,(A)}T^2R\cos\left(k\Delta z-\omega t+\right) = E_{I,(A)}T^2R\cos\left(2\pi\frac{2d}{\lambda}-\omega t\right) \tag{10.6.50}$$

The total wave at $t=0$ and $z=0$ is therefore:

$$E_{\text{tot}} = E_{I,(A\to A)} + E_{R1,(A\to A)} + E_{T,(B\to A)} = E_{I,(A)}RT^2\cos\left(\frac{4\pi d}{\lambda}\right) \tag{10.6.51}$$

where λ is the wavelength in the second medium (inside the film).

In the limit that $d \ll \lambda$ the two reflections (taken at $t=0$ and $z=0$):

$$E_{R1,(A\to A)} = -RE_{I,(A)} \qquad \text{and} \qquad E_{T,(B\to A)} = E_{I,(A)}T^2R \tag{10.6.52}$$

are exactly out of phase. For $T\approx 1$, there will be complete destructive interference and no reflection. But there will also be complete destructive interference whenever $\cos\left(\frac{4\pi d}{\lambda}\right)=1$, which is when:

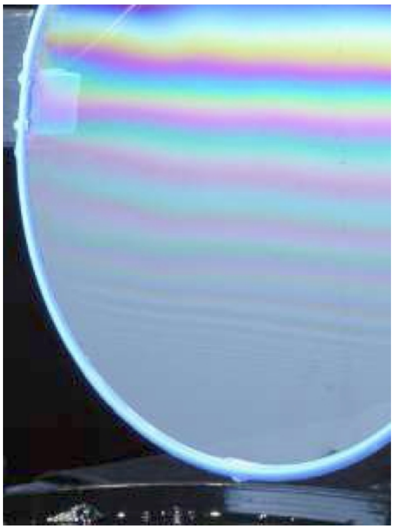
$$d = \frac{\lambda}{2},\frac{2\lambda}{2},\frac{3\lambda}{2},\frac{4\lambda}{2}\cdots \qquad \text{(complete destructive interference)} \tag{10.6.53}$$

On the other hand if the two waves are completely in phase there will be constructive interference. This happens when $\cos\left(\frac{4\pi d}{\lambda}\right)=-1$ which is when:

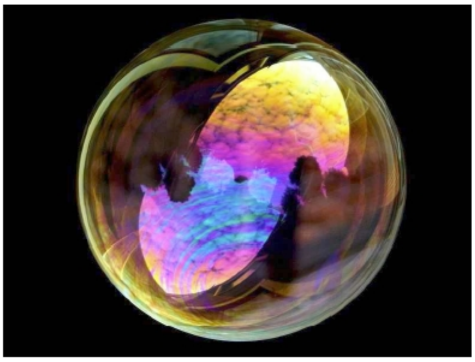
$$d = \frac{\lambda}{4},\frac{3\lambda}{4},\frac{5\lambda}{4},\cdots \qquad \text{(complete constructive interference)} \tag{10.6.54}$$

If the material is much thicker than the wavelength of light, and not of completely uniform thickness, then there will be some constructive and some destructive interference and we won't see much interesting. However, if the material has a well-defined thickness which is of the same order of magnitude as the wavelength of visible light, we will see different wavelengths with different intensities. This happens in a soap film.

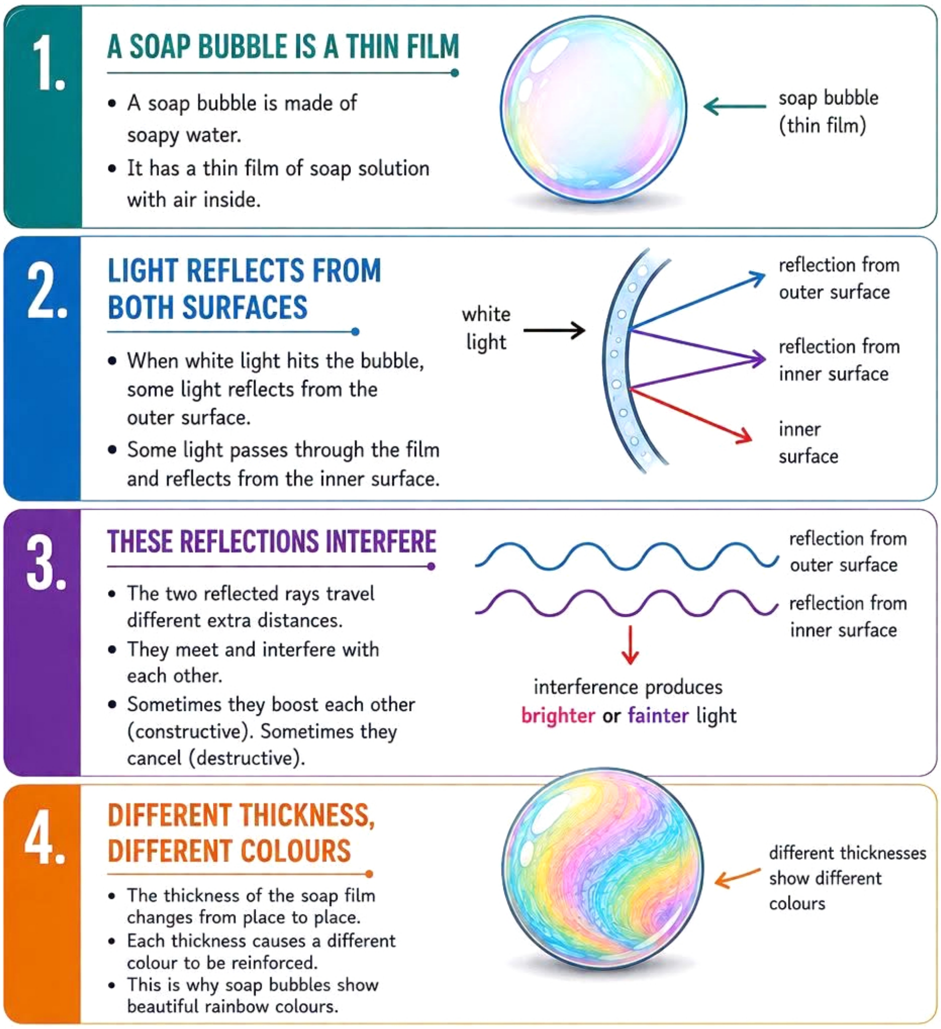
If we put a soap film vertically, then gravity will make it denser at the bottom. The result is the following:



Note at the very top, the film is black because there is complete destructive interference for all wavelengths. Similar patterns can be seen in soap bubbles:



Explanation:



1. A SOAP BUBBLE IS A THIN FILM

- A soap bubble is made of soapy water.
- It has a thin film of soap solution with air inside.

soap bubble
(thin film)

2. LIGHT REFLECTS FROM BOTH SURFACES

- When white light hits the bubble, some light reflects from the outer surface.
- Some light passes through the film and reflects from the inner surface.

white
light
reflection from
outer surface
reflection from
inner surface
inner
surface

3. THESE REFLECTIONS INTERFERE

- The two reflected rays travel different extra distances.
- They meet and interfere with each other.
- Sometimes they boost each other (constructive). Sometimes they cancel (destructive).

reflection from
outer surface
reflection from
inner surface
interference produces
brighter or fainter light

4. DIFFERENT THICKNESS, DIFFERENT COLOURS

- The thickness of the soap film changes from place to place.
- Each thickness causes a different colour to be reinforced.
- This is why soap bubbles show beautiful rainbow colours.

different thicknesses
show different
colours

Colour due to thin-film interference is known as "iridescence". The color of many butterflies and the gorgets of hummingbirds is due to iridescence:

10.6.1.3 Fresnel coefficients

Now let's consider the more general case. Suppose we have a plane wave moving in the $\vec{k}$ direction towards a surface with normal vector $\vec{n}$. Thus the angle θ_1 that the wave is coming in at satisfies:

$$\vec{n}\circ\vec{k}=\|\vec{k}\|\|\vec{n}\|\cos(\theta_1) \tag{10.6.55}$$

The two vectors $\vec{k}$ and $\vec{n}$ form a plane.

There are two linearly independent possibilities for the polarization: the electric field $\vec{E}$ can be polarized in the $\vec{k}-\vec{n}$ plane of the boundary, or transverse to that plane.

We know that these are named "vertical polarizations" and "horizontal polarization" respectively. Snell's law then tells us the directions of the transmitted and reflected electric fields. The magnetic field is always determined by the electric field through (see page 4145):

$$\omega\vec{B}=\vec{k}\times\vec{E} \tag{10.6.56}$$

What we need to solve for is the amplitude of the transmitted and reflected fields! The two cases look like (crosses indicate vectors point into the page, and dots that the vectors come out):

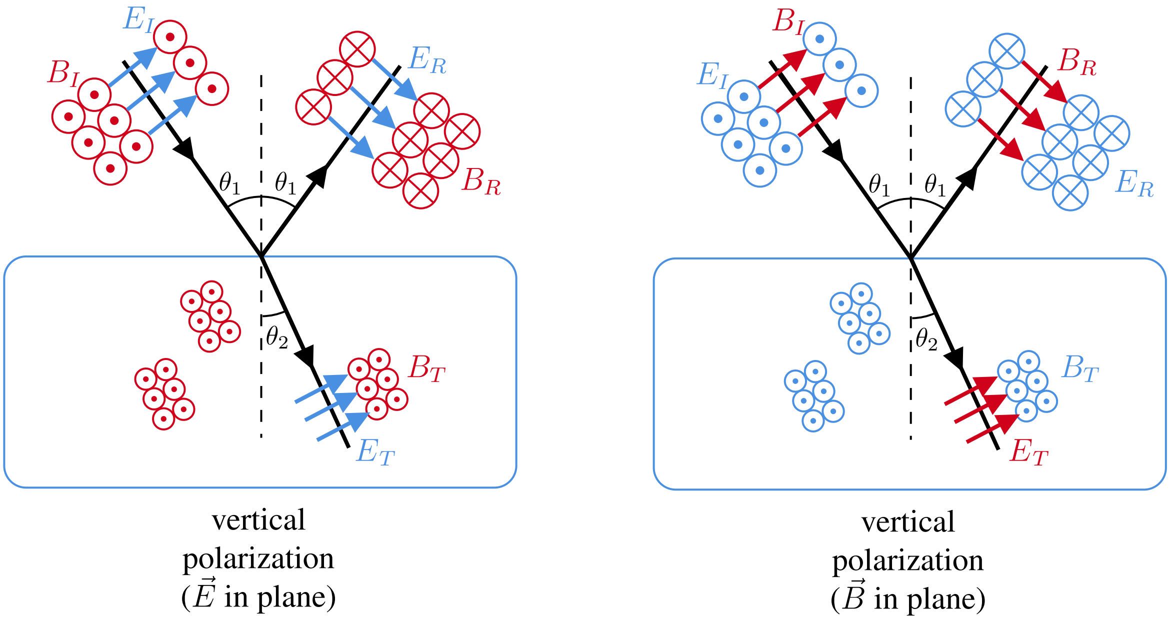


Figure 10.223: Two linearly independent linear polarizations are vertical and horizontal

Let's start with vertical polarization. From the left figure above we see that $\vec{B}$ is always parallel to the surface, so $B_\perp=0$. The electric field has for components project on the surface of the interface between the two medium (i.e. the parallel component):

$$E_\parallel^I=E^I\cos(\theta_1)\qquad E_\parallel^R=E^R\cos(\theta_1)\qquad E_\parallel^T=E_T\cos(\theta_2) \tag{10.6.57}$$

as well as:

$$E_\perp^I=E^I\sin(\theta_1)\qquad E_\perp^R=-E^R\sin(\theta_1)\qquad E_\perp^T=E_T\sin(\theta_2) \tag{10.6.58}$$

The reader can check that when $\theta_1=\theta_2=0$, this reduces to the normal incidence case see earlier above, so we have the sines and cosines right.

Note the relative sign between $E_\perp^I$ and $E_\perp^R$. You can check this sign because when $\theta=\pi/2$, then E_I points up and E_R points down, i.e. they have opposite signs. There is similar sign flip between B_I and B_R, as can be seen in the figure, since $\vec{B}$ always lags behind $\vec{E}$ by $\pi/2$.

Now we simply plug these relations into our boundary conditions and solve as seen earlier above (see page 4477):

$$\varepsilon_1 E_\perp^{(1)}=\varepsilon_2 E_\perp^{(2)} \qquad E_{||}^{(1)}=E_{||}^{(2)} \tag{10.6.59}$$

imply:

$$\begin{gathered}\varepsilon_1 E_I\sin(\theta_1)-\varepsilon_1 E_R\sin(\theta_1)=\varepsilon_2 E_T\sin(\theta_2)\\ E_I\cos(\theta_1)+E_R\cos(\theta_1)=E_T\cos(\theta_2)\end{gathered} \tag{10.6.60}$$

Hence:

$$\begin{gathered}\varepsilon_1\sin(\theta_1)(E_I-E_R)=\varepsilon_2 E_T\sin(\theta_2)\\ \cos(\theta_1)(E_I+E_R)=E_T\cos(\theta_2)\end{gathered} \tag{10.6.61}$$

The relation:

$$B_\perp^{(1)}=B_\perp^{(2)} \tag{10.6.62}$$

is trivially satisfied since $B_\perp=0$. Finally, the relation:

$$\frac{1}{\mu_1}B_{||}^{(1)}=\frac{1}{\mu_2}B_{||}^{(2)} \tag{10.6.63}$$

implies:

$$\frac{1}{\mu_1}(B_I-B_R)=\frac{1}{\mu_2}B_T \tag{10.6.64}$$

Using $B=E/v$ this last relation becomes:

$$\frac{1}{v_1\mu_1}(E_I-E_R)=\frac{1}{v_2\mu_2}E_T \tag{10.6.65}$$

Injecting it in:

$$\varepsilon_1\sin(\theta_1)(E_I-E_R)=\varepsilon_2 E_T\sin(\theta_2) \tag{10.6.66}$$

we get:

$$\varepsilon_1 v_1\mu_1\sin(\theta_1)=\varepsilon_2 v_2\mu_2\sin(\theta_2) \tag{10.6.67}$$

Using:

$$v=\frac{1}{\sqrt{\mu\varepsilon}} \qquad \text{and} \qquad n=\frac{c}{v}=\sqrt{\frac{\mu\varepsilon}{\mu_0\varepsilon_0}} \tag{10.6.68}$$

We have for example:

$$\varepsilon_1 v_1 \mu_1 = \frac{\varepsilon_1 \mu_1}{\sqrt{\varepsilon_1 \mu_1}} = \frac{\sqrt{\varepsilon_1 \mu_1}}{\sqrt{\varepsilon_1 \mu_1}} \frac{\varepsilon_1 \mu_1}{\sqrt{\varepsilon_1 \mu_1}} = \sqrt{\varepsilon_1 \mu_1} \tag{10.6.69}$$

Hence:

$$\sqrt{\varepsilon_1 \mu_1} \sin(\theta_1) = \sqrt{\varepsilon_2 \mu_2} \sin(\theta_2) \tag{10.6.70}$$

we then get by dividing both sides by $\sqrt{\varepsilon_0 \mu_0}$:

$$n_1 \sin(\theta_1) = n_2 \sin(\theta_2) \tag{10.6.71}$$

which is Snell's law. It is reassuring that our derivation here reproduces Snell's law...

To simplify the solution it is helpful to define one parameter which depends on the angles but not on the materials:

$$\alpha \equiv \frac{\cos(\theta_2)}{\cos(\theta_1)} \tag{10.6.72}$$

and another which depends only on the materials:

$$\beta = \frac{Z_1}{Z_2} = \frac{n_2 \mu_1}{n_1 \mu_2} = \frac{n_1 \varepsilon_2}{n_2 \varepsilon_1} = \frac{\varepsilon_2 v_2}{\varepsilon_1 v_1} = \sqrt{\frac{\varepsilon_2 \mu_1}{\varepsilon_1 \mu_2}} \tag{10.6.73}$$

Then the equations:

$$\begin{gathered}\frac{1}{v_1 \mu_1}(E_I - E_R) = \frac{1}{v_2 \mu_2} E_T \\ \cos(\theta_1)(E_I + E_R) = E_T \cos(\theta_2)\end{gathered} \tag{10.6.74}$$

reduce to:

$$\begin{gathered}E_I - E_R = \beta E_T \\ E_I + E_R = \alpha E_T\end{gathered} \tag{10.6.75}$$

with solutions (keep in mind that's for the vertical polarization!):

$$E_R^{\text{vert}} = \frac{\alpha - \beta}{\alpha + \beta} E_I^{\text{vert}}, \quad E_T^{\text{vert}} = \frac{2}{\alpha + \beta} E_I^{\text{vert}}, \quad n_1 \sin(\theta_1) = n_2 \sin(\theta_2) \tag{10.6.76}$$

The solution for horizontal polarization would lead to a similar result:

$$E_R^{\text{horiz}} = \frac{\alpha\beta - 1}{\alpha\beta + 1} E_I, \quad E_T^{\text{horiz}} = \frac{2}{\alpha\beta + 1} E_I, \quad n_1 \sin(\theta_1) = n_2 \sin(\theta_2) \tag{10.6.77}$$

These are known as "Fresnel coefficients". The Fresnel coefficients tell us how much of each polarization is reflected and transmitted. Since any polarization vector can be written as a linear combination of vertical and horizontal polarizations, we can use the Fresnel coefficients to understand how any polarizations reflect.

To interpret the Fresnel coefficients, we would like to know not just the amplitude of the wave transmitted, but the intensity of the light that passes through, or equivalently the power. Recall that the power in a plane wave in the vacuum is (see section Electrodynamics page 4156):

$$P_{\text{tot}} = c\varepsilon_0 \|\vec{E}\|^2 \tag{10.6.78}$$

For a plane wave in a medium, ε changes and only the component of the velocity moving into the medium is relevant, so this becomes (if we don't multiply the $\cos(\theta)$ we wouldn't have conservation of energy as we will check it further below!):

$$P=v\cos(\theta)\varepsilon\|\vec{E}\|^2=\cos(\theta)\sqrt{\frac{\varepsilon}{\mu}}\|\vec{E}\|^2=\frac{\cos(\theta)}{Z}\|\vec{E}\|^2=\frac{\cos(\theta)}{Z}E^2 \tag{10.6.79}$$

Thus the fraction of power reflected for vertical and horizontal polarizations is by using the Fresnel coefficients relations:

$$\frac{P_R^{\text{vert}}}{P_I^{\text{vert}}}=\left(\frac{\alpha-\beta}{\alpha+\beta}\right)^2 \qquad \frac{P_R^{\text{horiz}}}{P_I^{\text{horiz}}}=\left(\frac{\alpha\beta-1}{\alpha\beta+1}\right)^2 \tag{10.6.80}$$

For the fraction of power transmitted, and:

$$\frac{P_T^{\text{vert}}}{P_I^{\text{vert}}}=\frac{\cos(\theta_2)}{\cos(\theta_1)}\frac{Z_1}{Z_2}\left(\frac{2}{\alpha+\beta}\right)^2=\alpha\beta\left(\frac{2}{\alpha+\beta}\right)^2 \tag{10.6.81}$$

and:

$$\frac{P_T^{\text{horiz}}}{P_I^{\text{horiz}}}=\frac{\cos(\theta_2)}{\cos(\theta_1)}\frac{Z_1}{Z_2}\left(\frac{2}{\alpha\beta+1}\right)^2=\alpha\beta\left(\frac{2}{\alpha\beta+1}\right)^2 \tag{10.6.82}$$

Remark

If $\theta_1=\theta_2=0$ we have $\alpha=1$ and if $\mu_1=\mu_2$ (no polarization), then:

$$\frac{P_R^{\text{vert}}}{P_I^{\text{vert}}}=\left(\frac{\alpha-\beta}{\alpha+\beta}\right)^2=\left(\frac{n_1-n_2}{n_1+n_2}\right)^2=R \tag{10.6.83}$$

and is named the "reflectance" or "reflectivity" or "power reflection coefficient".

For an air-water interface R is equal to approximately 4%. By depositing a thin metallic layer on the interface, we can bring back the reflective power very close to 100%: we then speak of "mirror". It is also possible to deposit a thin layer of MgF_2 to reduce the reflective power; we then speak of "anti-reflective layer".

One can check that for either polarization (just put the above relation inside this identity) energy conservation is respected:

$$P_T+P_R=P_I\Leftrightarrow\frac{P_T}{P_I}+\frac{P_R}{P_I}=1 \tag{10.6.84}$$

If the reader remember, for the normal case we get earlier for the reflected power:

$$P_R=\frac{E_R^2}{Z_1}A=\left(\frac{Z_2-Z_1}{Z_2+Z_1}\right)^2\frac{E_I^2}{Z_1}A=\left(\frac{Z_1-Z_2}{Z_1+Z_2}\right)^2P_I \tag{10.6.85}$$

and the for transmitted power :

$$P_T=\frac{E_T^2}{Z_2}A=\left(\frac{2Z_2}{Z_2+Z_1}\right)^2\frac{E_I^2}{Z_2}A=\frac{4Z_1Z_2}{(Z_1+Z_2)^2}\frac{E_I^2}{Z_1}A=\frac{4Z_1Z_2}{(Z_1+Z_2)^2}P_I \tag{10.6.86}$$

And obviously we get the equality with the previous expression only if the conditions of the normal incidence are met. That is:

$$\alpha = 1, \beta = \frac{Z_1}{Z_2} \qquad (10.6.87)$$

And that makes completely sense! This is another evidence that our previous results are not so wrong...

For example, the air-glass interface has $\beta = 1.5$. Then the transmitted and reflected power in vertical and horizontal polarizations are:

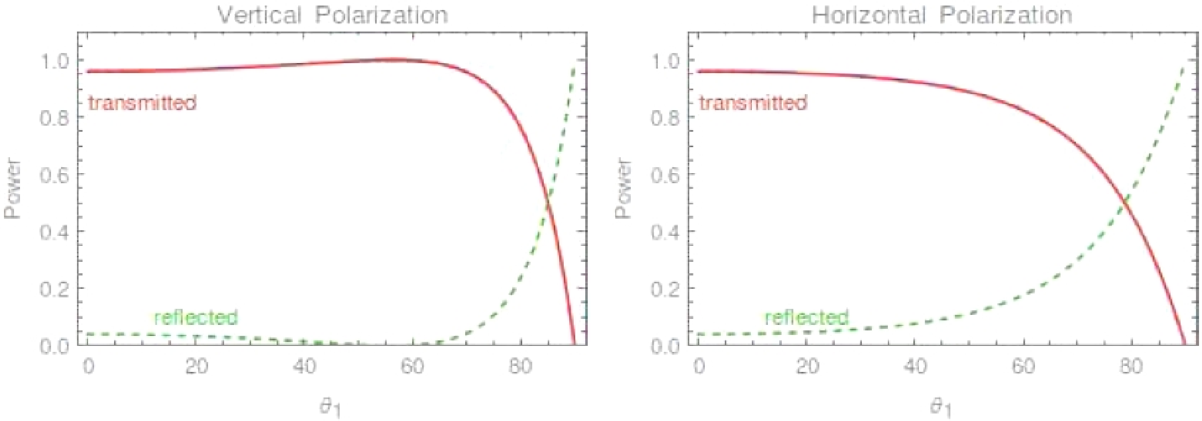

Figure 10.224: **Transmitted and reflected power as a function of incident angle for the two polarizations**

We can also plot the ratio of power reflected in vertical to horizontal polarizations:

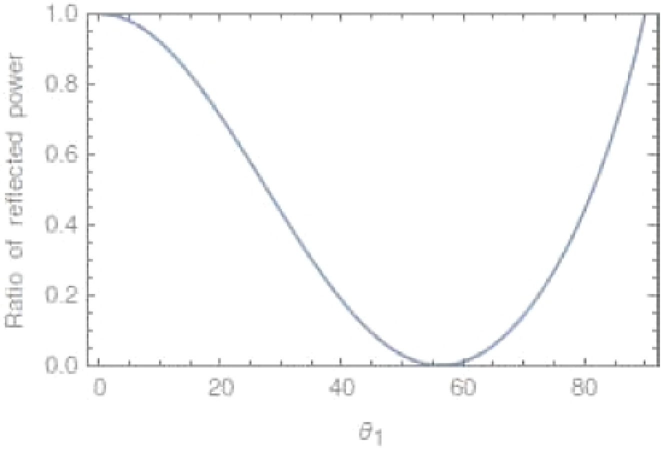

Figure 10.225: **Ratio $P_R^{\text{vert}}/P_R^{\text{horiz}}$ of power reflected vertically polarized horizontally**

From these plots we see there is an angle where the vertical polarization exactly vanishes. This angle is named the "Brewster's angle", θ_B. We can see from the plots that for the glass-air interface $\theta_B \approx 56°$. At this angle, the reflected light is completely (uniquely) polarized.

We can also see that Brewster's angle is an angle of incidence at which light with a particular polarization is perfectly transmitted through a transparent dielectric surface, with no reflection.

What is the general formula for θ_B? From the fraction of power reflected for vertical and horizontal polarizations is:

$$\frac{P_R^{\text{vert}}}{P_I^{\text{vert}}} = \left(\frac{\alpha - \beta}{\alpha + \beta}\right)^2 \qquad \frac{P_R^{\text{horiz}}}{P_I^{\text{horiz}}} = \left(\frac{\alpha\beta - 1}{\alpha\beta + 1}\right)^2 \tag{10.6.88}$$

we see that $P_R^{\text{vert}} = 0$ when $\alpha = \beta$. That is:

$$\frac{\cos(\theta_2)}{\cos(\theta_B)} = \sqrt{\frac{\varepsilon_2\mu_1}{\varepsilon_1\mu_2}} \tag{10.6.89}$$

For most materials $\mu_1 \sim \mu_2 \approx \mu_0$. Then we can use $n = \sqrt{\mu\varepsilon}$ to get:

$$\frac{\cos(\theta_2)}{\cos(\theta_B)} = \frac{n_2}{n_1} \tag{10.6.90}$$

Using also:

$$n_1 \sin(\theta_B) = n_2 \sin(\theta_2) \tag{10.6.91}$$

we can solve for θ_B giving:

$$\tan(\theta_B) = \frac{n_2}{n_1} \tag{10.6.92}$$

Hence the Brewster's angle:

$$\boxed{\theta_B = \tan^{-1}\left(\frac{n_2}{n_1}\right)} \tag{10.6.93}$$

For the air-water interface, $\theta_B = \tan^{-1}(1.5) = 56.3°$. One can see from the previous figure that one does not have to be exactly at this angle to have little reflected vertical polarization. Angles close to θ_B work almost as well.

What is going on physically at Brewster's angle? We know that Snell's law:

$$n_1 \sin(\theta_1) = n_2 \sin(\theta_2) \tag{10.6.94}$$

is always satisfied. At Brewster's angle, when $\theta_1 = \theta_B$, we found also $n_1 \cos(\theta_2) = n_2 \cos(\theta_1)$.

Dividing these two relations gives:

$$\cos(\theta_1)\sin(\theta_1) = \cos(\theta_2)\sin(\theta_2) \tag{10.6.95}$$

or equivalently:

$$\sin(2\theta_1) = \sin(2\theta_2) \qquad \text{when } \theta_1 = \theta_B \tag{10.6.96}$$

Now, by definition θ_1 and θ_2 are both between 0 and $\frac{\pi}{2}$, so $2\theta_1$ and $2\theta_2$ are between 0 and π. Thus:

$$\sin(2\theta_1) = \sin(2\theta_2) \tag{10.6.97}$$

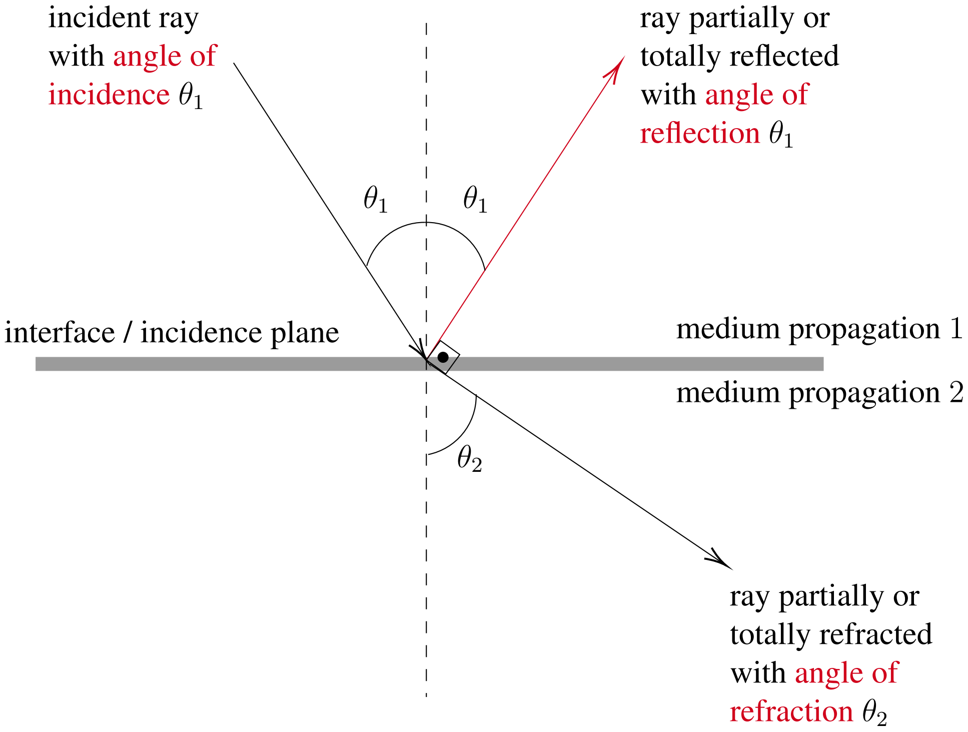
has two solutions. Either $\theta_1 = \theta_2$, which corresponds to $n_1 = n_2$ so the light just passes through, or:

$$\frac{\pi}{2} - 2\theta_1 = 2\theta_2 - \frac{\pi}{2} \qquad (10.6.98)$$

which simplifies to:

$$\theta_1 + \theta_2 = \frac{\pi}{2} \qquad (10.6.99)$$

Using simple geometry we see that the transmitted (i.e. refracted) and reflected waves are perpendicular at Brewster's angle:



incident ray
with angle of
incidence θ_1
ray partially or
totally reflected
with angle of
reflection θ_1
θ_1
θ_1
interface / incidence plane
medium propagation 1
medium propagation 2
θ_2
ray partially or
totally refracted
with angle of
refraction θ_2

Since the reflected wave has to be produced by the motion of particles in the surface we can interpret why there may be no reflection of the vertical polarization component at Brewster's angle: at this angle particles moving in the surface can only produce light polarized transverse to their direction of motion and a Brewster's angle the vertical motion is hard or even impossible.

10.6.2 Fraunhofer Diffraction

From the point of view of geometrical optics, a light beam is a cylinder of section Σ which brings together a large number of parallel rays. It is therefore assumed to be straight when it is set in a homogeneous medium.

The "energy emittance" M $[\mathrm{W}\cdot\mathrm{m}^{-2}]$ of the beam varies only if a lens (or another device) make vary its section Σ or if the medium absorbs energy.

The light beam "bursts" when an obstacle allows only a portion of its section Σ.

Huygens' principle shows that it is the edges of the obstacle that generate this diffraction.

The phenomenon is general but is well observed only if the ratio L/Σ is very large. L being the length of the edges. This condition is necessary so that the intensity of the undiffracted portion of the beam does not mask the effect.

D1. We speak of "Fraunhofer diffraction" when, as assumed above, the incident light rays are parallel and the phenomenon observed at relatively large distance from the screen.

D2. We speak of "Fresnel diffraction" when the incident rays form a divergent beam from a point source or if we observe the phenomenon at close range.

Let us consider a generic case and in fact the most widespread case in the physics laboratories which is the diffraction by a narrow rectangular aperture!

For this, we consider that the incident beam, perpendicular to the aperture, has a plane electromagnetic periodic wavefront and is given by (see section Wave Mechanics page 3479):

$$f(x,t)=\hat{f}\sin(kx-\omega t) \tag{10.6.100}$$

where for recall, its wavelength is given by:

$$\lambda=\frac{2\pi}{k} \tag{10.6.101}$$

10.6.2.1 Case of a small rectangular aperture (slit)

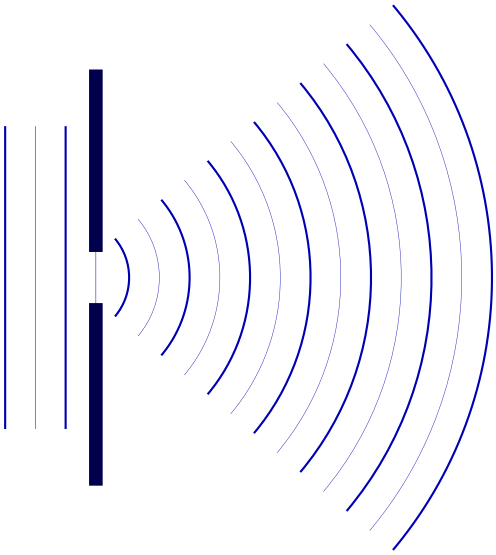
The span width e of the aperture is oriented along the y axis, the height h (parameter that can not be represented in the figure below because it is a view from above) is assumed as very big so we can neglect the border effects.

Following the Huygens principle (see page 4470), the front of the plane wave, delimited by the aperture, is a multitude of sources $\mathrm{d}f(x,t)$, of width $\mathrm{d}y$, which emit in phase, spherical wavelet described by their associated field vector:

$$\mathrm{d}f(x,t)=\frac{\hat{f}}{e}\mathrm{d}y\sin(kx-\omega t) \tag{10.6.102}$$

Now consider an observation point P, at a distance R from the source (assimilated to an aperture). We have proved during our study of the emission sources of spherical type (see section Electrodynamics page 4160) that their amplitude decreases inversely proportional to the distance as:

$$\mathrm{d}f(x,t)=\frac{\hat{f}}{eR}\mathrm{d}y\sin(kx-\omega t) \tag{10.6.103}$$



Remark

Using modern phasor notation the above relation can be found in many textbooks in the following form:

$$\mathrm{d}f(x,t)=\frac{\hat{f}}{eR}e^{\mathrm{i}(kx-\omega t)}\mathrm{d}y$$

or some textbooks replace the source strength per unit length $\hat{f}/e$ (assumed uniform!) by a new term like:

$$\mathrm{d}f(x,t)=\frac{\hat{\rho}_L}{R}e^{\mathrm{i}(kx-\omega t)}\mathrm{d}y$$

However, the wavelets, each depending on the point of the aperture to which it is assimilated, will not all travel the same distance R but a distance proper distance r. However, if R is sufficiently distant from the aperture, we will allow ourselves to approximate:

$$\frac{\hat{f}}{eR}\cong\frac{\hat{f}}{er} \tag{10.6.104}$$

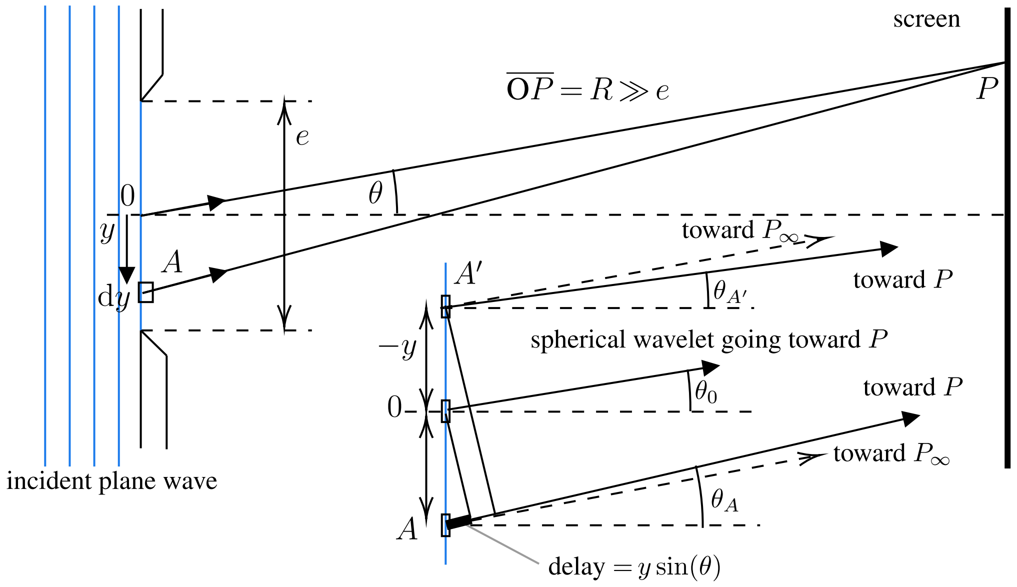
remains still the periodic term $\sin(kx-\omega t)$ where we put $x=r$. But we have for extremal values:

$$R-\frac{e}{2}\sin(\theta)\leq r\leq R+\frac{e}{2}\sin(\theta) \tag{10.6.105}$$

These extremal values correspond respectively, to the advance and the delay of the wave function describing the propagation of the wavelet at the borders of the aperture.

Indeed, it is enough to see the figure below, considering $R \gg e$ and therefore:

$$\theta := \theta_{A'} \cong \theta_0 \cong \theta_A \tag{10.6.106}$$



screen
$\overline{\mathrm{O}P} = R \gg e$
P
e
θ
0
y
A
dy
toward P_∞
A'
toward P
$\theta_{A'}$
spherical wavelet going toward P
$-y$
θ_0
toward P
0
toward P_∞
θ_A
A
delay $= y\sin(\theta)$
incident plane wave

Thus, by placing the origin of the y coordinate in the middle of the aperture, we have:

$$\mathrm{d}f(x,t) = \frac{\hat{f}}{eR}\mathrm{d}y\sin(kr-\omega t) = \frac{\hat{f}}{eR}\mathrm{d}y\sin(k(R+y\sin(\theta))-\omega t) \tag{10.6.107}$$

So the different wavelets are out of phase and produce interferences.

Definition (#10.6.497): In wave mechanics, we speak of "interference" to describe a phenomenon in which two waves superpose to form a resultant wave of greater, lower, or the same amplitude. Interference usually refers to the interaction of waves that are correlated or coherent with each other, either because they come from the same source or because they have the same or nearly the same frequency. Interference effects can be observed with all types of waves, for example, light, radio, acoustic, surface water waves or matter waves.

The diffracted wave in the direction of θ, is given by the sum of all contributions:

$$f(x,t) = \frac{\hat{f}}{eR}\int\limits_{-e/2}^{+e/2}\sin(k(R+y\sin(\theta))-\omega t)\mathrm{d}y = \frac{\hat{f}}{eR}\int\limits_{-e/2}^{+e/2}\sin((kR-\omega t)+ky\sin(\theta))\mathrm{d}y \tag{10.6.108}$$

Knowing that (trigonometric relation are explicited on request of a reader):

$$\begin{aligned}\int\limits_{-e/2}^{+e/2}\sin(a+by)\mathrm{d}y&=\int\limits_{-e/2}^{+e/2}(\cos(a)\sin(by)+\sin(a)\cos(by))\mathrm{d}y\\&=\cos(a)\int\limits_{-e/2}^{+e/2}\sin(by)\mathrm{d}y+\sin(a)\int\limits_{-e/2}^{+e/2}\cos(by)\mathrm{d}y\\&=-\frac{\cos(a)\cos(by)}{b}+\frac{\sin(a)\sin(by)}{b}\Bigg|_{-e/2}^{+e/2}\\&=\frac{2\sin(a)\sin\left(b\dfrac{e}{2}\right)}{b}\end{aligned}\tag{10.6.109}$$

We have therefore:

$$\begin{aligned}f(x,t)&=\frac{\hat{f}}{eR}\int\limits_{-e/2}^{e/2}\sin((kR-\omega t)+ky\sin(\theta))\mathrm{d}y=\frac{\hat{f}}{eR}\frac{2\sin(kR-\omega t)\sin\left(k\sin(\theta)\dfrac{e}{2}\right)}{k\sin(\theta)}\\&=\frac{\hat{f}}{R}\frac{\sin\left(k\sin(\theta)\dfrac{e}{2}\right)}{\dfrac{ek\sin(\theta)}{2}}\sin(kR-\omega t)=\frac{\hat{f}}{R}\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)}\sin(kR-\omega t)\end{aligned}\tag{10.6.110}$$

We have proved in the section Electrodynamics that the energy (i.e. the intensity) of an electromagnetic wave was given (in vacuum) by the average scalar value of the Poynting vector:

$$\bar{S}=\frac{\hat{E}\hat{B}}{2\mu_0}\tag{10.6.111}$$

We therefore have by considering that the magnetic and electric field are proportional to the term:

$$\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)}\tag{10.6.112}$$

the following result:

$$\bar{S}\propto\overline{S_0}\left(\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)}\right)^2=\overline{S_0}\left(\frac{\sin\left(\pi\Gamma\sin(\theta)\right)}{\pi\Gamma\sin(\theta)}\right)^2\tag{10.6.113}$$

which is the luminous emittance emitted in the direction θ and where have put:

$$\Gamma=\frac{e}{\lambda}\tag{10.6.114}$$

If we introduce the sinus cardinal sinc that we have meet in our study of Fourier transforms in the section of Sequences and Series and that was defined in the section Trigonometry then we can write the previous relation in a more clearly condensed way:

$$\bar{S}\propto\overline{S_0}\mathrm{sinc}^2(\pi\Gamma\sin(\theta))\tag{10.6.115}$$

For which can have a generic form plotted with Maple™ 4.00b using:

```
>Gamma:=3;plot((sin(Gamma*x)/(Gamma*x))^2, x=-Pi..Pi);
```

So we can get the same result by taking the squared modulus of the Fourier transform of a monochromatic signal through a rectangular window. Thus, it seems possible to study the phenomena of diffraction by using the Fourier transform, and this area is named "Fourier optics" that we will study later.

Here is a graphical representation of the relation $\bar{S}/\overline{S_0}$ for different values of the ratio $\Gamma = e/\lambda$:

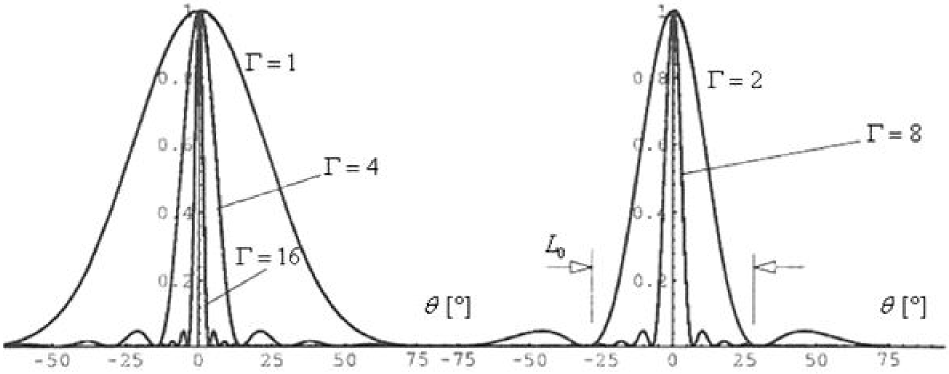


Figure 10.226: **Representation of diffraction fringes**

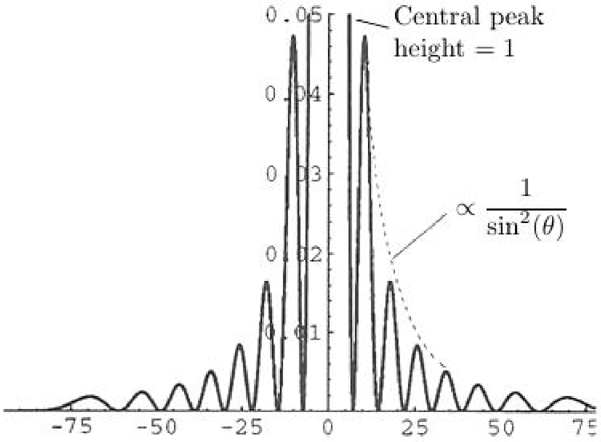
On either side of the central fringe, there are other fringes, more narrow and arranged symmetrically. Their intensity decreases very rapidly as the preponderant term at the denominator:

$$\frac{\overline{S_{\max}}}{\overline{S_0}} \propto \frac{1}{(\pi\Gamma\sin(\theta))^2} = \frac{\lambda^2}{\pi^2 e^2}\frac{1}{\sin^2(\theta)} \qquad (10.6.116)$$



from which we have a real image here:

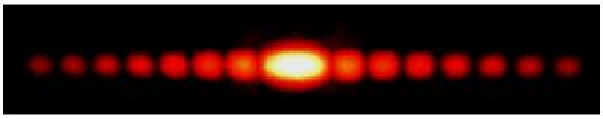


Figure 10.227: **Photo of a real Fraunhofer diffraction fringe of a rectangular aperture**

Between the fringes, there are dark areas that are the seat of destructive interference. Their position is given by the condition:

$$\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)=0\Rightarrow\frac{\pi e}{\lambda}\sin(\theta)=n\pi \tag{10.6.117}$$

excepted for $n=0\Rightarrow\theta=0$ where we observe a maximum!

So we see black bands in the directions:

$$\theta_n=\arcsin\left(\frac{n\lambda}{e}\right)\qquad\forall n\in\mathbb{N}^* \tag{10.6.118}$$

Thus the angular width of the central band is twice the angular value obtained for the first minimum:

$$L_0=2R\arcsin\left(\frac{\lambda}{e}\right) \tag{10.6.119}$$

We get the width of the following peaks as follows:

Two successive minima satisfy the conditions:

$$\sin(\theta_n)=\frac{n\lambda}{e}\qquad\sin(\theta_{n+1})=\frac{(n+1)\lambda}{e} \tag{10.6.120}$$

Therefore:

$$\begin{aligned}\sin(\theta_n)-\sin(\theta_{n+1})=\frac{\lambda}{e}&=2\sin\left(\frac{\theta_{n+1}-\theta_n}{2}\right)\cos\left(\frac{\theta_{n+1}-\theta_n}{2}\right)\\&=2\sin\left(\frac{\Delta\theta}{2}\right)\cos\left(\frac{\theta_{n+1}-\theta_n}{2}\right)\end{aligned} \tag{10.6.121}$$

Put putting:

$$\frac{\theta_{n+1}+\theta_n}{2}\cong\theta \tag{10.6.122}$$

Therefore it comes:

$$\Delta\theta=2\arcsin\left(\frac{\lambda}{2e\cos(\theta)}\right) \tag{10.6.123}$$

Since the emittance decreases very rapidly, only the first bands (for which $\cos(\theta)\cong 1$) are observable. Therefore it remains:

$$L_n=2R\arcsin\left(\frac{\lambda}{2e}\right)\cong\frac{L_0}{2} \tag{10.6.124}$$

The positions of the maxima are then given by the condition:

$$\begin{aligned}\frac{\mathrm{d}M}{\mathrm{d}\theta}&=0=\frac{\mathrm{d}}{\mathrm{d}\theta}\left(\frac{\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)}{\frac{\pi e}{\lambda}\sin(\theta)}\right)=\frac{\lambda}{\pi e}\frac{\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)}{\sin(\theta)}\\&=\frac{\lambda}{\pi e}\frac{1}{\sin^2(\theta)}\left[\sin(\theta)\frac{\mathrm{d}}{\mathrm{d}\theta}\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)-\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)\frac{\mathrm{d}}{\mathrm{d}\theta}\sin(\theta)\right]\\&=\frac{\lambda}{\pi e}\frac{1}{\sin^2(\theta)}\left[\sin(\theta)\cos\left(\frac{\pi e}{\lambda}\sin(\theta)\right)\frac{\pi e}{\lambda}\cos(\theta)-\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)\cos(\theta)\right]\\&=\cos\left(\frac{\pi e}{\lambda}\sin(\theta)\right)\cot(\theta)-\frac{\lambda}{\pi e}\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)\frac{\cot(\theta)}{\sin(\theta)}\\&\Rightarrow\cos\left(\frac{\pi e}{\lambda}\sin(\theta)\right)\cot(\theta)=\frac{\lambda}{\pi e}\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)\frac{\cot(\theta)}{\sin(\theta)}\Rightarrow\tan\left(\frac{\pi e}{\lambda}\sin(\theta)\right)\\&=\frac{\pi e}{\lambda}\sin(\theta)\end{aligned}\tag{10.6.125}$$

Let us put:

$$\phi=\frac{\pi e}{\lambda}\sin(\theta)\tag{10.6.126}$$

The numerical resolution of:

$$\tan(\phi)=\phi\tag{10.6.127}$$

gives:

$$\phi=\pm\{0,4.49,7.72,10.9,14.1\ldots\}\tag{10.6.128}$$

The positions of the successive maxima are then:

$$\begin{aligned}&\phi=0\Rightarrow\theta=0\\&\phi=4.49\Rightarrow\theta=\arcsin\left(\frac{4.49}{\pi}\frac{\lambda}{e}\right)\cong\arcsin\left(1.5\frac{\lambda}{e}\right)\end{aligned}\tag{10.6.129}$$

etc. We could have also easily get a decent approximation of this result, considering that the intensity is maximum when:

$$\left.\frac{\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)}{\frac{\pi e}{\lambda}\sin(\theta)}\right|_{\max}\cong\left.\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)\right|_{\max}\Rightarrow\sin\left(\frac{\pi e}{\lambda}\sin(\theta)\right)=1\Rightarrow\frac{\pi e}{\lambda}\sin(\theta)=(2n+1)\frac{\pi}{2}\tag{10.6.130}$$

Which bring us to write:

$$\theta_{\max,n}=\arcsin\left(\frac{(2n+1)\lambda}{2e}\right)\tag{10.6.131}$$

with $n\in\mathbb{N}^*$.

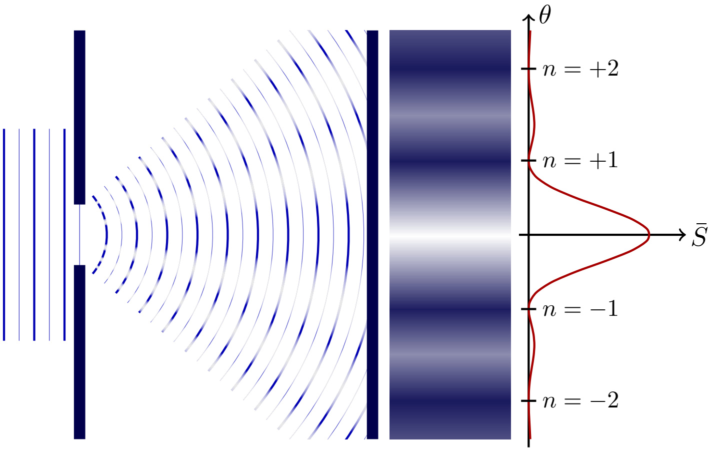

Figure 10.228: **The big picture of the diffraction single slit projection (author: Izaak Neutelings)**

A remarkable result of the Fraunhofer experience is that it challenges the corpuscular view of light as we had in the 119th century (holocene calendar).

Indeed, many experiments such at the projection of the shadow of an object on a wall seemed to show that the light was such a particle that does not pass through materials and being net stopped by any obstacle either in its center or by its edges (you must draw your attention to the "edges" in particular).

But, Fraunhofer experience and in particular that of Fresnel regarding the edges (we will see further because it is mathematically more difficult to study), show that the light appears to behave not as a single particle but as a wave (from the Huygens principle that we used for our developments) as we showed to us the earlier developments that perfectly explain the experimental results of Fraunhofer diffraction.

But then why keep the corpuscular model of light? Simply because of other experimental and theoretical results of which the best known are the photoelectric effect or Compton scattering (see section Nuclear Physics page 5096), which can be explained theoretically quite well if it is not perfectly with a corpuscular model light (and also with some other particle of different size, charge, spin, etc.).

By the early 11800s (holocene calendar), there were two theories about the nature of light. One of them, going back to Newton, is that light is a ray. But there was another idea – going back even farther (to Christiaan Huygens) – that light might also be a wave. And this gained a lot of support in 11799 (holocene calendar), when Thomas Young first passed light through two thin, nearby slits. So if you're a good theorist, and you're interested in studying light, what do you do?

Well, if you're famed French mathematician and physicist Simeon Poisson, you would think of the most ridiculous configuration you could imagine in the hopes of disproving the light-is-a-wave theory. And that's exactly what he did in 11818 (holocene calendar).

He imagined that you took a wave source of light, and had it shine on and around a completely black, spherical obstacle, setting up a screen behind it. Obviously, he reasoned, you would see some light on the screen indicating the outside of the sphere, and darkness, or a shadow, on the inside.

But, he calculated, if the wave theory of light were correct, you would get something completely absurd!

Sure, you'd get light on the outside, and shadow on the inside, but what's that at the very center? Poisson predicted, using the wave theory of light, that you'd actually get a bright spot of light at the very center of this shadow! How absurd was that! And therefore, he reasoned, the wave theory of light was absolutely crazy, and had to be wrong.

Shortly after Poisson's prediction, Francois Arago decided to put the theory to the test, and actually performed the experiment to look for the "theoretically absurd" spot.

And what happens if, in fact, you perform this experiment yourself? :

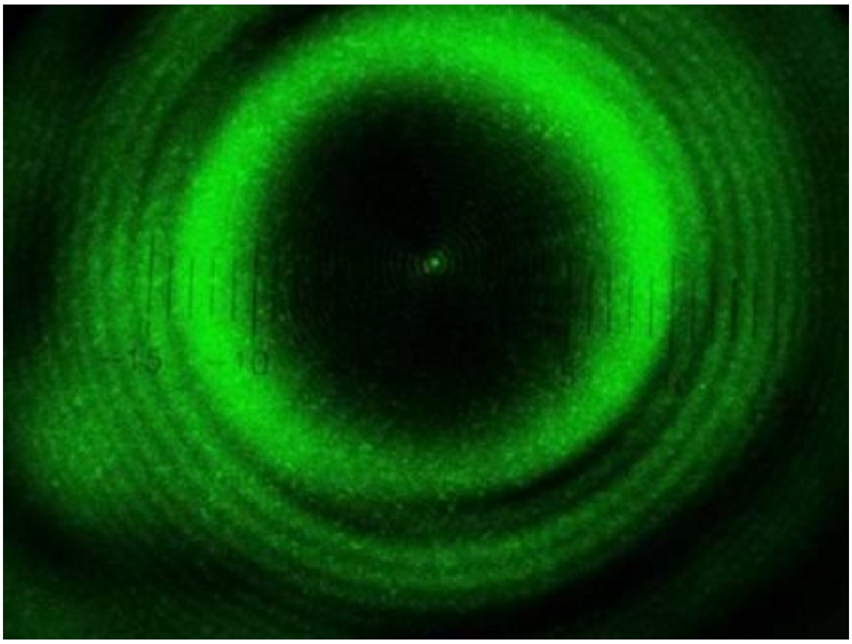

Figure 10.229: Arago spot (source: Thomas Bauer at Wellesley)

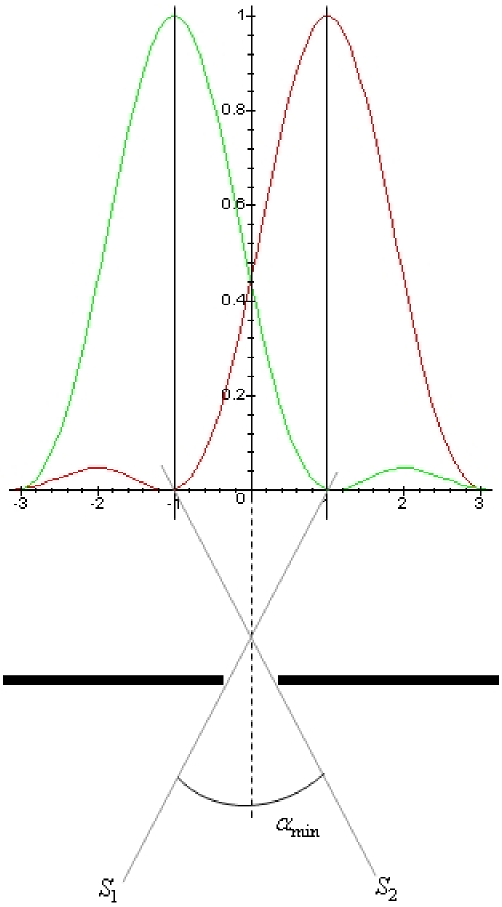
Amazingly, the spot is real! If your theory is any good, scientifically, this is exactly what it will do. It will not only explain what's already been observed, it will allow you to apply it to new situations, and make testable predictions about what you can expect to find. The crazier the prediction, and the more successful the experiment, the more compelling the theory becomes.

10.6.2.1.1 Optical resolution in the far field region for small rectangular aperture

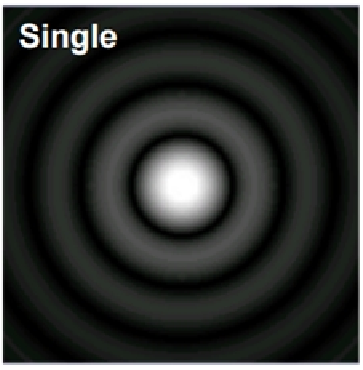
According to the criterion of the English physicist Lord Rayleigh: the "optical resolution" (or "power angular resolution") of a circular aperture, is the angle α_{min} between two light rays of wavelength λ, emitted from two point sources S_1,S_2, far away, whose diffraction figures are separated such that the first zero of the diffraction pattern is found at the place of the maximum of the other as illustrated below:

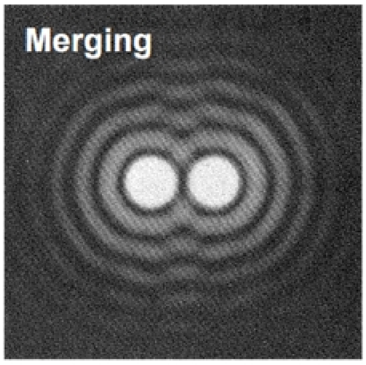


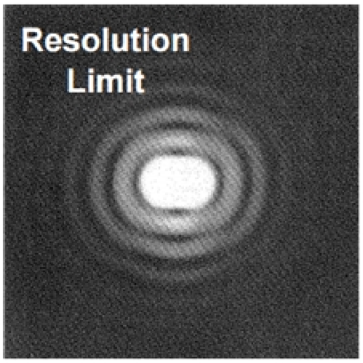
1
0.8
0.6
0.4
0.2
-3
-2
-1
0
2
3
$\alpha_{\min}$
S_1
S_2

Figure 10.230: Optical resolution as defined by Lord Rayleigh

Or with a photo of experiment perhaps it's better:







Resolution
Limit

This concept is used extensively in photography, astronomy, radio astronomy, etc. So the reader should pay a special attention to it!

Now we have proved that the minima for a rectangular aperture were given by:

$$\sin(\theta_n) = \frac{n\lambda}{e} \tag{10.6.132}$$

And if we take the case where $n=1$, we fall back on the relation available in many books without proof:

$$\boxed{\theta \cong \sin(\theta_n) = \frac{\lambda}{e} = \alpha_{\text{min}}} \tag{10.6.133}$$

named "Rayleigh criterion of a small rectangular aperture (slit)".

Therefore the angular resolution of a rectangular aperture is proportional to the ratio of the wavelength λ to the thickness e of the slot. Obviously in practice the goal is to have either:

1. A large as possible value of the angle α_{min} so that the objects (both source in this case) does not coincide and that their images are therefore distinct.
2. A small as possible value so that the sole observed object (only one source) do not have a blurry image. This is one reason why many popular books say you have to have a smaller wavelength than the observed object so that it is observable (so not too be blurred!).

To increase the resolving power to decrease the blur effect, so you have to be working with shorter wavelengths or increase the thickness of the slot of the instrument, as the wavelength is often imposed by the observed object, it is natural to make vary e.

Therefore if the light that passes through a slot (rectangular or circular!) forms an image on a screen, and that this image is observed under a microscope, for example, it is impossible, whatever the magnification of the microscope ,to observe more details in the image than it is allowed by the resolving power of the slot. We must take these considerations into account when we design of optical instruments.

10.6.2.2 Case of a network of small rectangular apertures (slits)

Let us now consider an array of N apertures of width $e\cong\lambda$, of height $H\gg e$ and distant each other by d. A single incident beam illuminates all apertures.

Remark

The study of this model will allow us to understand partially how the prism works and also the goniometer in astronomy for spectrum analysis as well as X-ray diffraction by a network of atoms (the importance of the latter being quite significant!).

Given the following figure:

to the screen at $R \to +\infty$

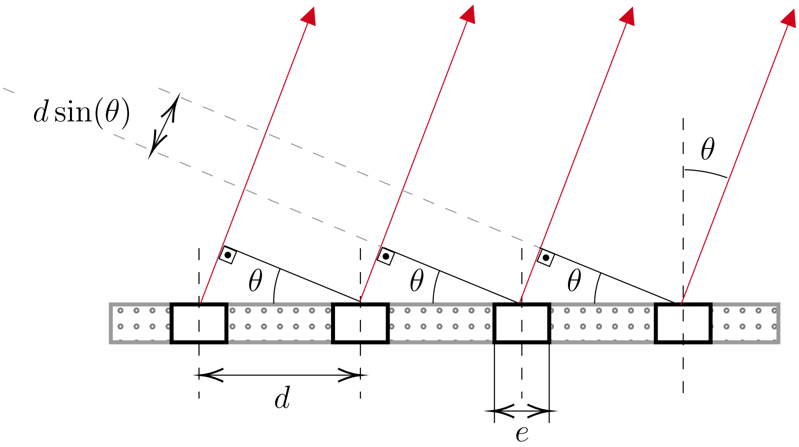


Figure 10.231: **Basic principle of the rectangular aperture network**

We see in the diagram above that for some directions θ, the distance $d\sin(\theta)$ is such that constructive or destructive interference are occurring. In optics, these devices are therefore wave splitters, that is to say that a wave is separated into two or more to make them interfere. We name these kind of configurations "wavefront splitting systems".

Let us consider that this network is placed in the YZ plane and the beam direction is along the X axis. We put ourselves in an observation point P in the XY plane. Following the properties of electromagnetic waves (see section Electrodynamics page 4138), the electric field vector $\vec{E}_i$ of the wave emitted by the i-th slot is perpendicular to the direction of observation and can be expressed as:

$$E_i(\theta,R,t)=\frac{\hat{E}_i(\theta)}{R}\sin(kR-\omega t) \tag{10.6.134}$$

and we also proved earlier above that:

$$f(R,t)=\frac{\hat{f}}{R}\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)}\sin(kR-\omega t) \tag{10.6.135}$$

where by analogy between these two relations, we recognize that:

$$\hat{E}_i(\theta)=\hat{f}\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)} \tag{10.6.136}$$

and therefore it comes:

$$\begin{gathered}\frac{\hat{E}_i(\theta)}{R}\sin(kR-\omega t)=\frac{\hat{E}_{i,\theta=0}}{R}\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)}\sin(kR-\omega t)\\ \Rightarrow\frac{\hat{E}_i(\theta)}{R}=\frac{\hat{E}_{i,\theta=0}}{R}\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)}\Rightarrow\hat{E}_i(\theta)=\hat{E}_{i,\theta=0}\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)}\end{gathered}\tag{10.6.137}$$

In any direction θ, the waves issued from the two adjacent apertures are out of phase of $d\sin(\theta)$ (where d is the step value between two apertures) and at the point P of observation, the resulting electric field is given by the sum of the contributions of each aperture with its own i-th shift. Therefore:

$$\begin{aligned}E(\theta,R,t)&=\sum_{i=1}^{N}E_i(\theta,R,t)=\sum_{i=1}^{N}\hat{E}_i(\theta)\sin(k(R+(i-1)d\sin(\theta))-\omega t)\\&=\hat{E}\sum_{i=1}^{N}\sin((kR-\omega t)+k(i-1)d\sin(\theta))\end{aligned}\tag{10.6.138}$$

So we see that each wave is out of phase of:

$$\Delta\varphi=kd\sin(\theta)=\frac{2\pi}{\lambda}d\sin(\theta)=c^{te}\tag{10.6.139}$$

We can now represent $E(\theta,R,t)$ using phasors (see section Wave Mechanics page 3510) in the phase space such that:

$$E(\theta,R,t)=\hat{E}\sum_{j=1}^{N}e^{\mathrm{i}[(kR-\omega t)+k(j-1)d\sin(\theta)]}=\hat{E}\sum_{j=1}^{N}e^{\mathrm{i}(kR-\omega t)}e^{\mathrm{i}k(j-1)d\sin(\theta)}\tag{10.6.140}$$

Which gives graphically for the second term containing the summation variable j for a fixed distance R:

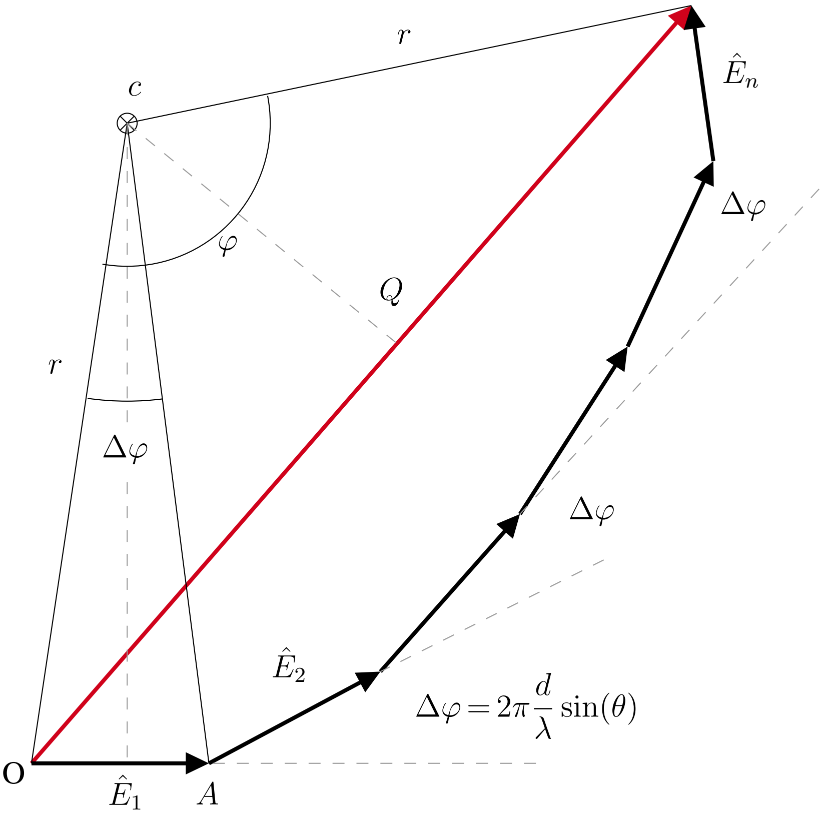

Figure 10.232: **Representation of the summation of terms**

We see that the $\vec{E}_i$ put together form a regular polygon inscribed in a circle of radius:

$$r = \frac{\frac{\hat{E}_i}{2}}{\sin\left(\frac{\Delta\varphi}{2}\right)} \tag{10.6.141}$$

The norm of the resulting electric field being equal to the chord defined by the angle:

$$\varphi = \sum_{i=1}^{N} \Delta\varphi \tag{10.6.142}$$

we will have:

$$\hat{E}_{\text{resultant}} = 2\rho\sin\left(\frac{\varphi}{2}\right) = 2\frac{\hat{E}_i}{2}\frac{\sin\left(\frac{N\Delta\varphi}{2}\right)}{\sin\left(\frac{\Delta\varphi}{2}\right)} = \hat{E}_i\frac{\sin\left(N\frac{\pi}{\lambda}d\sin(\theta)\right)}{\sin\left(\frac{\pi}{\lambda}d\sin(\theta)\right)} \tag{10.6.143}$$

The light energy (i.e. intensity) emitted in the direction θ is proportional to the square of the electric field (see section Electrodynamics page 4156), then we have for destructive or constructive interference:

$$\overline{S}(\theta, N, d) = \overline{S}_i(\theta)\left(\frac{\sin\left(N\frac{\pi}{\lambda}d\sin(\theta)\right)}{\sin\left(\frac{\pi}{\lambda}d\sin(\theta)\right)}\right)^2 \tag{10.6.144}$$

We now substitute $\overline{S}_i(\theta)$ by the expression found in our earlier study of diffraction by a single aperture:

$$\overline{S}\propto\overline{S}_0\left(\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)}\right)^2=\overline{S}_0\left(\frac{\sin(\pi\Gamma\sin(\theta))}{\pi\Gamma\sin(\theta)}\right)^2 \tag{10.6.145}$$

Thus we get to the addition of interference and diffraction effects:

$$\boxed{\overline{S}(\theta,N,d)=\overline{S}_i(\theta)\left(\frac{\sin\left(N\dfrac{\pi}{\lambda}d\sin(\theta)\right)}{\sin\left(\dfrac{\pi}{\lambda}d\sin(\theta)\right)}\right)^2=\overline{S}_0\left(\frac{\sin\left(\dfrac{\pi e}{\lambda}\sin(\theta)\right)}{\dfrac{\pi e}{\lambda}\sin(\theta)}\right)^2\left(\frac{\sin\left(N\dfrac{\pi}{\lambda}d\sin(\theta)\right)}{\sin\left(\dfrac{\pi}{\lambda}d\sin(\theta)\right)}\right)^2} \tag{10.6.146}$$

Although this relation seems complicated, its parameters do not have the same practical significance. Indeed, consider the function:

$$\psi=\left(\frac{\sin(Nx)}{\sin(x)}\right)^2=\frac{A}{B} \tag{10.6.147}$$

The term A has maxima when:

$$Nx_{\text{max}}=\frac{\pi}{2}+m\pi\Leftrightarrow=\frac{\pi}{2}N+m\frac{m\pi}{N} \tag{10.6.148}$$

and is equal to zero if:

$$Nx_{\text{null}}=m\pi\Leftrightarrow x_{\text{null}}=m\frac{\pi}{N} \tag{10.6.149}$$

with $m\in\mathbb{N}$.

Although the term B makes the relation diverge for $x=m\pi$, l'Hôpital's rule (see section Differential and Integral Calculus page 1461) provides that:

$$\lim_{x\to m\pi}\left(\frac{\sin(Nx)}{\sin(x)}\right)^2=\left(\lim_{x\to m\pi}\frac{\sin(Nx)}{\sin(x)}\right)^2=\left(\lim_{x\to m\pi}\frac{\mathrm{d}_x\sin(Nx)}{\mathrm{d}_x\sin(x)}\right)^2=\left(\lim_{x\to m\pi}\frac{N\cos(Nx)}{\cos(x)}\right)^2=N^2 \tag{10.6.150}$$

It follows that for $x=m\pi$ and therefore for zero values of A and B, the function ψ presents enormous peak height:

$$\psi=N^2 \tag{10.6.151}$$

Since the huge amplitude, the main peaks are those we observe experimentally the more easy. Thus, the angular position of the maxima of the function ψ is given by:

$$B=\sin(x_{\text{main peaks}})=0\Rightarrow x_{\text{main peaks}}=m\pi \tag{10.6.152}$$

with $m\in\mathbb{Z}$.

The value m, designate the "order number of the maximum's interference".

Let us apply these results to the interference relation:

$$\overline{S}(\theta,N,d)=\overline{S}_i(\theta)\left(\frac{\sin\left(N\dfrac{\pi}{\lambda}d\sin(\theta)\right)}{\sin\left(\dfrac{\pi}{\lambda}d\sin(\theta)\right)}\right)^2 \tag{10.6.153}$$

The peak of order m is center on the equivalent value θ that cancel the numerator and the denominator of this fraction such that:

$$\frac{\pi}{\lambda}d\sin(\theta)=m\pi\Rightarrow\sin(\theta)=m\frac{\lambda}{d} \tag{10.6.154}$$

with $m\in\mathbb{Z}$, hence:

$$\boxed{\sin(\theta_m)=m\frac{\lambda}{d}} \tag{10.6.155}$$

Thus an aperture network that we know the step value d can be used to measure the wavelength λ of an incident unknown light beam.

However, if the incident light is polychromatic (typically for astronomical observations), the above relation gives us for a given wavelength given the position of the interference fringes. Thus, an astronomer passing polychromatic light of its telescope through a diffraction network can make a spectroscopic analysis of the light.

This relation also gives us that for fixed values of m and d that the greater is λ the greater is the angle θ is in a range $[0,2\pi]$. Thus, the spectral lines arising from the impact of a polychromatic beam show a spectrum from violet (shorter wavelength so small angle) to red (high angle so large wavelength).

Using a goniometer, we measure the angles θ_m of the main peaks of order m for the greatest possible number of m values. We deduce from these measurement the slope λ of the function plot:

$$\lambda=d\frac{\Delta\sin(\theta_m)}{\Delta n} \tag{10.6.156}$$

The peak bottom is located at an angle $\theta_m+\Delta\theta_m$ where the numerator:

$$\sin\left(N\frac{\pi}{\lambda}d\sin(\theta)\right) \tag{10.6.157}$$

cancel for the first time after passage of the peak.

Since the argument of this function increases of $m\pi$ between two successive peaks (among all main and secondary peaks), it is equal to $N(m\pi)$ at the place of the peak of order m (main peak therefore) and has to travel π radians further to reach the bottom of the peak.

The numerator is then:

$$N\frac{\pi}{\lambda}d\sin(\theta_m+\Delta\theta_m)=mn\pi+\pi=(mn+1)\pi\Rightarrow\sin(\theta_m+\Delta\theta_m)=\left(m+\frac{1}{N}\right)\frac{\lambda}{d} \tag{10.6.158}$$

The angular distance $\Delta\theta_m$ between the top and the bottom of the main peak is the given by:

$$\sin(\theta_m+\Delta\theta_m)-\sin(\theta_m)=\left(m+\frac{1}{N}\right)\frac{\lambda}{d}-m\frac{\lambda}{d}=\frac{1}{N}\frac{\lambda}{d} \qquad (10.6.159)$$

But from the first order, we have $\theta_m \ll \Delta\theta_m$. The difference of two sinus gives (see section Trigonometry page 2519):

$$\begin{aligned}\sin(\theta_m+\Delta\theta_m)-\sin(\theta_m)&=2\sin\left(\frac{\theta_m+\Delta\theta_m-\theta_m}{2}\right)\cos\left(\frac{\theta_m+\Delta\theta_m+\theta_m}{2}\right)\\&=2\sin\left(\frac{\Delta\theta_m}{2}\right)\cos\left(\frac{2\theta_m+\Delta_m}{2}\right)\cong 2\sin\left(\frac{\Delta\theta_m}{2}\right)\cos(\theta_m)\end{aligned} \qquad (10.6.160)$$

A Maclaurin development (see section Sequences and Series page 1703) gives when taking the first term of the development $\sin(\alpha)\cong\alpha$:

$$2\sin\left(\frac{\Delta\theta_m}{2}\right)\cos(\theta_m)\cong\Delta\theta_m\cos(\theta_m) \qquad (10.6.161)$$

But we also have the identity (see section Trigonometry page 2519):

$$\cos(\theta_m)=\sqrt{1-\sin^2(\theta_m)} \qquad (10.6.162)$$

Hence the angular width of a peak of order m:

$$\Theta_m=2\Delta\theta_m=2\frac{1}{N}\frac{\lambda}{d}\frac{1}{\cos(\theta)}\frac{1}{Nd}\frac{2\lambda}{\sqrt{1-\sin^2(\theta_m)}}=\frac{1}{N}\frac{2\lambda}{\sqrt{d^2-d^2\sin^2(\theta_m)}} \qquad (10.6.163)$$

But as:

$$\sin(\theta_m)=m\frac{\lambda}{d}\Leftrightarrow d\sin(\theta_m)=m\lambda \qquad (10.6.164)$$

Therefore:

$$\boxed{\Theta_m=\frac{1}{N}\frac{2\lambda}{d^2-(m\lambda)^2}} \qquad (10.6.165)$$

It is clear that two superposed light lines will be seen as distinct if they are separated by an angular distance equal to their angular width. The expression:

$$\sin(\theta_m)=m\frac{\lambda}{d} \qquad (10.6.166)$$

establishes that to two angular positions correspond two wavelengths. So we can give the separation of two light lines by $\Delta\lambda=\lambda_2-\lambda_1$ instead of $\Delta\theta=\theta_2-\theta_1$.

Therefore from:

$$\Theta_m=2\Delta\theta_m=\frac{2}{N}\frac{\lambda}{d}\frac{1}{\cos(\theta_m)} \qquad (10.6.167)$$

we get:

$$\cos(\theta_m)\Delta\theta_m=\frac{1}{N}\frac{\lambda}{d} \tag{10.6.168}$$

But:

$$\sin(\theta_m)=m\frac{\lambda}{d}\Rightarrow m\frac{\delta\lambda}{d}=\Delta\sin(\theta_m) \tag{10.6.169}$$

When $\Delta\theta_m$ and θ_m are small, we have:

$$\Delta\sin(\theta_m)\cong\cos(\theta_m)\Delta\theta_m \tag{10.6.170}$$

Which brings us to write by substitution:

$$m\frac{\Delta\lambda}{d}\cong\frac{1}{N}\frac{\lambda}{d}\Rightarrow\frac{\Delta\lambda}{\lambda}\cong\frac{1}{mN} \tag{10.6.171}$$

The resolving power R of a network is its ability to separate two spectral lines of neighbouring wavelengths λ and $\lambda+\Delta\lambda$ such as:

$$\boxed{R=\frac{\lambda}{\Delta\lambda}\cong mN} \tag{10.6.172}$$

We see that the resolving power increases proportionally with the diffraction order. This relation is very important in spectroscopy for astronomy. We can also calculate what should be the minimum number N of lines that must have a network capable of separating two wavelengths in a spectrum of given order m.

10.6.2.3 Young's interference experiment

According to the wave-particle duality principle, light behaves both as a wave and as a particle (material particle). It is the solving of problems like those of the black-body (see section Thermodynamics page 3704), of the photoelectric effect (see section Nuclear Physics page 5106) or that of the Compton effect (see section Nuclear Physics page 5096) , which revealed the existence of this duality.

But we will now study the most mind blowing proof of the duality aspect of the matter at the atomic scale using the Young's experiment. We will address this in a simplified manner as a special case of the rectangular slots network that has the advantage of being able to be easy to put in practice in an experiment showing the dual and probabilistic behaviour of matter at the atomic scale.

So to study this subject, let us consider a light source S, which radiates monochromatic wave Ψ of wavelength λ through two slots F_1 and F_2 perforated in an opaque barrier to light, as shown in the figure below:

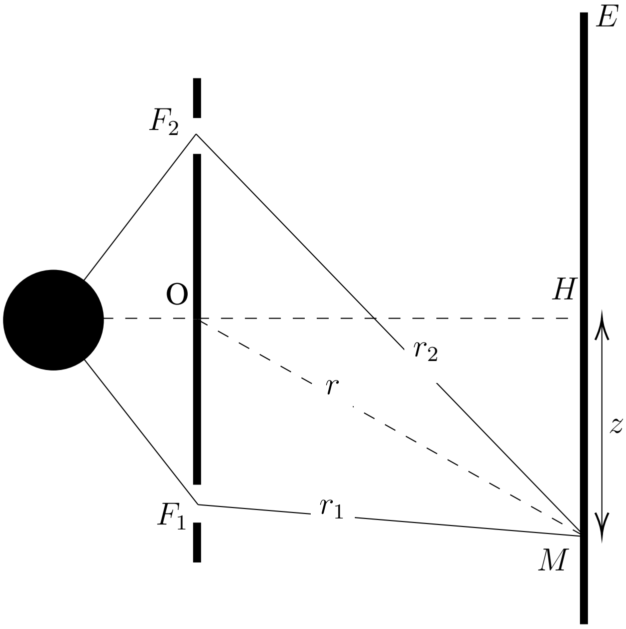

Figure 10.233: **Implementation of Young's experience-slit**

> **Remark**
>
> The advantage of that device is that it can produce two sources of coherent light. That is to say two sources whose phase difference is constant throughout the experiment.

We have on a viewing (projection) screen E at a point H such that the distance is:

$$\overline{\text{O}H} = D \gg \overline{F_1F_2} = a \qquad (10.6.173)$$

where a would typically be of the order of the millimetres and D of the meter.

The wave Ψ will after passing through the slots F_1 and F_2, as we have already seen it just previously, generates sub-waves $\Psi_1(r_1,t)$ and $\Psi_2(r_1,t)$ of same pulsation ω that will travel respectively the paths r_1 and r_2 and that will go interfere at the point M of the screen E that we are interested for.

If the interference is constructive in M, this point will then be located on a bright fringe and if the interference is destructive M, it will be on a dark fringe. To observe this, let us first write the resulting wave at M:

$$\Psi_M = \Psi_1(r_1,t) + \Psi(r_2,t) \qquad (10.6.174)$$

in which we have in terms of phasor (see section Wave Mechanics page 3510):

$$\Psi_1(r_1,t) = Ae^{\mathrm{i}(kr_1-\omega t)} \quad \text{and} \quad \Psi_2(r_2,t) = Ae^{\mathrm{i}(kr_2-\omega t)} \qquad (10.6.175)$$

where A is the amplitude, k is the wave vector and t is the time variable as we have already discussed in detail in the section of Wave Mechanics.

Now let make a change of variable (just to not have to manage long exponential functions):

$$\Psi_1(r_1,t) = Ae^{\mathrm{i}kD_1} \quad \text{and} \quad \Psi_2(r_2,t) = Ae^{\mathrm{i}kD_2} \qquad (10.6.176)$$

Remark

We will see later that in fact $D_1 = r_1$ and $D_2 = r_2$.

To calculate the intensity at the point M, we will take the complex norm (module) of Ψ_M that is thus written as the product of the complex variable and its conjugate (see section Numbers page 244):

$$I = |\Psi_M| = \Psi_M \bar{\Psi}_M = (\Psi_1 + \Psi_2)(\overline{\Psi_1 + \Psi_2}) \tag{10.6.177}$$

Remark

This calculation is very important because the analogy with the Wave Quantum Physics is very strong at this level and similar to the calculation of the probability amplitude (see section Wave Quantum Physics page 4693).

Therefore:

$$\begin{aligned} I &= A^2\left(e^{\mathrm{i}kD_1} + e^{\mathrm{i}kD_2}\right)\left(e^{-\mathrm{i}kD_1} + e^{-\mathrm{i}kD_2}\right) = A^2\left[1 + e^{\mathrm{i}k(D_1 - D_2)} + e^{\mathrm{i}k(D_2 - D_1)} + 1\right] \\ &= A^2\left[2 + e^{\mathrm{i}k(D_1 - D_2)} + e^{\mathrm{i}k(D_2 - D_1)}\right] = A^2\left[2 + \cos(k(D_1 - D_2)) + \cos(k(D_2 - D_2))\right] \\ &= A^2[2 + 2\cos(k(D_1 - D_2))] \end{aligned} \tag{10.6.178}$$

The intensity is then maximum if and only if:

$$\cos(k(D_1 - D_2)) = 1 \tag{10.6.179}$$

So that:

$$k(D_1 - D_2) = 2n\pi \Leftrightarrow D_1 - D_2 = n\lambda \tag{10.6.180}$$

with $n \in \mathbb{N}$. Which gives:

$$D_1 - D_2 = (r_1 - \omega t) - (r_2 - \omega t) = r_1 - r_2 = n\lambda \tag{10.6.181}$$

Remark

It is here that we see obviously that $D_1 = r_1$ and $D_2 = r_2$

The intensity is zero if and only if:

$$\cos(k(D_1 - D_2)) = -1 \tag{10.6.182}$$

So that:

$$k(D_1 - D_2) = 2\left(n + \frac{1}{2}\right)\pi \Leftrightarrow D_1 - D_2 = \left(n + \frac{1}{2}\right)\lambda \tag{10.6.183}$$

with $n \in \mathbb{N}$. Which gives:

$$r_1 - r_2 = \left(n + \frac{1}{2}\right)\lambda \tag{10.6.184}$$

Now we must calculate $r_1 - r_2$ in function of z to find out what we see on the projection screen E.

For this let us consider the following figure:

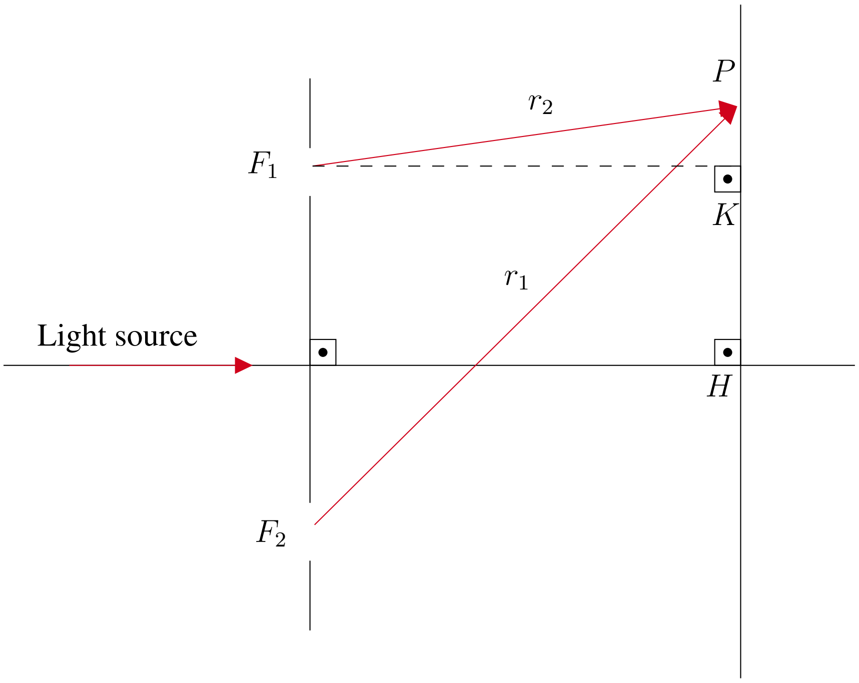

Figure 10.234: **Magnification and special case of Young experiment**

where $\overline{F_1P}$ and $\overline{F_2P} = r_2$.

We have on our figure:

$$r_1^2 = D^2 + \overline{PK}^2 \tag{10.6.185}$$

But:

$$\overline{PK} = z - \frac{a}{2} \tag{10.6.186}$$

So we have:

$$r_1^2 = D^2 + \left(z - \frac{a}{2}\right)^2 \Rightarrow r_1 = D\sqrt{1 + \frac{1}{D^2}\left(z - \frac{a}{2}\right)^2} \tag{10.6.187}$$

As z and a are small relatively to D and using the approximation:

$$\sqrt{1+\varepsilon} \cong 1 + \frac{\varepsilon}{2} \tag{10.6.188}$$

if ε is small compared to 1. Then we have:

$$r_1 = D\sqrt{1 + \frac{1}{D^2}\left(z - \frac{a}{2}\right)^2} \cong D\left(1 + \frac{1}{2D^2}\left(z - \frac{a}{2}\right)^2\right) = D + \frac{1}{2D}\left(z - \frac{a}{2}\right)^2 \tag{10.6.189}$$

Also:

$$r_2=D\sqrt{1+\frac{1}{D^2}\left(z+\frac{a}{2}\right)^2}\cong D\left(1+\frac{1}{2D^2}\left(z+\frac{a}{2}\right)^2\right)=D+\frac{1}{2D}\left(z+\frac{a}{2}\right)^2 \tag{10.6.190}$$

So subtracting those two relations we get:

$$r_1-r_2=-z\frac{a}{D} \tag{10.6.191}$$

So finally using the relation:

$$r_1-r_2=n\lambda \tag{10.6.192}$$

It comes:

$$z=-\frac{n\lambda D}{a} \tag{10.6.193}$$

Thus, the distance between two consecutive maxima is:

$$i_{\max}=\frac{\lambda D}{a} \tag{10.6.194}$$

and is named "interfringe".

For fringes with zero intensity it comes immediately:

$$z=-\left(n+\frac{1}{2}\right)\frac{\lambda D}{a} \tag{10.6.195}$$

This relation indicates that the intensity I has minima (dark fringes) and maxima (bright fringes) distributed along the z direction periodically. This does not surprise us more than that for now because it derives from the more general case studied above.

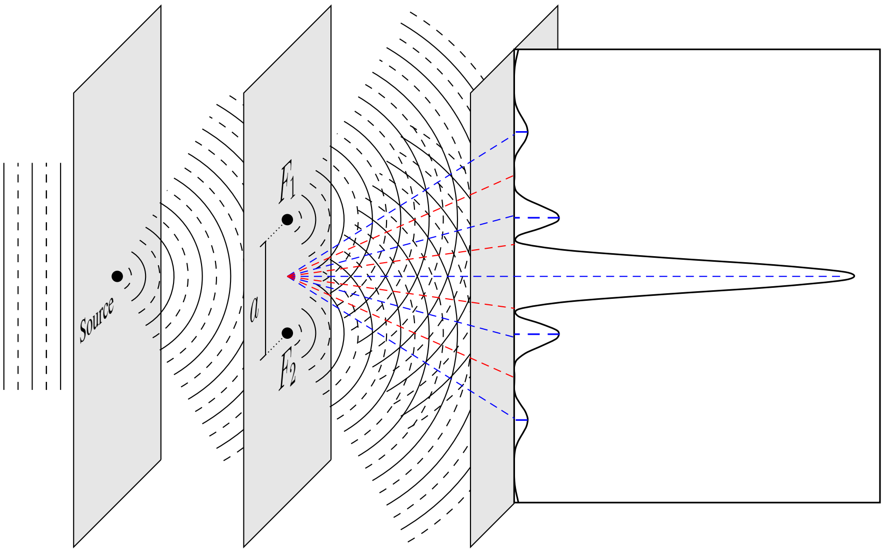

Figure 10.235: **Interfinge simplified schema for the Young experiment**

It should be noticed that the above calculations show that the intensity of the fringes is equal everywhere. But we observe experimentally (see figure above) that their intensity decreases with distance from the projection screen center. As we have already seen it, two are at the origin of this observation:

1. The slots have a given width, which implies a diffraction phenomenon. Indeed, a light sent on a small hole does not go out isotropically. This results in that the light is predominantly directed forward. This effect is reflected in the figure observed after Young's slots: the intensity of fringes decreases gradually as we moves away from the center of the projection screen.

2. The fact that the waves emitted in F_1 and F_2 are spherical waves, that is to say, their amplitude decreases gradually as we go away from the screen projection center. Thus the amplitude of F_1 and F_2 will not be the same at the point M.

So our calculations are remains approximate relatively to the study we made of the rectangular slots network but that is how Young's slots experiment is presented in most schools and this is enough to highlight the main result.

The original experiment of Thomas Young can be interpreted using the simple Fresnel's laws as we have done with the network of rectangular of slots. Which highlights the wave nature of light. But this experience has subsequently be refined, particularly by ensuring that the source S emits a quantum at a time. For example, it is possible in the third quarter of the 120th century (holocene calendar) to emit photons or electrons or atoms one by one. These are detected one by one placed on the screen after the double-slit. We see then that these impacts form gradually the interference pattern. By conventional laws concerning the trajectories of these particles, it is impossible to interpret this phenomenon!!! Hence the importance of the theoretical study of the Young's experiment!!!

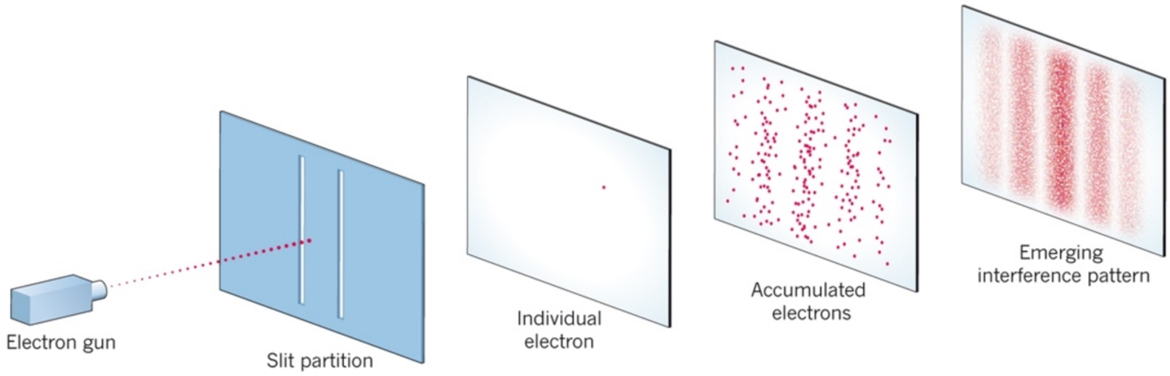

Figure 10.236: **Young's interference experiment (source: ?)**

From left to right, top to bottom, here are the patterns obtained by accumulating 10, 300, $2,000$ and $6,000$ electrons with a flow of 10 electrons / second (the same experiment with the same result has been reproduced with neutrons and atoms!). The accumulation of electrons eventually form interference fringes which is quite confusing a priori!

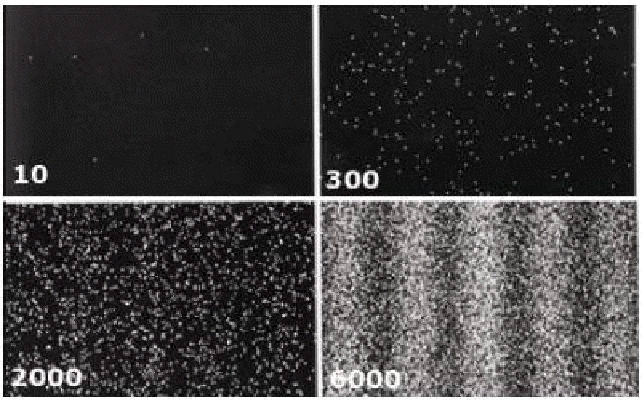

Figure 10.237: **Photos of patterns obtained in a real Young's experience (source: ?)**

We will come back on this crucial phenomenon in the section of Wave Quantum Physics to say a little bit more about it.

For summary here is another more detailed schema of what we haven seen so far:

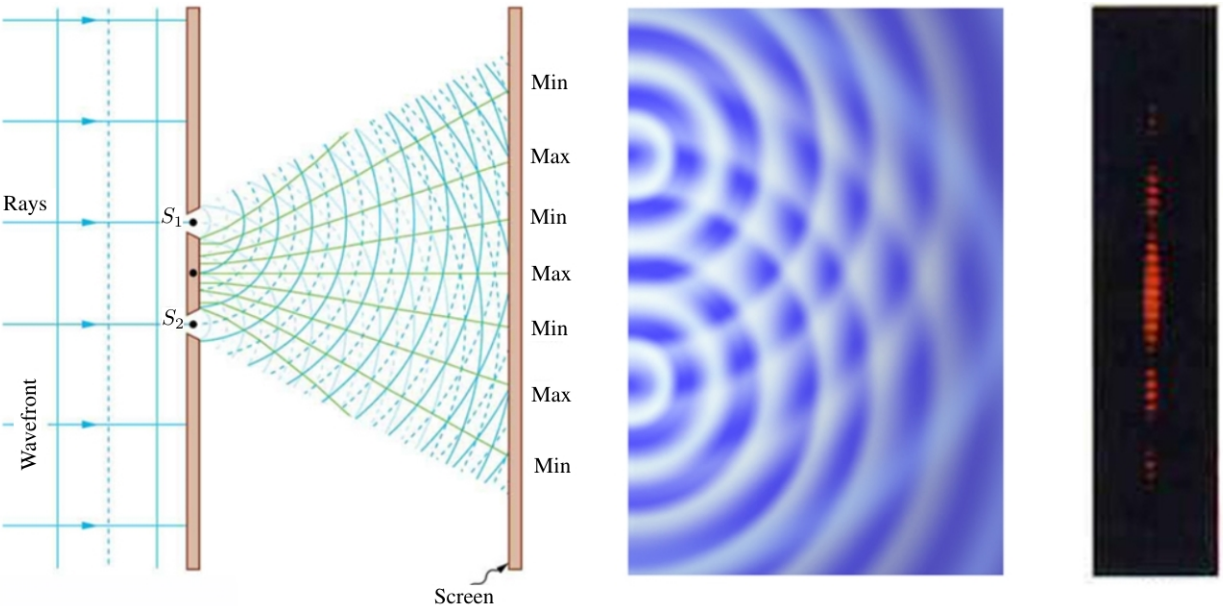

Figure 10.238: **Young experiment summary (source: OpenStax)**

MIT's experiment of 12025 (holocene calendar) on *Coherent and Incoherent Light Scattering by Single-Atom Wave Packets* (see [172]) offers a groundbreaking look into the quantum behavior of light and atoms. By using ultracold atoms released from an optical lattice, researchers created a highly controlled version of the double-slit experiment - this time with single atoms acting as slits and single photons as probes. They observed how light scattered off these atoms, revealing whether the scattering was coherent (wave-like) or incoherent (particle-like). Crucially, they showed that the coherence of scattered light is independent of whether the atom is trapped or free, challenging assumptions about the role of atomic motion and entanglement in quantum measurements.

This experiment directly addresses a century-old debate between Albert Einstein and Niels Bohr. Einstein believed that photons should behave like particles, passing through one slit and exerting a measurable force - thus preserving classical realism. But MIT's results confirm that light's wave–particle duality is fundamentally incompatible with such realism: observing which slit a photon passes through destroys the interference pattern, proving that both wave and particle aspects cannot be seen simultaneously. In doing so, the experiment validates Bohr's interpretation of quantum mechanics and shows that Einstein's view, while brilliant, doesn't hold up under quantum scrutiny!

10.6.3 Fresnel diffraction

In optics, the "Fresnel diffraction" is diffraction mathematical analysis method that is applied to the propagation of waves in the near field. In other words it is used to calculate the diffraction pattern generated by waves passing through an aperture or around an object, when viewed from relatively close to the object. In contrast the diffraction pattern in the far field region is given by the "Fraunhofer diffraction" methods used earlier above.

Remarks

R1. The formula we used earlier for the Fraunhofer diffraction and the one we will use now for the Fresnel diffraction are in fact both an approximation of a formula named the "Fresnel-Kirchhoff diffraction" who takes into account secondary waves that are propagating in various directions as per Huygens' principle (for a nice derivation see [568]).

R2. Also the reader should notice that our previous study of Fraunhofer diffraction and the one that will follow on Fresnel diffraction belongs to the field of "scalar diffraction theory", which ignores polarization effects. In some situations, ignoring polarization is benign, but in other situations ignoring polarization effects produces significant errors!

Disclaimer! The huge majority of what will follow, including the figures is inspired and copied from the very excellent textbooks on Optics from Eugene Hecht [239].

10.6.3.1 Case of a rectangular aperture

Consider the configuration depicted in the figure below:

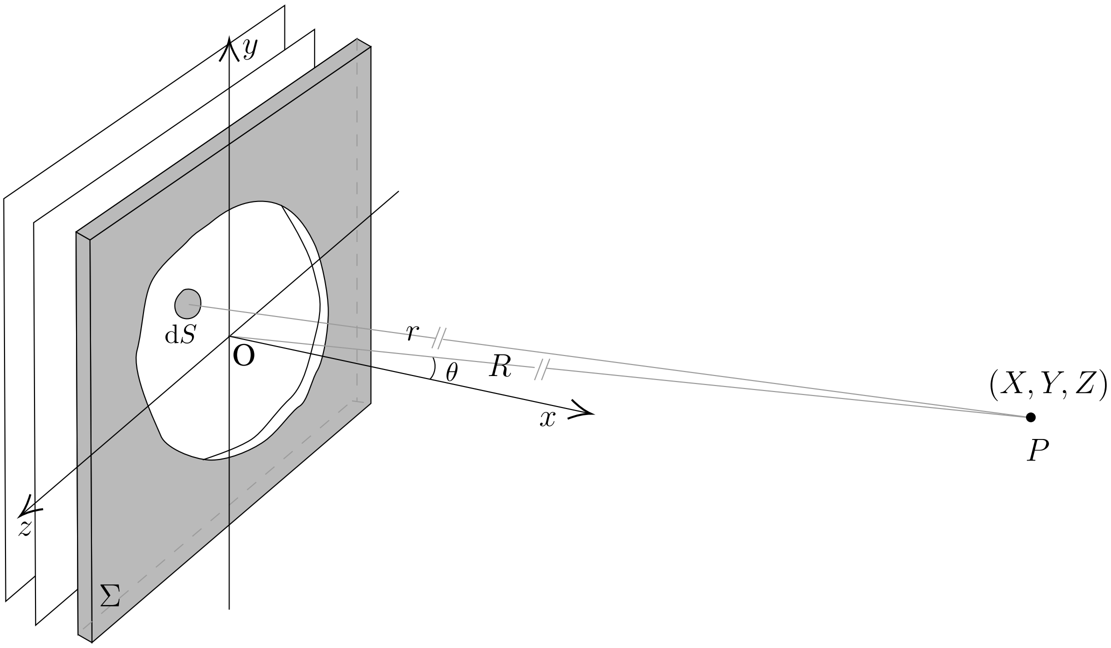

Figure 10.239: Fraunhofer diffraction from an arbitrary aperture, where r and R are very large compared to the size of the hole (source: [239])

A monochromatic plane wave propagating in the x-direction is incident on the opaque diffracting screen Σ with an aperture of area A. We wish to find the consequent (far-field) flux-density distribution in space or equivalently at some arbitrary distant point P. According to the Huygens principle, a differential area $\mathrm{d}S$, within the aperture, may be envisioned as being covered with coherent secondary point sources. But $\mathrm{d}S$ is much smaller in extent than is λ, so that all the contributions at P remain in-phase and interfere constructively. This is true regardless of θ; that is, $\mathrm{d}S$ emits a spherical wave. If ρ_A is the source strength per unit area, assumed to be constant over the entire aperture, then the optical disturbance at P due to $\mathrm{d}S$ is either the real or imaginary part of:

$$\mathrm{d}f=\frac{\hat{f}}{Ar}e^{\mathrm{i}(\omega t-kr)}\mathrm{d}S=\frac{\rho_A}{r}e^{\mathrm{i}(\omega t-kr)}\mathrm{d}S \tag{10.6.196}$$

The choice is yours and depends only on whether you like sine or cosine waves, there being no difference except for a phase shift. The distance from $\mathrm{d}S$ (of coordinate $(0,y,z)$) to P (of coordinate (X,Y,Z)) is (see figure above):

$$r=\left[X^2+(Y-y)^2+(Z-z)^2\right]^{1/2} \tag{10.6.197}$$

and as we have seen, the Fraunhofer condition occurs when this distance approaches infinity. As before, it will suffice to replace r by the distance $\overline{OP}$, that is, R, in the amplitude term, as long as the aperture is relatively small. But the approximation for the phase needs to be treated a bit more carefully; $k=2\pi/\lambda$ is a large number. To that end we expand out the above relation, by making use of:

$$R=\left[X^2+Y^2+Z^2\right]^{1/2} \tag{10.6.198}$$

we get:

$$r=(X^2+Y^2-2Yy+y^2+Z^2+2Zz+z^2)^{1/2}=R\left[1+\left(y^2+z^2\right)/R^2-2(Yy+Zz)/R^2\right]^{1/2} \tag{10.6.199}$$

In the far-field case R is very large in comparison to the dimensions of the aperture, and the $\left(y^2+z^2\right)/R^2$ term is certainly negligible. Since P is very far from Σ,θ can still be kept small, even though Y and Z are fairly large, and this mitigates any concern about the directionality of the emitters (the obliquity factor). Now:

$$r\cong R\left[1-2(Yy+Zz)/R^2\right]^{1/2} \tag{10.6.200}$$

and dropping all but the first two terms in the binomial expansion (see section Algebra page 1366), we have:

$$r\cong R\left[1-(Yy+Zz)/R^2\right] \tag{10.6.201}$$

The total disturbance arriving at P is:

$$\tilde{f}\cong\frac{\rho_A e^{\mathrm{i}(\omega t-kR)}}{R}\iint\limits_{\text{Aperture}} e^{\mathrm{i}k(Yy+Zz)/R}\mathrm{d}S \tag{10.6.202}$$

Consider now the specific configuration shown in the figure below:

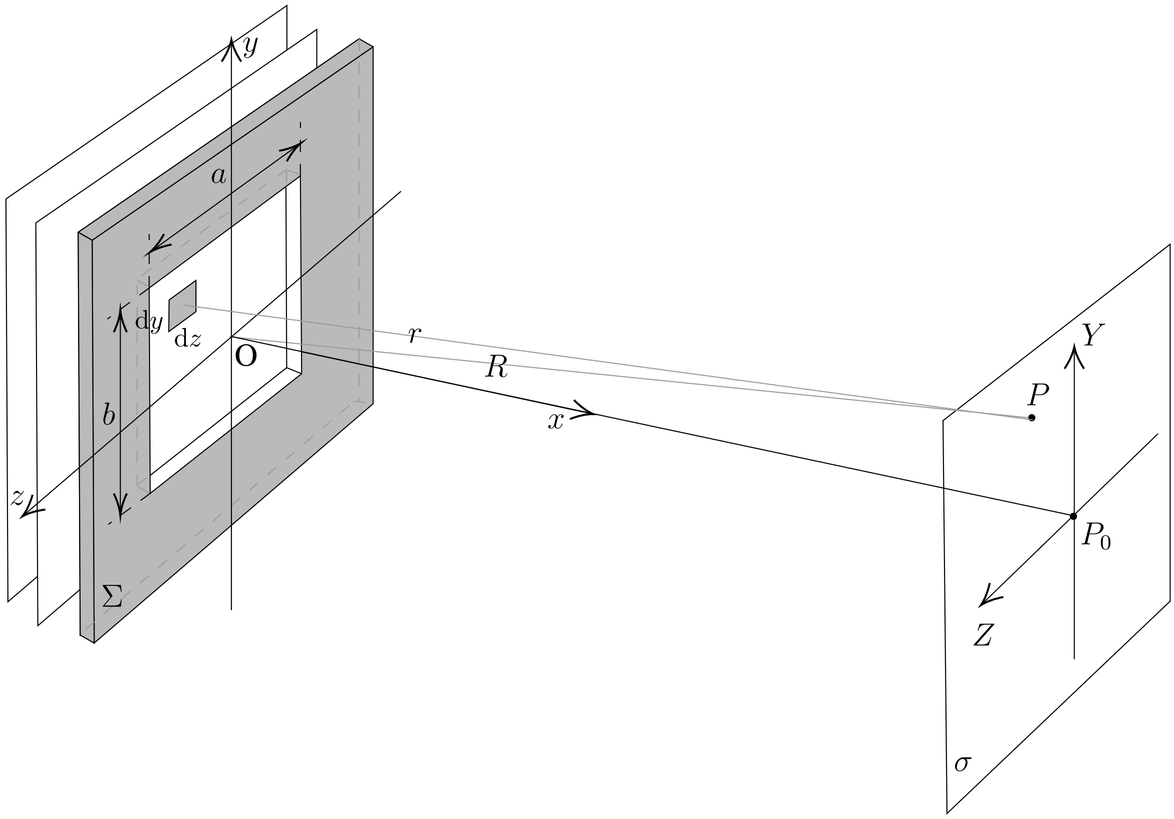

Figure 10.240: **A rectangular aperture for near-field analysis (source: [239])**

The previous relation can now be written as:

$$f \cong \frac{\rho_A e^{\mathrm{i}(\omega t - kR)}}{R} \int\limits_{-b/2}^{b/2} e^{\mathrm{i}kYy/R} \mathrm{d}y \int\limits_{-a/2}^{a/2} e^{\mathrm{i}kZz/R} \mathrm{d}z \tag{10.6.203}$$

where $\mathrm{d}S = \mathrm{d}y\mathrm{d}z$. With $\beta' \equiv kbY/2R$ and $\alpha' \equiv kaZ/2R$, we have (we used Euler formula as proved at page 251):

$$\int\limits_{-b/2}^{+b/2} e^{\mathrm{i}kYy/R} \mathrm{d}y = b\left(\frac{e^{\mathrm{i}\beta'} - e^{-\mathrm{i}\beta'}}{2\mathrm{i}\beta'}\right) = b\left(\frac{\sin(\beta')}{\beta'}\right) \tag{10.6.204}$$

and similarly:

$$\int\limits_{-a/2}^{+a/2} e^{\mathrm{i}kZz/R} \mathrm{d}z = a\left(\frac{e^{\mathrm{i}\alpha'} - e^{-\mathrm{i}\alpha'}}{2\mathrm{i}\alpha'}\right) = a\left(\frac{\sin(\alpha')}{\alpha'}\right) \tag{10.6.205}$$

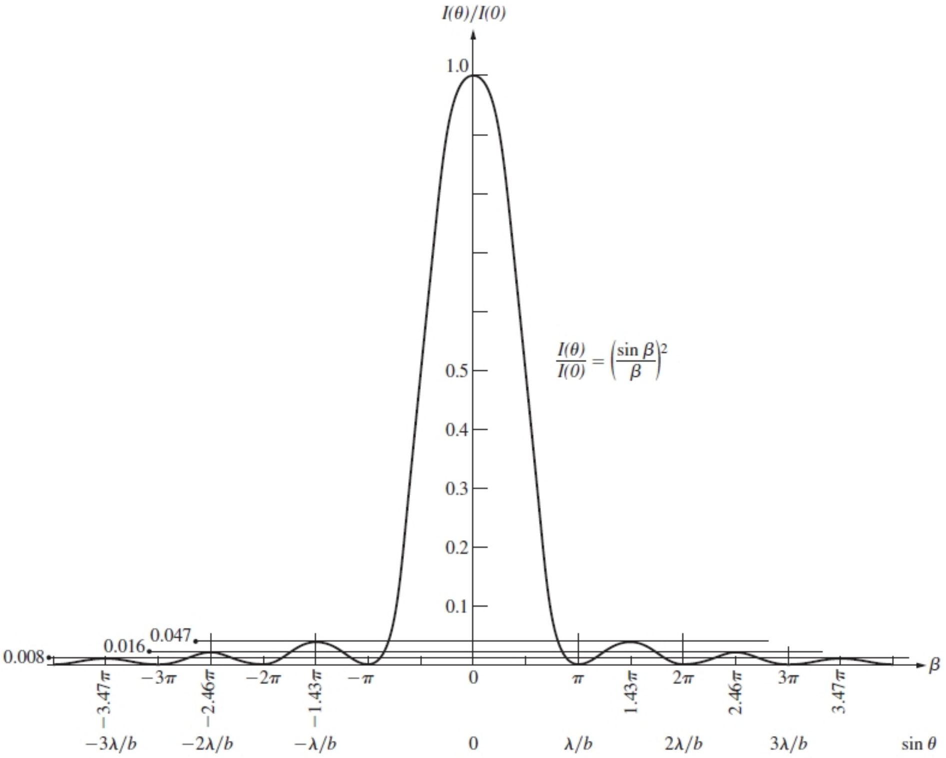
so that:

$$\boxed{f \cong \frac{A\rho_A e^{\mathrm{i}(\omega t - kR)}}{R} \left(\frac{\sin(\alpha')}{\alpha'}\right)\left(\frac{\sin(\beta')}{\beta'}\right) = \frac{A\rho_A e^{\mathrm{i}(\omega t - kR)}}{R} \mathrm{sinc}^2(\alpha')\,\mathrm{sinc}^2(\beta')} \tag{10.6.206}$$

where A is the area of the aperture. Let us denote that relation as following:

$$I(Y,Z) \cong I(0)\mathrm{sinc}^2(\alpha')\mathrm{sinc}^2(\beta') \tag{10.6.207}$$

where $I(0)$ is the irradiance at P_0; that is, at $Y=0, Z=0$. At values of Y and Z such that $\alpha'=0$ or $\beta'=0, I(Y,Z)$ assumes the following familiar shape (source: [239]):



When β' and α' are non-zero integer multiples of π or, equivalently, when Y and Z are non-zero integer multiples of $\lambda R/b$ and $\lambda R/a$, respectively, $I(Y,Z)=0$, and we have a rectangular grid of nodal lines. Notice that the pattern in the Y-Z directions varies inversely with the y-,z-aperture dimensions. A horizontal, rectangular opening will produce a pattern with a vertical rectangle at its center and vice versa:

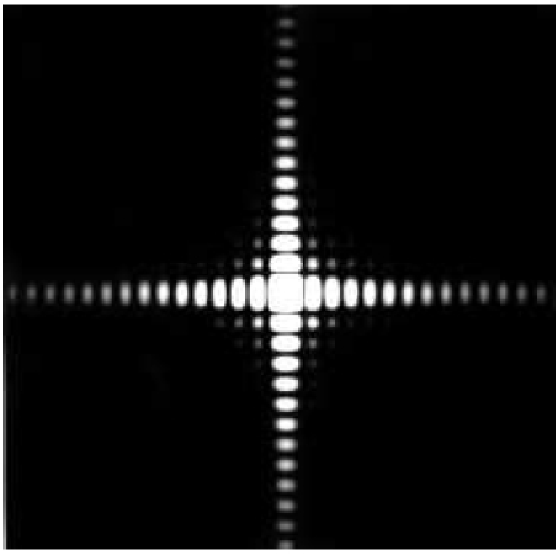


Figure 10.241: **Fraunhofer pattern of a square aperture (source: [239])**

An illustration or 3D computer simulation would give the following figures (source: [239]):

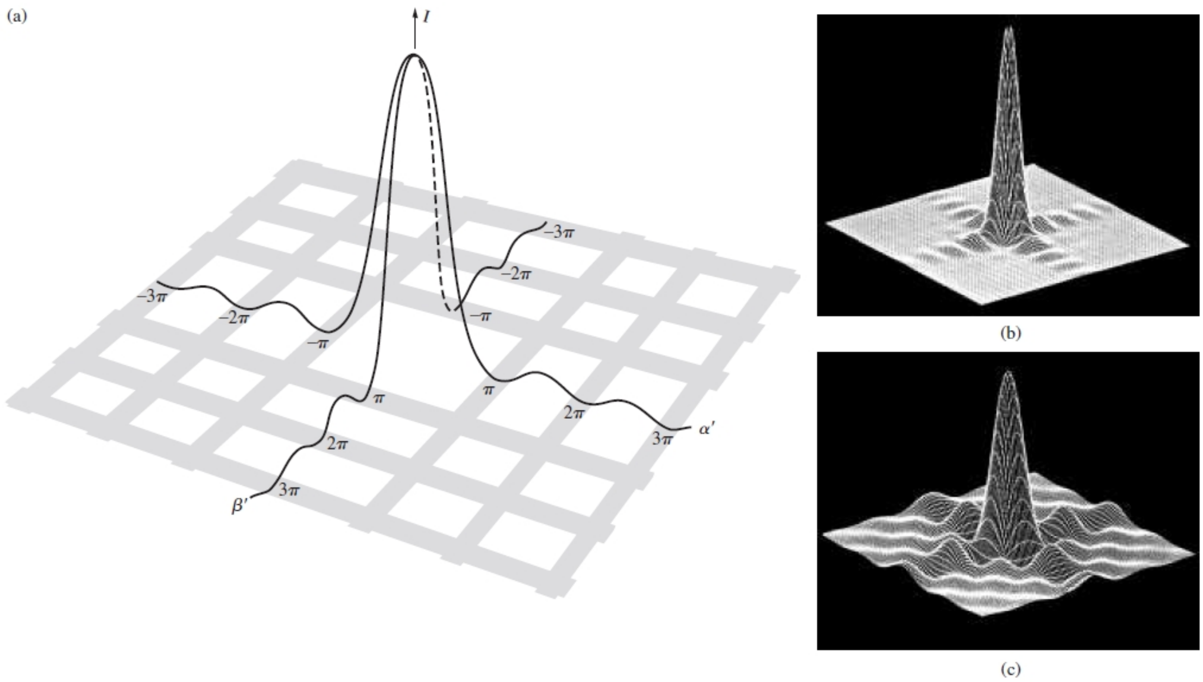

Figure 10.242: **(a) The irradiance distribution for a square aperture. (b) The irradiance produced by Fraunhofer diffraction at a square aperture. (c) The electric-field distribution produced by Fraunhofer diffraction via a square aperture. (source: R.G. Wilson, Illinois Wesleyan University)**

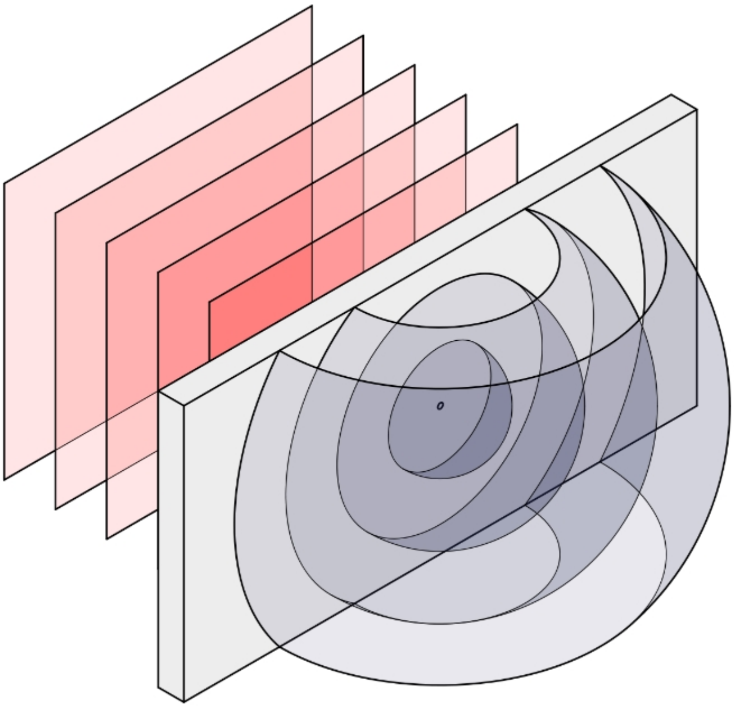
10.6.3.2 Case of a circular aperture

Most experimental situations in optics (e.g. telescopes, microscopes, LASER) have circular apertures, so the study of diffractions from such apertures is of particular interest. It is interesting to know that in 11818 (holocene calendar) Augustin Fresnel entered a competition sponsored by the French Academy. His paper on the theory of diffraction ultimately won first prize, but not until it had provided the basis for a rather interesting story. The judging committee consisted of Pierre Laplace, Jean. B. Biot, Siméon D. Poisson, Dominique F. Arago and Joseph L. Gay-Lussac... a quite formidable group indeed. Poisson, who was an ardent critic of the wave description of light, deduced a remarkable and seemingly untenable conclusion from Fresnel's theory. He showed that a bright spot would be visible at the center of the shadow of a circular opaque obstacle, a result that then proved the absurdity of Fresnel's treatment. This surprising prediction, fashioned by Poisson as the death blow to the wave theory, was almost immediately verified experimentally by Arago; the spot actually existed! Amusingly enough, "Poisson's spot" or "Arago spot", as it is now called, had been observed many years earlier (11723 according to holocene calendar), but this work had long gone unnoticed.

We start with a plane wave incident normally on a circular hole with radius a:

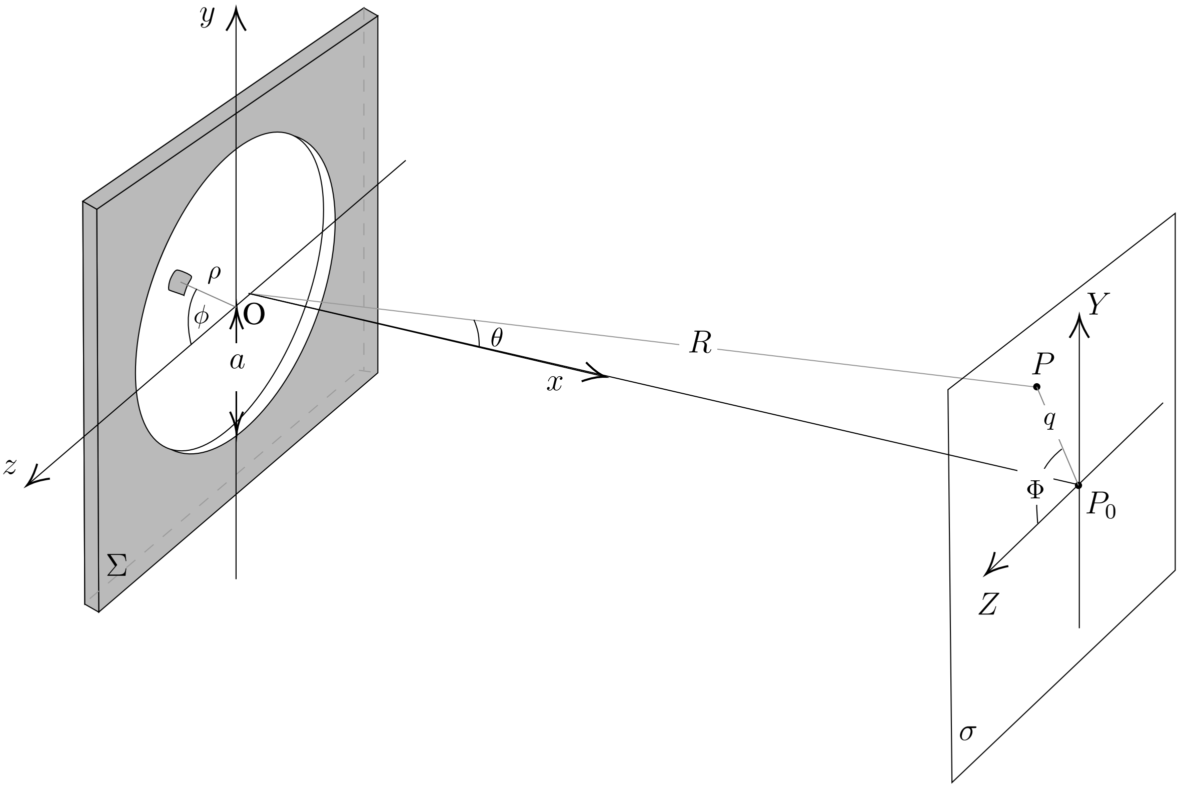


in an otherwise opaque screen, and ask ourselves what is the distribution of the intensity of the light on a screen on distance $R \gg a$ away?

We can use the same expression for the f field that we had for the rectangular aperture as for any possible aperture, as long as the limits of integration are appropriate. So we can write for the optical disturbance at point P in the far-field case:

$$f \cong \frac{\rho_A}{R} e^{\mathrm{i}(kR-\omega t)} \iint\limits_{\text{aperture}} e^{-\mathrm{i}k(Yy+Zz)/R} \mathrm{d}y\mathrm{d}z \tag{10.6.208}$$

For a circular aperture this integration is most easily done with cylindrical coordinates. Look at the figure (source: [239]):



Then we have:

$$\begin{aligned}z&=\rho\cos(\phi)\\y&=\rho\sin(\phi)\\Z&=q\cos(\Phi)\\Y&=q\sin(\Phi)\end{aligned}\tag{10.6.209}$$

The differential area is now:

$$\mathrm{d}S=\mathrm{d}x\mathrm{d}y=\rho\mathrm{d}\rho\mathrm{d}\phi\tag{10.6.210}$$

Then:

$$Yy+Zz=\rho q\cos(\varphi)\cos(\Phi)+\rho q\sin(\varphi)\sin(\Phi)\tag{10.6.211}$$

or:

$$Yy+Zz=\rho q\cos(\varphi-\Phi)\tag{10.6.212}$$

and the integral becomes:

$$f\cong\frac{\rho_A}{R}e^{\mathrm{i}(kR-\omega t)}\int\limits_0^a\int\limits_0^{2\pi}e^{\mathrm{i}K\rho q\cos(\varphi-\Phi)/R}\rho\mathrm{d}\rho\mathrm{d}\varphi\tag{10.6.213}$$

In order to do this integral we need to learn a little about Bessel functions (see section Sequences and Series page 1768) and especially the following first kind of order 0 in its integral representation (see section Differential and Integral Calculus page 1564):

$$J_0(u)=\frac{1}{2\pi}\int\limits_0^{2\pi}e^{\mathrm{i}u\cos(v)}\mathrm{d}v\tag{10.6.214}$$

that is a special case (for reminder...) of a more general definition of Bessel functions :

$$J_m(u)=\frac{1}{2\pi}\int\limits_0^{2\pi} e^{\mathrm{i}(mv+u\cos(v))}\mathrm{d}v \tag{10.6.215}$$

They have a number of interesting properties such as the recurrence relations (see section Sequences and Series page 1770):

$$\frac{\mathrm{d}}{\mathrm{d}u}[u^m J_m(u))]=u^m J_{m-1}(u) \tag{10.6.216}$$

so that for example when $m=1$:

$$\int\limits_0^u u' J_0(u')\mathrm{d}u'=uJ_1(u) \tag{10.6.217}$$

In order to numerically calculate the value of a Bessel function one uses the expansion (see section Sequences and Series page 1770):

$$J_m(x)=\sum_{s=0}^{+\infty}\frac{(-1)^2}{s!(m+s)!}\left(\frac{x}{2}\right)^{m+2s} \tag{10.6.218}$$

Now we want to evaluate the integral:

$$f\cong\frac{\rho_A}{R}e^{\mathrm{i}(kR-\omega t)}\int\limits_0^a\int\limits_0^{2\pi} e^{-\mathrm{i}k\rho q\cos(\varphi-\Phi)/R}\rho\mathrm{d}\rho\mathrm{d}\varphi \tag{10.6.219}$$

which we can do at any value of Φ since the problem is symmetric about Φ. So we can simplify things greatly if we do the integral at $\Phi=0$:

$$f\cong\frac{\rho_A}{R}e^{\mathrm{i}(kR-\omega t)}\int\limits_0^a\int\limits_0^{2\pi} e^{-\mathrm{i}k\rho q\cos(\varphi)/R}\rho\mathrm{d}\rho\mathrm{d}\varphi \tag{10.6.220}$$

which becomes:

$$f\cong\frac{\rho_A}{R}e^{\mathrm{i}(kR-\omega t)}2\pi\int\limits_0^a J_0\left(-\frac{k\rho q}{R}\right)\rho\mathrm{d}\rho \tag{10.6.221}$$

Now J_0 is an even function so we can drop the minus sign and rewrite the expression as:

$$f\cong\frac{\rho_A}{R}e^{\mathrm{i}(kR-\omega t)}2\pi\int\limits_0^a J_0\left(\frac{k\rho q}{R}\right)\rho\mathrm{d}\rho \tag{10.6.222}$$

To do this integral we change variables:

$$\begin{aligned}w&=\frac{k\rho q}{R}\\ \rho&=\frac{wR}{kq}\\ \mathrm{d}\rho&=\frac{R}{kq}\mathrm{d}w\end{aligned} \tag{10.6.223}$$

So that:

$$\begin{aligned}\int\limits_0^a J_0\left(\frac{k\rho q}{R}\right)\rho\mathrm{d}\rho &= \int\limits_0^{kaq/R}\left(\frac{R}{kq}\right)^2 J_0(w)w\mathrm{d}w = \left(\frac{R}{kq}\right)^2\left(\frac{kaq}{R}\right)J_1\left(\frac{kaq}{R}\right)\\ &= a^2\left(\frac{R}{kaq}\right)J_1\left(\frac{kaq}{R}\right) = a^2\frac{J_1\left(\dfrac{kaq}{R}\right)}{\dfrac{kaq}{R}}\end{aligned} \tag{10.6.224}$$

So finally we have the result:

$$\boxed{f \cong \rho_A\frac{e^{\mathrm{i}(kR-\omega t)}}{R}2\pi a^2\frac{J_1\left(\dfrac{kaq}{R}\right)}{\dfrac{kaq}{R}}} \tag{10.6.225}$$

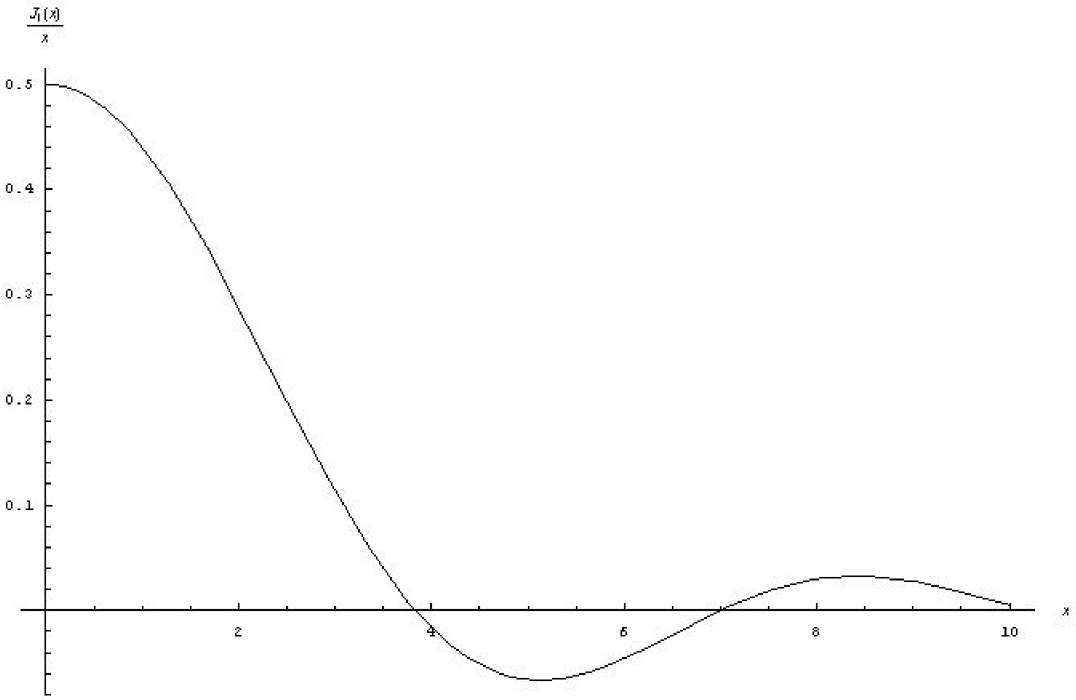
Or recognizing that πa^2 is the area of the aperture A and squaring to get the intensity we write:

$$I \cong I_0\left[\frac{2J_1\left(\dfrac{kaq}{R}\right)}{\dfrac{kaq}{R}}\right]^2 \tag{10.6.226}$$

If we want to write this in terms of the angle θ then one uses the fact that $q/R = \sin(\theta)$:

$$I(\theta) \cong I_0\left[\frac{2J_1(ka\sin(\theta))}{ka\sin(\theta)}\right]^2 \tag{10.6.227}$$

Below is a plot made with Mathematica of the function $J_1(x)/x$. Notice how it peaks at $1/2$ which is why there is the factor of two in the expression for the irradiance:



We easily do the plot of $(J_1(x)/x)^2$ with Maple™ 4.00b for example:

```
>with(plots):
>i:=(BesselJ(1,Pi*theta)/(Pi*theta))^2;
>plot(i,theta=-4..4);
```

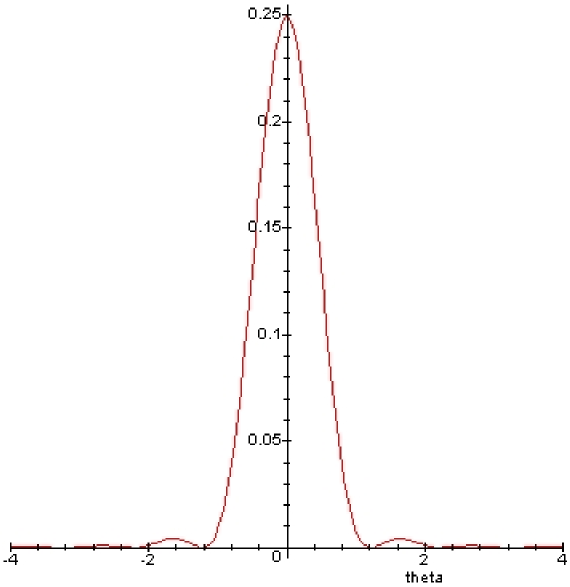


Figure 10.243: **Fresnel circular aperture diffraction pattern 2D plot in Maple™ 4.00b**

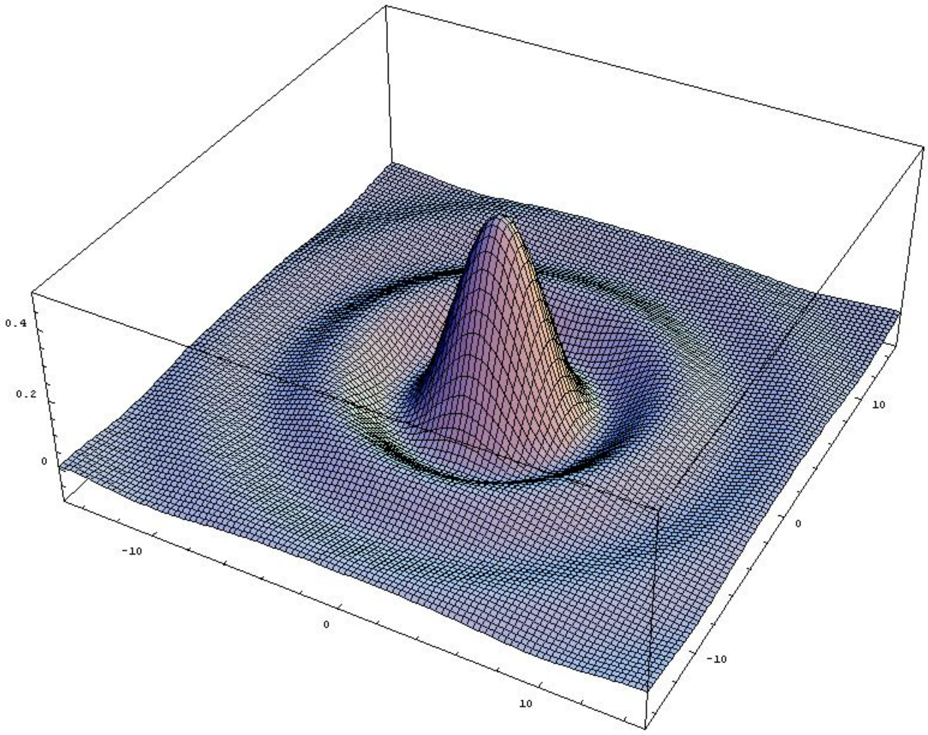
Below is a 3D plot also made with Mathematica of the same thing (i.e. $J_1(r)/r$). Notice the rings:



Below is a 3D plot of $(J_1(r)/r)^2$ which corresponds to the irradiance one sees. The central peak out to the first ring of zero is named the "Airy disk" (which contains 84% of the total light intensity) - named after Sir George Biddell Airy, an English astronomer who described this pattern mathematically in 11834 (holocene calendar). We can plot that with Maple™ 4.00b:

```
>with(plots):
>i:=(BesselJ(1,Pi*sqrt(x^2+y^2))/(Pi*sqrt(x^2+y^2)))^2;
>contourplot(i,x=-3..3,y=-3..3,filled=true,coloring=[white,blue],
contours=[0.001,0.003,0.008,0.012,0.016,0.02],grid=[100,100]);
```

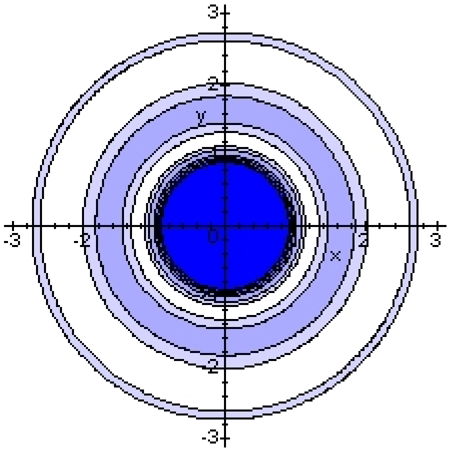


Figure 10.244: **Fresnel Airy disk 2D plot in Maple™ 4.00b**

or the same thing in 3D still with Maple™ 4.00b:

```
>with(plots):
>plot3d((BesselJ(1,Pi*sqrt(x^2+y^2))/(Pi*sqrt(x^2+y^2)))^2,x=-4..4,
y=-4..4,orientation=[30,70],axes=box,style=patchcontour,contours=40,
view=0..0.01,grid=[100,100]);
```

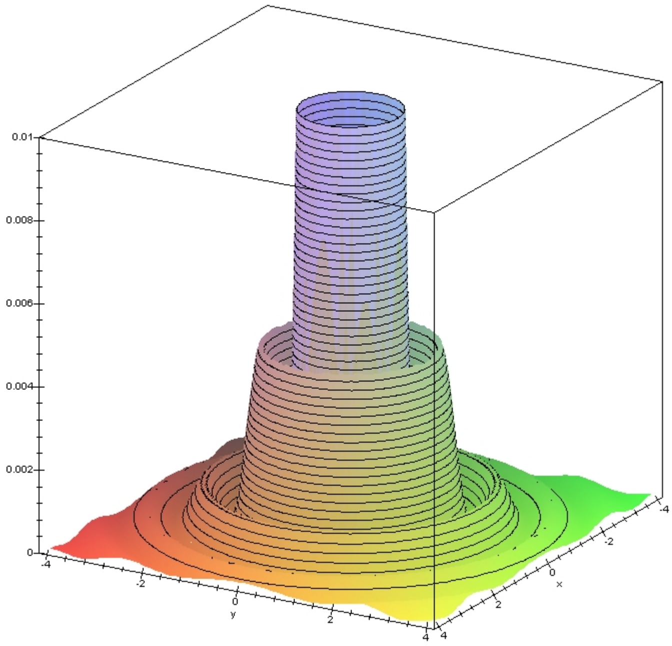

Figure 10.245: Fresnel circular aperture diffraction pattern 3D plot in Maple™ 4.00b

Remark

For information a Poisson's sport doesn't appear during a total solar eclipse because the Sun (actually a G2V-type star, aka yellow dwarf) is an extended, non-coherenct light source. Poisson's spot (or Arago spot) results from Fresnel diffraction of a coherent plane wavefront.

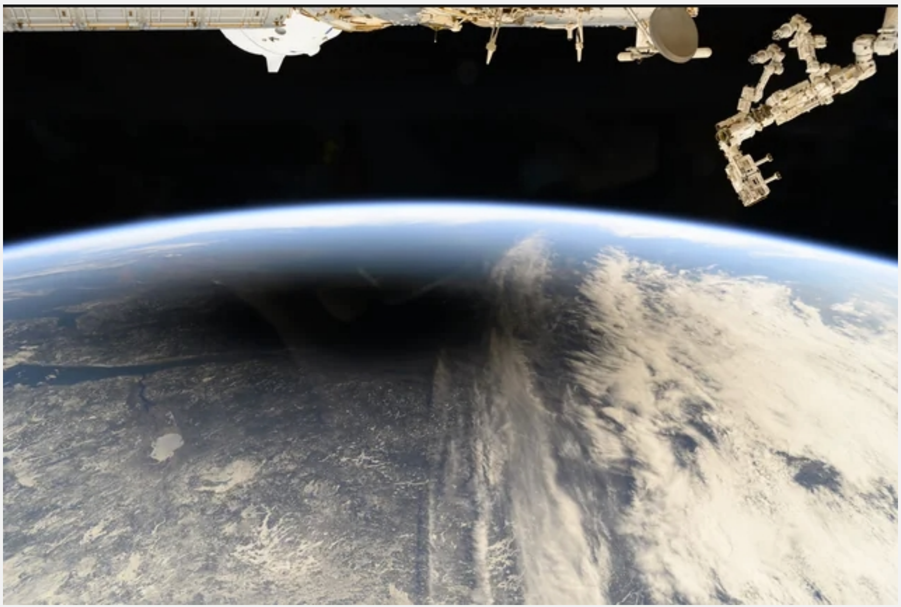

Figure 10.246: Photo of the total solar eclipse from 12024 (holocene calendar) as seen from the International Space Station

10.6.3.2.1 Optical resolution in the near field region for circular aperture

Notice that the destructive part of the pattern where $J_1(r)/r=0$ can be numerically evaluated to give $r\cong 3.83$ for the first ring.

For our circular aperture above this means the first zero occurs at:

$$\frac{kaq_1}{R}\cong 3.83 \tag{10.6.228}$$

or:

$$\frac{2\pi}{\lambda}\frac{aq_1}{R}\cong 3.83 \tag{10.6.229}$$

Therefore:

$$q_1\cong\frac{1.22R\lambda}{2a} \tag{10.6.230}$$

In our case a is the radius of the aperture and we can rewrite the expression using the diameter $D=2a$:

$$q_1\cong\frac{1.22R\lambda}{D} \tag{10.6.231}$$

The factor 1.22 is more precisely $1.21966989\ldots$

Light passing through any circular aperture is going to be diffracted in this manner and this sets the limit of resolution on an optical device such as a telescope. Say one is trying resolve two sources, we can say the limit of resolution is when the central spot of one Airy disk is on the zero of the other Airy pattern (say differently: the central maximum of the Airy pattern of one point emitter is directly overlapping with the first minimum of the Airy pattern of the other). This is known as the "Rayleigh criterion[22]" or "Rayleigh resolution criterion".

While it is possible to define other criteria, this is the most commonly used. See:

---

[22] There are other existing criterion in practice like the "Sparrow limit", the "Abbe Limit", the "FWHM", etc. Astronomical studies of equal brightness stars have shown that Sparrow's criterion is by far more useful.

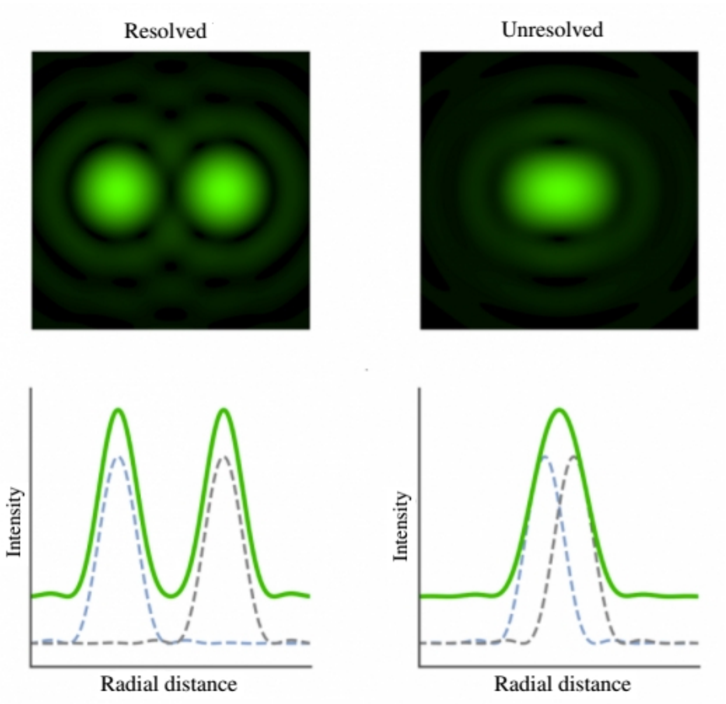

Figure 10.247: Overlap of PSFs (point spread function) and resolution

In the above figure the two sources can clearly be resolved (according to Rayleigh criterion). On the right the two sources are going to be difficult to resolve...

So we say that the limit of our resolution occurs when the distance Δq between two sources is:

$$\Delta q \cong \frac{1.22R\lambda}{D} \tag{10.6.232}$$

Or in the small angle limit $\Delta\theta = \Delta q/R$, we get the famous "spatial coherence":

$$\boxed{\Delta\theta \cong \frac{1.22\lambda}{D}} \tag{10.6.233}$$

By convention (as an approximate condition) we declare that two particles are too close together to resolve (identify as two separate particles rather than one) if their central diffraction peaks overlap. since the angle spanned by the central diffraction peak is $1.22\lambda/D$,this means that we say we can't resolve objects unless the angle between them (as measured from the microscope lens) is greater than $1.22\lambda/D$.

✍**Example:**

A positive lens having a 40 [mm] diameter is used to form the image of two stars on a CCD in a camera. If the stars are $1,000$ light-years from Earth, how far apart are they if they are just resolvable according to the Rayleigh criterion assuming $\lambda = 550\,[\text{nm}]$?

The solution is obviously given by:

$$\Delta\theta \cong \frac{1.22\lambda}{D} = \frac{1.22\,(550\cdot 10^{-9})}{40\cdot 10^{-3}} \cong 1.6775\cdot 10^{-5}\,[\text{rad}]$$

The stars' separation, L, is then:

$$L \cong R\Delta\theta \cong 1000\left(1.6775\cdot 10^{-5}\right)$$

and therefore $L \cong 0.0168$ light-year.

If the smallest resolvable separation between images is to be reduced (i.e., if the resolving power is to be increased), the wavelength, for instance, might be made smaller. Using ultraviolet rather than visible light in microscopy allows for the perception of finer detail (that's also why microchips are made with ultraviolet LASER, indeed it is the highest non-destructive light frequency that permits small angular separation of integrated transistors without being destructive for silicon wafers). The electron microscope utilizes equivalent wavelengths of about 10^{-4} to 10^{-5} that of light. This makes it possible to examine objects that would otherwise be completely obscured by diffraction effects in the visible spectrum. On the other hand, the resolving power of a telescope can be increased by increasing the diameter of the objective lens or mirror. Besides collecting more of the incident radiation, this will also result in a smaller Airy disk and therefore a sharper, brighter image.

So now in the case of a telescope the circular opening of the telescope generates a circular interference pattern.

Because of this interference pattern, when we make an image of a star, it does NOT focus to a perfect point. Rather, it focuses to a disk, and if we set our telescope for high magnification and examine the image carefully, we can see that there is a disk with faint rings around it - this is the interference pattern that is caused by the circular aperture of our telescope:

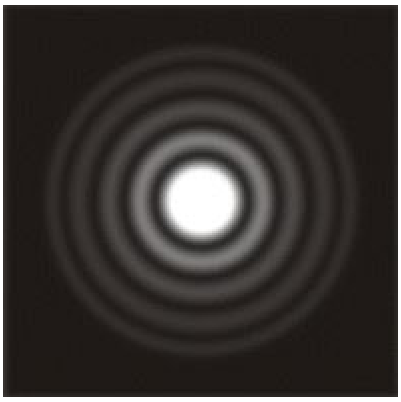

Figure 10.248: **Idealized picture of Airy disk**

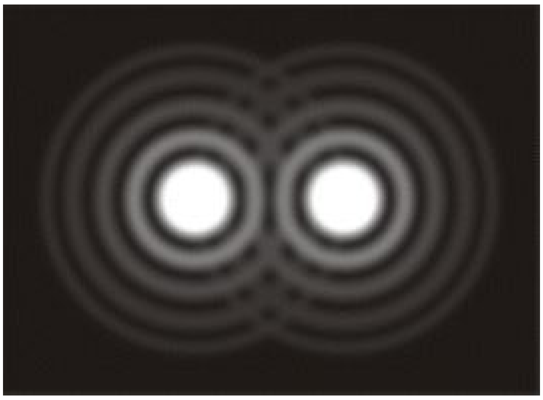

Figure 10.249: **When close stars appear as two Airy disks**

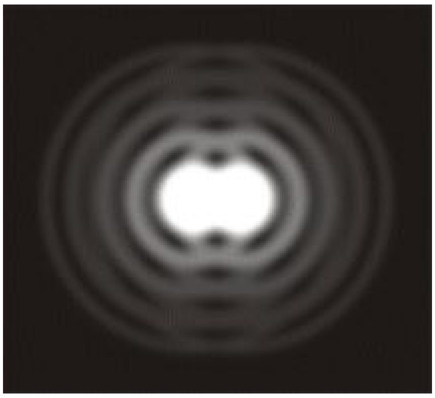

Figure 10.250: **Too close Airy disk that starts to make distinction difficult**

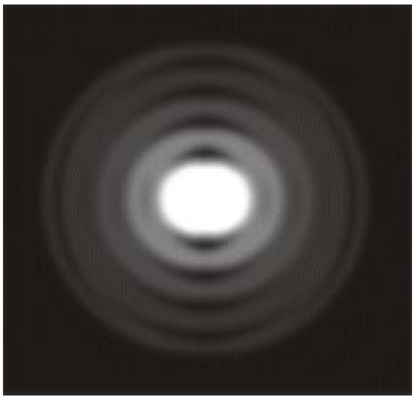

Figure 10.251: **When closer together than the radius of the Airy disk, we can no longer tell them apart**

The angular resolution may be converted into a spatial resolution, ΔL, by multiplication of the angle (in radians) with the distance to the object. For a microscope, that distance is close to the focal length f of the objective. For this case, the Rayleigh criterion reads:

$$\Delta L \cong 1.22 \frac{f\lambda}{D_{\text{scope}}} \qquad (10.6.234)$$

This is the size, in the imaging plane, of smallest object that the lens can resolve, and also the radius of the smallest spot to which a collimated beam of light can be focused.

With regard to telescopes, what is important in this equation is that the size of the Airy disk depends on the diameter of the objective ONLY, and as the diameter of the objective gets bigger, the Airy disk gets smaller.

This means as the diameter of our scope gets bigger, we can see smaller and smaller detail –or equivalently, we can split stars that are closer together. Conversely, this means that there is a limit to the detail we can see with our scope. That limit is dictated ENTIRELY by the diameter of the scope, and it is due to the diffraction effects caused by the scope opening.

For this reason, the radius of the Airy disk, as calculated above, is known as the "diffraction limit". Note then that when we can see the rings of the Airy Disk, this signals to us that we are operating at the limit of the scope's power to resolve detail.

The diffraction limit equation gives an answer in radians, whereas most dimensions in astronomy are given in degrees, minutes, or seconds of arc. Also because of various other factors, the actual limit of detail that an observer can see does not match exactly to the diffraction limit. Interestingly, a skilled observer can do better than the diffraction formula would suggest.

In 11867 (holocene calendar), William Rutter Dawes determined the practical limit on resolving power for a telescope, known as the "Dawes limit". Dawes expressed this as the closest that two stars could be together in the sky and still be seen as two stars. The Dawes Limit is 4.56 seconds of arc, divided by the telescope aperture in inches. We can multiply the Dawes limit by 25.4 to convert to the metric system (in [mm]), which gets us to 115.8, and then round to a number that is more convenient when doing the math in our head, and we get the resolving power of the scope, P_R in seconds of arc:

$$P_R = \frac{115.8}{D_0} \cong \frac{120}{D_0} \qquad (10.6.235)$$

In meter we can often found that later rounder to 11.6 such that:

$$P_R \cong \frac{11.6}{D_0} \cong \frac{12}{D_0} \qquad (10.6.236)$$

✍**Example:**

Hubble's mirror is $2.4\,[\text{m}] = 240\,[\text{cm}]$ across. Plugging that into the above relation, we see that Hubble's resolution is:

$$P_R \cong \frac{11.6}{240} = 0.05'' \qquad (10.6.237)$$

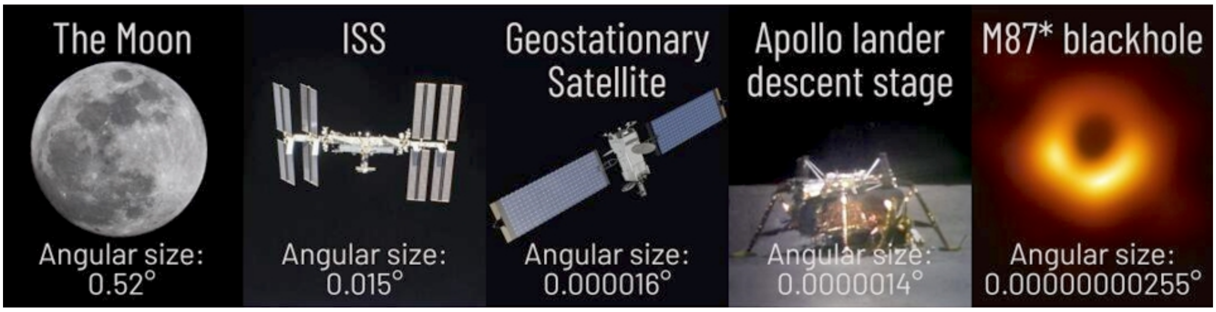
That's an incredibly small size; a human would have to be nearly 8,000 kilometres away to be 0.05 arcseconds in size!

Remark

With the example above it is quit easy to understand why the Hubble space telescope cannot resolve object size of the Apollo mission on the Moon as they're are not more much bigger than human size and especially that they are (at nearest point) 356,700 [km] away! In fact Hubble's space telescope resolution on the Moon is about 200 meters! In other words, even a football stadium on the Moon would look like a dot to Hubble (that's also point out the difference between "seeing" a candle on the Moon, and "resolve" it into a disc!).

That's a pretty big surprise to most people. They're used to seeing magnificent detail in Hubble images, stars in galaxies and wisps of gas in beautiful nebulae. But those objects are far, far larger than the Moon lander. Hubble's resolution is 0.1" no matter how far away an object is. Those wisps of gas appear to be finely resolved, but they're billions of kilometres across. That's a bit roomier than the lunar landers were.

An angle is a fraction of a circle. We can consider the angular size of an object to be equal to its actual (linear) size d, which in turn is roughly the fraction of a circle with a radius equal to the distance of the object, D (actually, d is the "chord" of an arc, and the arc is the fraction of the circumference, thus the cosine factor mentioned in other comments. But we can ignore that for small angles).



So: Fraction of circle (our angle) $= \alpha/360°$ (because there are 360 degrees in a circle).

Fraction of circle (size of object) $= d/(2\pi D)$ (because the circumference of the circle is 2π times the radius, and in this case we're using a circle of radius D).

So:

$$\frac{\alpha}{360^\circ}=\frac{d}{2\pi D} \tag{10.6.238}$$

Rearrange:

$$\frac{d}{D}\cdot\frac{360^\circ}{2\pi}=\alpha \tag{10.6.239}$$

But remember, we want our number to be in arcseconds, not degrees, so

Rearrange (60 arcminutes per degree, 60 arcseconds per arcminute):

$$\frac{d}{D}\cdot\frac{360^\circ\cdot 60'\cdot 60''}{2\pi}=\alpha \tag{10.6.240}$$

Calculating all that out, we get:

$$\frac{d}{D}\cdot 206,264.81''=\alpha \tag{10.6.241}$$

Round the constant up to $206,265$ and we're done.

So let's look at our lunar descent stage. It's 4 meters across, but $350,000,000$ meters away. That gives it an angular size of:

$$\frac{4}{350,000,000}\cdot 206,265\cong 0.002'' \tag{10.6.242}$$

Hey, wait a sec! This is far below Hubble's resolution! So the lander is way too small to be seen as anything more than a dot, even by Hubble.

Remark

At then end of the 120th century (holocene calendar), it seems that the KH-11 reconnaissance satellite series, first launched by the American National Reconnaissance Office, with their supposed 2.4 meter mirror (quite similar to Hubble!) observing in the visual (i.e. at a wavelength of 500 [nm]) have the best resolution power in the World with a diffraction limited resolution of around 0.05 arcsec, which from an orbital altitude of 250 [km] corresponds to a ground sample distance of 0.06 [m]...

10.6.3.3 Case of a circular obstacle

We can handle the case of diffraction by a circular obstacle quite easily now, using the result just obtained. For the field,

$$\begin{aligned}
f &\cong \frac{2\pi\rho_A e^{\mathrm{i}(kR-\omega t)}}{R}\int\limits_{a}^{+\infty}\rho J_0\left(\frac{kq\rho}{R}\right)\mathrm{d}\rho\\
&=\frac{2\pi\rho_A e^{\mathrm{i}(kR-\omega t)}}{R}\int\limits_{0}^{+\infty}\rho J_0\left(\frac{kq\rho}{R}\right)\mathrm{d}\rho-\frac{2\pi\rho_A e^{\mathrm{i}(kR-\omega t)}}{R}\int\limits_{0}^{a}\rho J_0\left(\frac{kq\rho}{R}\right)\mathrm{d}\rho\\
&=\rho_A e^{\mathrm{i}(kR-\omega t)}-\frac{\rho_A\pi a^2 e^{\mathrm{i}(kR-\omega t)}}{R}\frac{R}{kaq}2J_1\left(\frac{kaq}{R}\right)\\
&=\rho_A e^{\mathrm{i}(kR-\omega t)}-\frac{\rho_A\pi a^2 e^{\mathrm{i}(kR-\omega t)}}{R}\frac{2J_1\left(\dfrac{kaq}{R}\right)}{\dfrac{kaq}{R}}
\end{aligned}\tag{10.6.243}$$

Therefore the intensity is proportional to:

$$\begin{aligned}
I\propto\hat{f}^2&=\left(\rho_A-\frac{\rho_A\pi a^2}{R}\frac{2J_1\left(\dfrac{kaq}{R}\right)}{\dfrac{kaq}{R}}\right)^2\\
&=\rho_A^2\left[1-\frac{\pi a^2}{R}\frac{4J_1\left(\dfrac{kaq}{R}\right)}{\dfrac{kaq}{R}}+\left(\frac{\pi a^2}{R}\frac{2J_1\left(\dfrac{kaq}{R}\right)}{\dfrac{kaq}{R}}\right)^2\right]
\end{aligned}\tag{10.6.244}$$

This result has the curious property of not being zero inside the shadow of the obstacle (when $q\rightarrow 0$). To prove that fact let see first a special limit of the first order Bessel function.

Take the recurrence relation at $m=1$ and use the chain rule:

$$uJ_0(u)=\frac{\mathrm{d}}{\mathrm{d}u}\left[uJ_1(u)\right]=J_1(u)+u\frac{\mathrm{d}J_1}{\mathrm{d}u}(u)\tag{10.6.245}$$

Therefore:

$$J_0(u)=\frac{\mathrm{d}J_1}{\mathrm{d}u}(u)+\frac{J_1(u)}{u}\tag{10.6.246}$$

Note that $J_0(0)=1$ and $J_1(0)=0$:

$$1=\frac{\mathrm{d}J_1}{\mathrm{d}u}(0)+\lim_{u\rightarrow 0}\frac{J_1(u)}{u}=\frac{\mathrm{d}J_1}{\mathrm{d}u}(0)+\lim_{u\rightarrow 0}\frac{\dfrac{\mathrm{d}J_1}{\mathrm{d}u}(u)}{1}=2\frac{\mathrm{d}J_1}{\mathrm{d}u}(0)\tag{10.6.247}$$

or:

$$\lim_{u\rightarrow 0}\frac{J_1(u)}{u}=\frac{\mathrm{d}J_1}{\mathrm{d}u}(0)=\frac{1}{2}\tag{10.6.248}$$

In fact, there's a sharp peak exactly in the center, with peak intensity:

$$\begin{aligned}I_{\text{center},q=0} &\propto \lim_{q\rightarrow 0}\left[1-\frac{\pi a^2}{R}\frac{4J_1\left(\dfrac{kaq}{R}\right)}{\dfrac{kaq}{R}}+\left(\frac{\pi a^2}{R}\frac{2J_1\left(\dfrac{kaq}{R}\right)}{\dfrac{kaq}{R}}\right)^2\right]\\ &=1-\frac{2\pi a^2}{R}+\frac{\pi^2 a^4}{R^2}>0\end{aligned} \tag{10.6.249}$$

as $a/R \ll 1$.

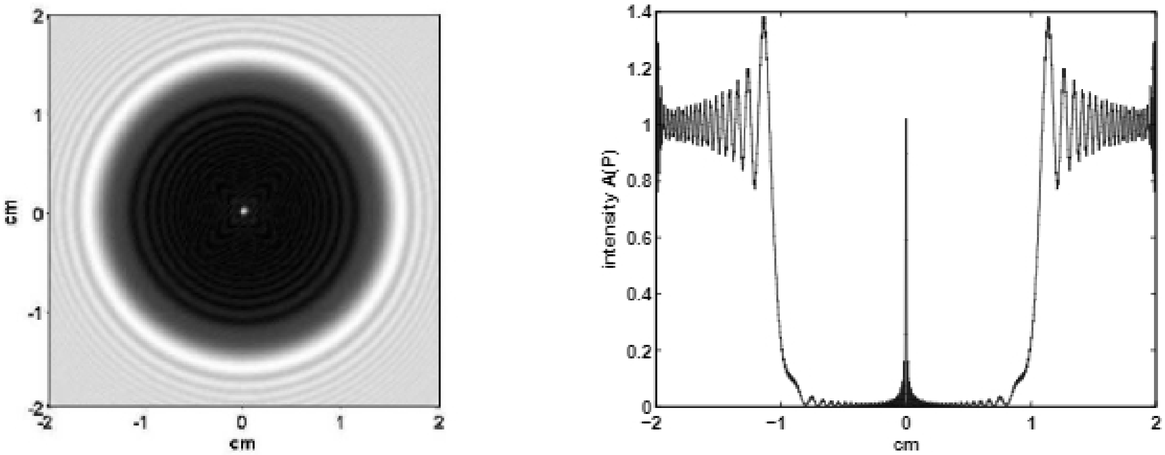


Figure 10.252: **Spot of Poisson-Arago Intensity distribution behind a coin ($a = 1$ [cm]) on a detector placed at $R = 5$ [m].**

10.6.4 Light polarization

It was not before the 119th century (holocene calendar) that it was discovered the polarization of light (we will immediately explain what it is). However, at the time of Newton, we already knew a phenomenon due to polarization: the existence of crystals named "birefringent crystals" (as the "Iceland spar") which have the property of refracting a single beam into two separate beams[23].

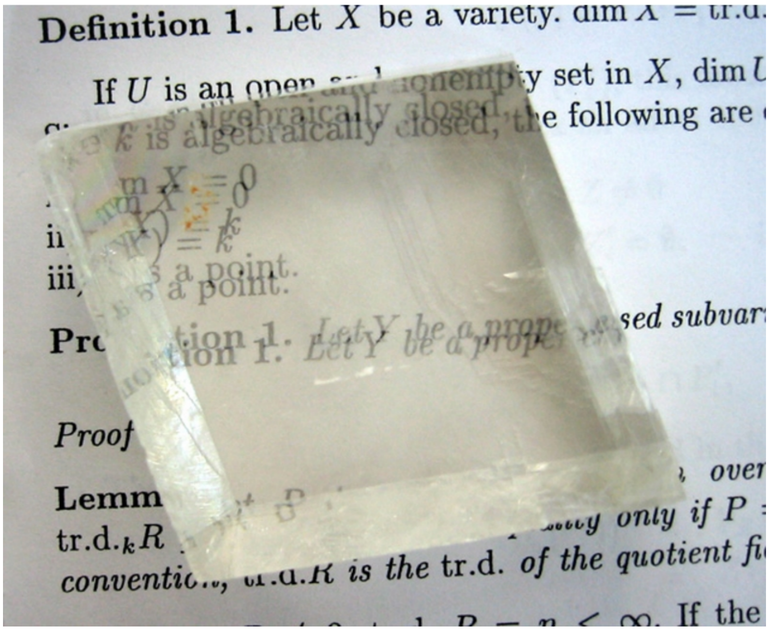

Figure 10.253: **Iceland spar (crystallized calcite)**

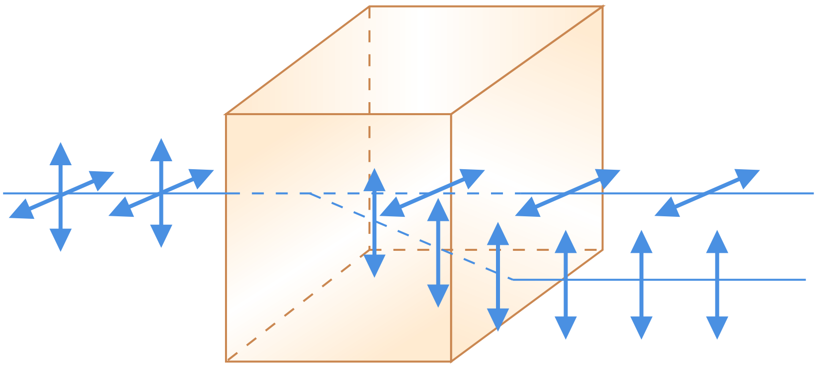
Now we know that the two rays refracted by such a crystal are polarized:



To understand the "polarization of light" let us come back to the case of a wave propagating on a string (see section Wave Mechanics page 3475). Such a wave can do it in a vertical plane (right) as well as in a horizontal plane (left) or in all intermediate levels:

---

[23] In the mid-12026 (holocene calendar) a peer-review scientific paper has been published about a potential observation of quantum vacuum birefringence ("vacuum crystallization") at the vicinity of the surface of a Magnetar-type star in accordance with the predictions of Quantum Field Theory in the context of ultra-intense magnetic fields (see [515]).

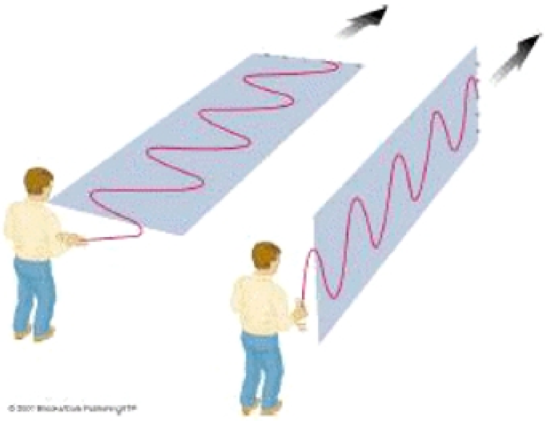


Figure 10.254: **Pictorial representation of the light polarization concept with a string (source: ?)**

In both cases, we say that the wave is "linearly polarized", which means that the oscillations are only and always in the same plane, named "polarization plane". Such a wave can pass through a vertical slot if it is polarized vertically, a horizontally polarized wave can not.

Let us recall that we have seen in the section of Electrodynamics that for electromagnetic waves, the electric $\vec{E}$ field oscillates (at least for the standard solution of Maxwell's equations) and is orthogonal to the direction of propagation.

The electric field vector $\vec{E}$ of a wave can be decomposed into two perpendicular components to each other, $(\vec{E}_x,\vec{E}_y)$ if the wave propagates in the z direction and each carrying half of the intensity of the wave. These two components change at any time when $\vec{E}$ varies. The result at any time is a total horizontal field and a total vertical field.

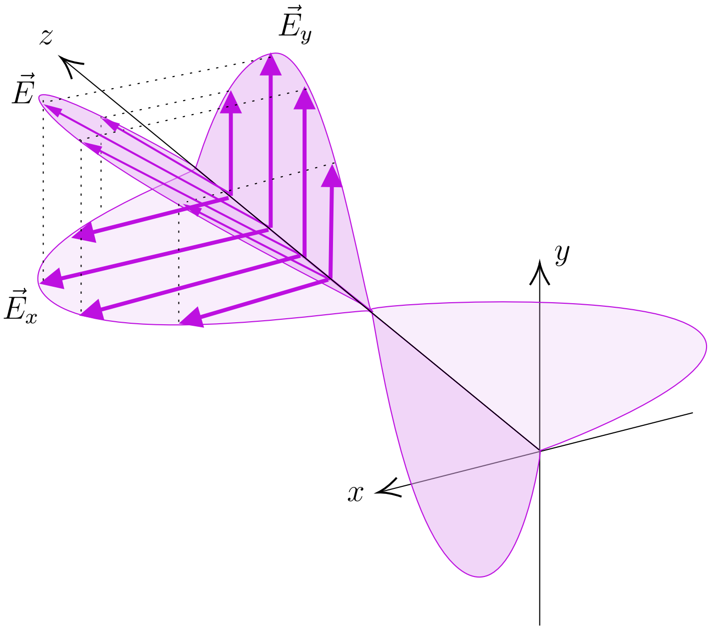

Figure 10.255: **Illustration of the decomposition of the electric field of a propagating wave (source: ?)**

If $\vec{E}$ revolves around the propagation direction with its end describing circle, then we say that the wave is "circularly polarized":

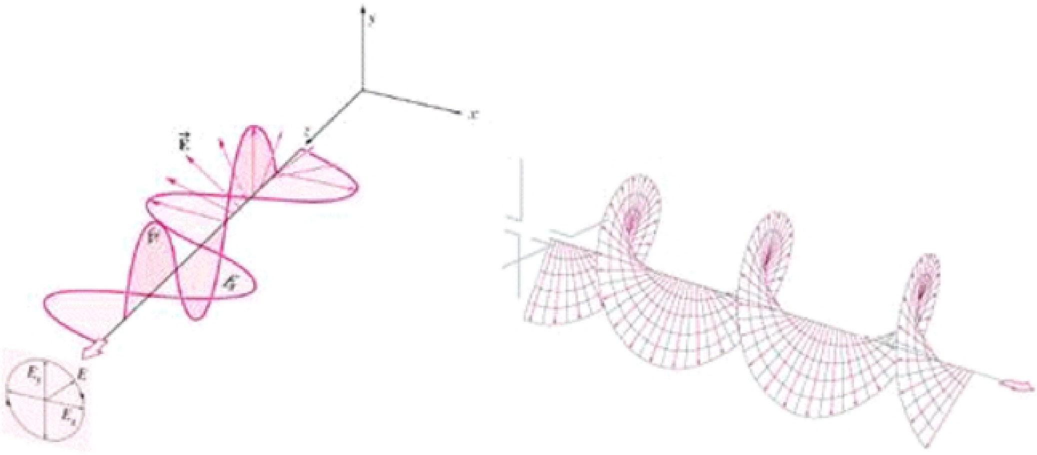

Figure 10.256: **Pictorial representation of a circular polarized wave (source: ?)**

Then $\vec{E}$ remains of constant modulus but turns while moving, making one complete turn for each distance equal to one wavelength λ.

Remark

The light is not necessarily polarized! Every atom emits a wave train that lasts less than one hundred-millionth of a second (these wave trains are perfectly explained by the spread of a the free particle in quantum physics with the Fourier transforms as proved in the section of Wave Quantum Physics) and all these waves have no phase correlation or orientation. The resultant field in a given position in space, is the geometric sum of all these wave trains: it is constantly changing.

Thus, the natural light is a random and quickly variable mixture of linearly polarized waves in all directions. Looking to the source we observe a resulting field $\vec{E}$ oscillating in a certain direction for a fraction of time and then suddenly jumps to a new random direction while remaining perpendicular to the direction of propagation:

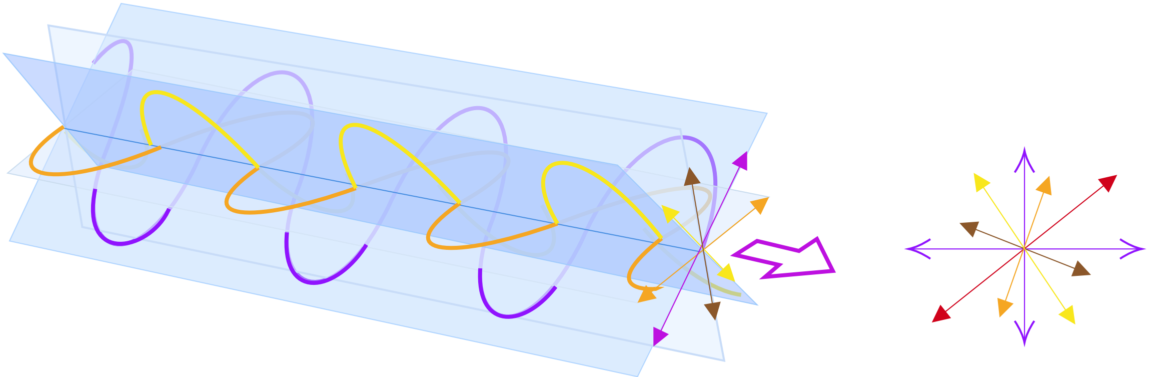

Figure 10.257: **Pictorial representation of "natural" light wave (source: ?)**

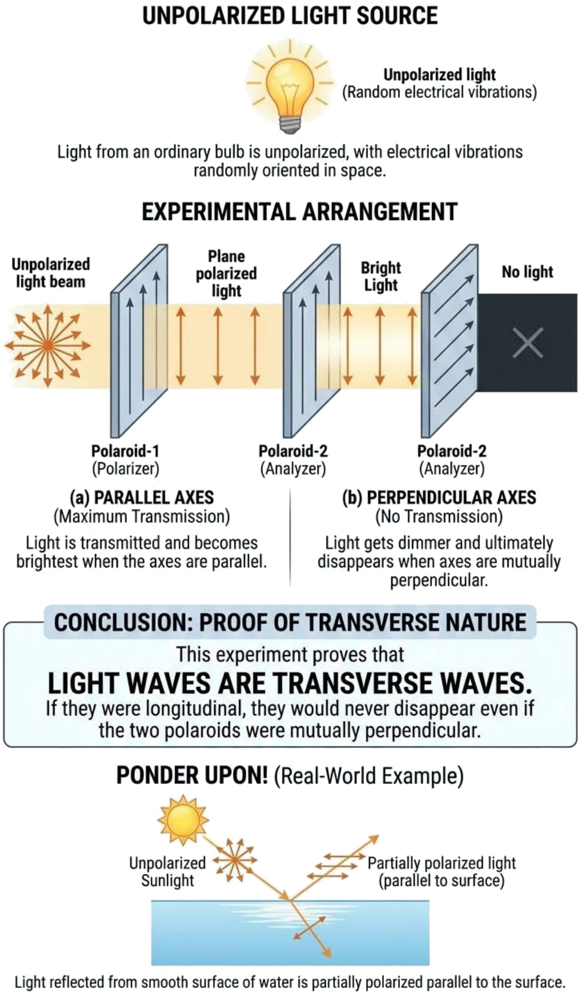

UNPOLARIZED LIGHT SOURCE

Polaroid-2
(Analyzer)
(a) PARALLEL AXES
(Maximum Transmission)
Light is transmitted and becomes brightest when the axes are parallel.
(b) PERPENDICULAR AXES
(No Transmission)
Light gets dimmer and ultimately disappears when axes are mutually perpendicular.
CONCLUSION: PROOF OF TRANSVERSE NATURE
This experiment proves that
LIGHT WAVES ARE TRANSVERSE WAVES.
If they were longitudinal, they would never disappear even if the two polaroids were mutually perpendicular.
PONDER UPON! (Real-World Example)
Unpolarized Sunlight
Partially polarized light
(parallel to surface)
Light reflected from smooth surface of water is partially polarized parallel to the surface.

This introduction done, let us move now to something a bit more formal:

We therefore saw in the section Electrodynamics that a hypothetical progressive monochromatic plane wave (even if physically it cannot exist ...) propagating in the vacuum consisted of an electric field $\vec{E}$ and a magnetic field $\vec{E}$ and was characterized by its pulsation ω (or corresponding wavelength λ), its electric field amplitude $\hat{E}$ and magnetic field amplitude $\hat{B}$ and its propagation direction given by a unit vector $\vec{u}_x$, $\vec{u}_y$, $\vec{u}_z$ at choice depending on the orientation of the selected reference frame.

We have also proved that these waves have remarkable structural properties, in particular:

- $\vec{E}$ and $\vec{B}$ are transverse, that is to say, their direction is at any point and at any time orthogonal to the direction of propagation (Malus theorem). This, allow us to define a wave plane, plane generated by the two directions of $\vec{E}$ and $\vec{B}$.
- The norms of these two vectors are connected by the relations $\hat{B}=\hat{E}/c$ where c is the speed of light in vacuum (this is this huge ratio between the magnetic field and electric field of an electromagnetic wave that makes developments presented further below are done preferably compared with the electric field component of the wave).
- Finally, these two vectors are orthogonal to each other, and the trihedron $(\vec{E},\vec{B},\vec{u}_i)$ is an

orthogonal trihedron .

These three properties can be summarized as we have prove it by the relation:

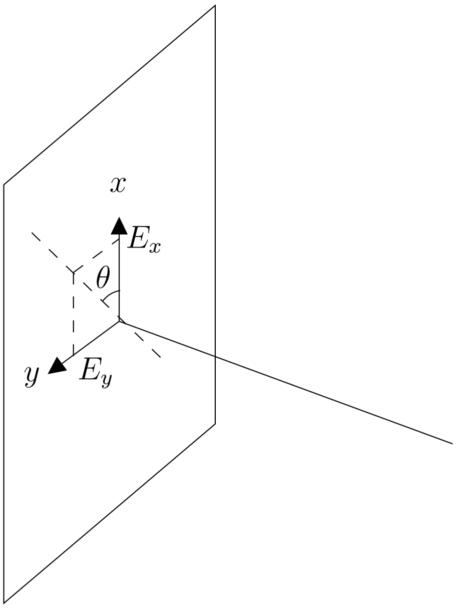
$$\vec{B}=\frac{\vec{u}_z\times\vec{E}}{c} \tag{10.6.250}$$

where we have chose the reference frame such as the wave propagates in the direction $\vec{u}_z$. Furthermore, we proved that the electric field is a trigonometric wave function given by:

$$\|\vec{E}\|=\hat{E}\cos(\omega t-kz+\varphi_1) \qquad \text{or} \qquad \|\vec{E}\|=\hat{E}\sin(\omega t-kz+\varphi_2) \tag{10.6.251}$$

Let us now position ourselves in a base (x,y,z). The most general expression of the electric field of a progressive monochromatic plane wave progressing in the $\vec{u}_z$ direction can be decomposed into two components:

$$\vec{E}=\begin{pmatrix}E_x\\E_y\\E_z\end{pmatrix}=\begin{pmatrix}\hat{E}\cos(\theta)\cos(\omega t-kz+\varphi_x)\\\hat{E}\sin(\theta)\cos(\omega t-kz+\varphi_y)\\0\end{pmatrix}=\begin{pmatrix}\hat{E}_{0x}\cos(\omega t-kz+\varphi_x)\\\hat{E}_{0y}\cos(\omega t-kz+\varphi_y)\\0\end{pmatrix} \tag{10.6.252}$$



The norm of the field is therefore given by:

$$\|\vec{E}(t)\|=\sqrt{\hat{E}\cos^2(\theta)\cos^2(\omega t-kz+\varphi_x)+\hat{E}^2\sin^2(\theta)\cos^2(\omega t-kz+\varphi_y)} \tag{10.6.253}$$

If $\varphi_x=\varphi_y$ (which is most often the case) we have then:

$$\|\vec{E}(t)\|=\hat{E}\cos(\omega t-kz+\varphi)\leq\hat{E} \tag{10.6.254}$$

By choosing another beginning of time, we are lead to write:

$$\vec{E}=\begin{pmatrix}\hat{E}_{0x}\cos(\omega t-kz)\\\hat{E}_{0y}\cos(\omega t-kz-\varphi)\\0\end{pmatrix} \tag{10.6.255}$$

with:

$$\varphi=\varphi_x-\varphi_y \tag{10.6.256}$$

Remark

The choice of writing $-\varphi$ instead of $+\varphi$ will be useful later for the use of remarkable trigonometric relations and will allow us to find the equation of an ellipse (...patience the proof is not far anymore).

Using the phasors (see section Wave Mechanics page 3510) the last relations can be reduced to:

$$\vec{E}=\Re\begin{pmatrix}\hat{E}_{0x}e^{\mathrm{i}(\omega t-kz)}\\ \hat{E}_{0y}e^{\mathrm{i}(\omega t-kz-\varphi)}\\ 0\end{pmatrix}=\Re\begin{pmatrix}\hat{E}\cos(\theta)e^{\mathrm{i}(\omega t-kz)}\\ \hat{E}\sin(\theta)e^{\mathrm{i}(\omega t-kz-\varphi)}\\ 0\end{pmatrix} \quad (10.6.257)$$

However, to describe this field, and therefore the whole wave, it is convenient to put ourselves in the plane $z=0$ and describe the evolution of the vector in $\vec{E}$ in this plane. That's what we'll do next. This is equivalent as to choose a coordinate origin following the z-axis. In this case, we can write:

$$\vec{E}=\Re\begin{pmatrix}\hat{E}_{0x}e^{\mathrm{i}(\omega t)}\\ \hat{E}_{0y}e^{\mathrm{i}(\omega t-\varphi)}\\ 0\end{pmatrix}=\Re\begin{pmatrix}\hat{E}\cos(\theta)e^{\mathrm{i}(\omega t)}\\ \hat{E}\sin(\theta)e^{\mathrm{i}\omega t}e^{-\varphi}\\ 0\end{pmatrix}=\hat{E}\Re\begin{pmatrix}\cos(\theta)\\ \sin(\theta)e^{-\varphi}\\ 0\end{pmatrix}e^{\mathrm{i}\omega t} \quad (10.6.258)$$

But the most general polarization is described by a complex vector normalized to unity in a two-dimensional space of components:

$$\lambda=\cos(\theta)e^{\mathrm{i}\varphi_x} \qquad \mu=\sin(\theta)e^{\mathrm{i}\varphi_y} \quad (10.6.259)$$

with:

$$|\lambda|^2+|\mu|^2=1 \quad (10.6.260)$$

such that:

$$\vec{E}=\hat{E}\cdot\Re\begin{pmatrix}\cos(\theta)e^{\mathrm{i}\varphi_x}\\ \sin(\theta)e^{\mathrm{i}\varphi_y}\\ 0\end{pmatrix}e^{\mathrm{i}\omega t} \quad (10.6.261)$$

10.6.4.1 Linear polarization

Definition (#10.6.498): We say that a wave is "linearly polarized" when $\varphi=0$ or $\varphi=\pi$.

In the first case ($\varphi=0\Rightarrow\varphi_x=\varphi_y$), we have:

$$\vec{E}=\Re\begin{pmatrix}\hat{E}_{0x}e^{\mathrm{i}\omega t}\\ \hat{E}_{0y}e^{\mathrm{i}\omega t}\end{pmatrix} \quad (10.6.262)$$

Therefore, we have $\hat{E}_{0x}$,$\vec{E}_{0y}$ which have respectively values between:

$$[-\hat{E}_{0x},+\hat{E}_{0x}],[-\hat{E}_{0y},+\hat{E}_{0y}] \quad (10.6.263)$$

With respect to a diagram that we will see below it should be taken into account that when a component is positive the other is also positive, and vice versa.

We then have at every instant:

$$\left.\begin{aligned} E_x &= \hat{E}_{0x}\cos(\omega t) \\ E_y &= \hat{E}_{0y}\cos(\omega t) \end{aligned}\right\} : \frac{E_x}{\hat{E}_{0x}} = \frac{E_y}{\hat{E}_{0y}} \tag{10.6.264}$$

which means that the field keeps a fixed direction. Hence the fact that we speak of linearly polarized wave.

If $\varphi = \pi$ we then have:

$$\vec{E} = \begin{pmatrix} \hat{E}_{0x}\cos(\omega t - kz) \\ \hat{E}_{0y}\cos(\omega t - kz - \pi) \\ 0 \end{pmatrix} = \begin{pmatrix} \hat{E}_{0x}\cos(\omega t - kz) \\ -\hat{E}_{0y}\cos(\omega t - kz) \\ 0 \end{pmatrix} \tag{10.6.265}$$

and that can therefore be written:

$$\vec{E} = \Re\begin{pmatrix} \hat{E}_{0x}e^{\mathrm{i}\omega t} \\ -\hat{E}_{0y}e^{\mathrm{i}\omega t} \end{pmatrix} \tag{10.6.266}$$

Therefore, we have $\hat{E}_{0x},\vec{E}_{0y}$ which have respectively values between:

$$[-\hat{E}_{0x}, +\hat{E}_{0x}], [-\hat{E}_{0y}, +\hat{E}_{0y}] \tag{10.6.267}$$

We then have at every instant:

$$\left.\begin{aligned} E_x &= \hat{E}_{0x}\cos(\omega t) \\ E_y &= -\hat{E}_{0y}\cos(\omega t) \end{aligned}\right\} : \frac{E_x}{\hat{E}_{0x}} = -\frac{E_y}{\hat{E}_{0y}} \tag{10.6.268}$$

which means that the field keeps a fixed direction. Hence the fact that we speak of linearly polarized wave.

10.6.4.2 Elliptical polarization

If φ is arbitrary, and placing ourselves at $h = 0$, we always have by starting from:

$$\vec{E} = \begin{pmatrix} \hat{E}_{0x}\cos(\omega t - kz) \\ \hat{E}_{0y}\cos(\omega t - kz - \varphi) \\ 0 \end{pmatrix} \tag{10.6.269}$$

The first relation:

$$\frac{E_x}{\hat{E}_{0x}} = \cos(\omega t) \tag{10.6.270}$$

as well as:

$$\frac{E_y}{\hat{E}_{0y}} = \cos(\omega t)\cos(\varphi) + \sin(\omega t)\sin(\varphi) \tag{10.6.271}$$

hence:

$$\sin(\omega t)\sin(\varphi)=\frac{E_y}{\hat{E}_{0y}}-\cos(\omega t)\cos(\varphi)=\frac{E_y}{\hat{E}_{0y}}-\frac{E_x}{\hat{E}_{0x}}\cos(\varphi) \tag{10.6.272}$$

Moreover, we can write:

$$\frac{E_x}{\hat{E}_{0x}}=\cos(\omega t)\Leftrightarrow\frac{E_x}{\hat{E}_{0x}}\sin(\varphi)=\cos(\omega t)\sin(\varphi) \tag{10.6.273}$$

In squaring the two previous relations:

$$\begin{gathered}\sin^2(\omega t)\sin^2(\varphi)=\left(\frac{E_y}{\hat{E}_{0y}}\right)^2-2\frac{E_y}{\hat{E}_{0y}}\frac{E_x}{\hat{E}_{0x}}\cos(\varphi)+\left(\frac{E_x}{\hat{E}_{0x}}\right)^2\cos^2(\varphi)\\ \left(\frac{E_x}{\hat{E}_{0x}}\right)^2\sin^2(\varphi)=\cos^2(\omega t)\sin^2(\varphi)\end{gathered} \tag{10.6.274}$$

and by summing, we eliminate the time and get:

$$\sin^2(\varphi)=\left(\frac{E_y}{\hat{E}_{0y}}\right)^2-2\frac{E_y}{\hat{E}_{0y}}\frac{E_x}{\hat{E}_{0x}}\cos(\varphi)+\left(\frac{E_x}{\hat{E}_{0x}}\right)^2 \tag{10.6.275}$$

$$\sin^2(\varphi)=\left(\frac{E_y}{\hat{E}_{0y}}\right)^2-2\frac{E_y}{\hat{E}_{0y}}\frac{E_x}{\hat{E}_{0x}}\cos(\varphi)+\left(\frac{E_x}{\hat{E}_{0x}}\right)^2 \tag{10.6.276}$$

We notice that if $\varphi=0$, $\varphi=\pi$ we fall back on:

$$\left(\frac{E_y}{\hat{E}_{0y}}\right)^2-2\frac{E_y}{\hat{E}_{0y}}\frac{E_x}{\hat{E}_{0x}}+\left(\frac{E_x}{\hat{E}_{0x}}\right)^2=\left(\frac{E_y}{\hat{E}_{0y}}-\frac{E_x}{\hat{E}_{0x}}\right)^2=0\Rightarrow\frac{E_y}{\hat{E}_{0y}}=\frac{E_x}{\hat{E}_{0x}} \tag{10.6.277}$$

By the way, in the prior previous relation we recognize the equation of an ellipse (see section Analytical Geometry page 2768):

$$y^2+x^2+(-2\cos(\varphi))xy+(-\sin^2(\varphi))=0 \tag{10.6.278}$$

similar in all respects to the general equation of the conical we have proved in the section of Analytical Geometry that was for recall:

$$\alpha y^2+\beta x^2+\gamma xy+\delta x+\varepsilon y+\xi=0 \tag{10.6.279}$$

In this case, the end of the vector $\vec{E}$ thus describes an ellipse and we talk therefore naturally of "elliptical polarization".

According to the value of φ, the ellipse may be traversed in one direction or the other. To determine this direction, let us derivate the expression of the field:

$$\vec{E}=\begin{pmatrix}\hat{E}_{0x}\cos(\omega t-kz)\\ \hat{E}_{0y}\cos(\omega t-kz-\varphi)\\ 0\end{pmatrix} \tag{10.6.280}$$

with respect to time and let us put ourselves at $t=0$ still in the same wave plane in $z=0$:

$$\mathrm{d}_t\vec{E}=\begin{pmatrix}-\hat{E}_{0x}\omega\sin(\omega t-kz)\\ \hat{E}_{0y}\omega\sin(\omega t-kz-\varphi)\\ 0\end{pmatrix}=\begin{pmatrix}0\\ -\hat{E}_{0y}\omega\sin(\varphi)\\ 0\end{pmatrix}_{t=0} \qquad (10.6.281)$$

Therefore:

- If $0<\varphi<\pi/2$ the ellipse is travelled in the forward direction (counter clock wise) as shown in the figure below. We say then that the polarization is "elliptical direct left".
- If $\pi/2<\varphi<\pi$ the ellipse is travelled also in the forward direction (counter clock wise) as shown in the figure below. We say then that the polarization is "elliptical direct right".
- If $\pi<\varphi<3\pi/2$ the ellipse is travelled clockwise. We say then that the polarization is "elliptical indirect right".
- If $3\pi/2<\varphi<2\pi$ the ellipse is travelled clockwise as shown in the figure below. We say when the polarization is "elliptical indirect left".

10.6.4.3 Circular polarization

If:

$$\varphi=\frac{\pi}{2}\qquad\varphi=\frac{3\pi}{2} \qquad (10.6.282)$$

and:

$$\hat{E}_{0x}=\hat{E}_{0y}=E_0 \qquad (10.6.283)$$

we have then the equation of the ellipse which reduces to:

$$E_x^2+E_y^2=E_{0x,y}^2 \qquad (10.6.284)$$

which is the equation of a circle of radius $E_{0x,y}$, the sign being always given by the sign of the sine:

- If $\varphi=\pi/2$ it is a "left circular polarization"
- If $\varphi=3\pi/2$it is a "right circular polarization

....see figure below for a visual summary.

10.6.4.4 Natural polarization

We can consider the emission of a source as a succession of progressive theoretical monochromatic plane waves whose expression will be:

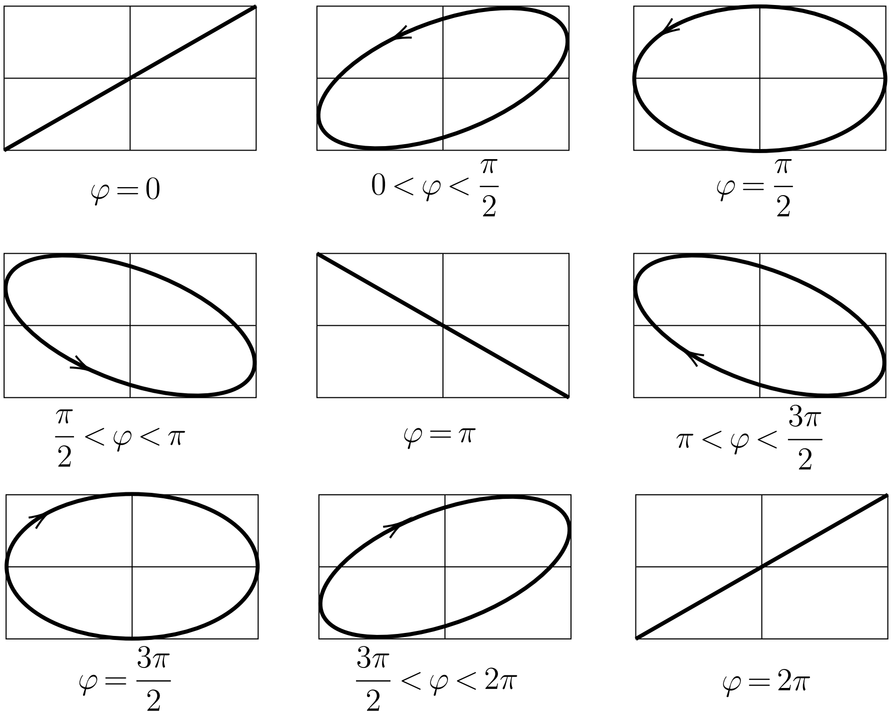
$$\vec{E}=\begin{pmatrix} \hat{E}_{0x}\cos(\omega t-kz) \\ \hat{E}_{0y}\cos(\omega t-kz-\varphi_l) \\ 0 \end{pmatrix} \tag{10.6.285}$$

These wave trains are in a particular polarization state. However, this states varies randomly from one wave train to another, and this in a very short time relative to the integration time of detectors. They therefore will see no particular bias and the field $\vec{E}$ will have no particular direction.

We speak therefore of "unpolarized light". If we overlay this light to a polarized wave, we get what we name a "partial polarization".

Finally, we can summarize what we have seen so far in the following figure where we have:

- The linear polarization: $\varphi=0,\varphi=\pi,\varphi=2\pi$
- The linear partial polarization (not represented below)
- The direct elliptical polarization left $0<\varphi<\pi/2$ or right $\pi/2<\varphi<\pi$
- The indirect elliptical polarization left $\pi<\varphi<3\pi/2$ or $3\pi/2<\varphi<2\pi$
- The partial elliptical polarization (not represented below)
- The circular polarization left $\varphi=\pi/2$ or right $\varphi=3\pi/2$
- The partial circular polarization (not represented below)



$\varphi=0$ $0<\varphi<\dfrac{\pi}{2}$ $\varphi=\dfrac{\pi}{2}$

$\dfrac{\pi}{2}<\varphi<\pi$ $\varphi=\pi$ $\pi<\varphi<\dfrac{3\pi}{2}$

$\varphi=\dfrac{3\pi}{2}$ $\dfrac{3\pi}{2}<\varphi<2\pi$ $\varphi=2\pi$

Figure 10.258: **Representations of different polarizations**

We can represent this with an animated plot in Maple™ 4.00b (we have not put the *.gif below as we don't wanted to overload the PDF too much...) using the following commands:

```
> with (plots):
> Ex:=1;Ey:=1;phi:=Pi/4;k:=1;omega:=1;
> animate3d([x,a*Ex*cos(omega*t-k*x),a*Ey*cos(omega*t-k*x-phi)],
a=0..1,x=-10..10,t=0..2*Pi,frames=15,grid=[35,35],style=patchnogrid,axes=boxed);
```

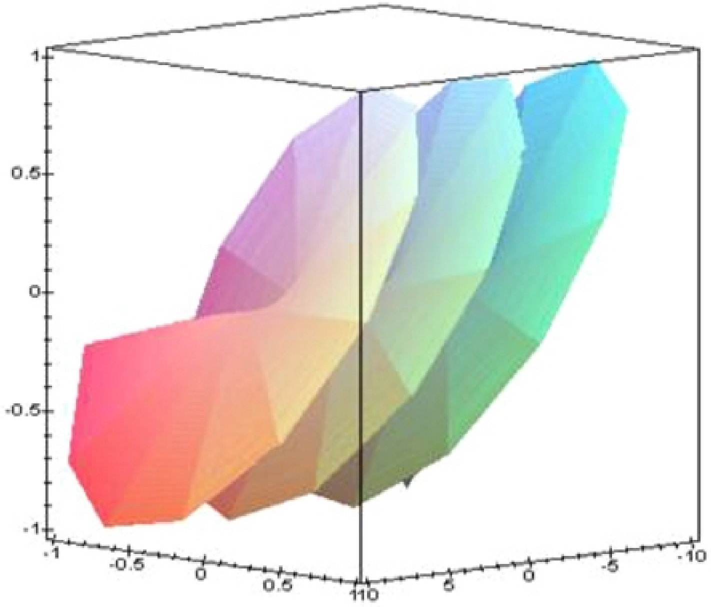


Figure 10.259: **Animation of a polarized wave in Maple™ 4.00b**

It is of course possible to change the parameters. For example, $\phi=\pi/2$ gives circular polarization, $\pi=\pi$ gives a linear polarization as we have prove above.

We can also put the figure of Wikipedia which also summarizes very well the subject:

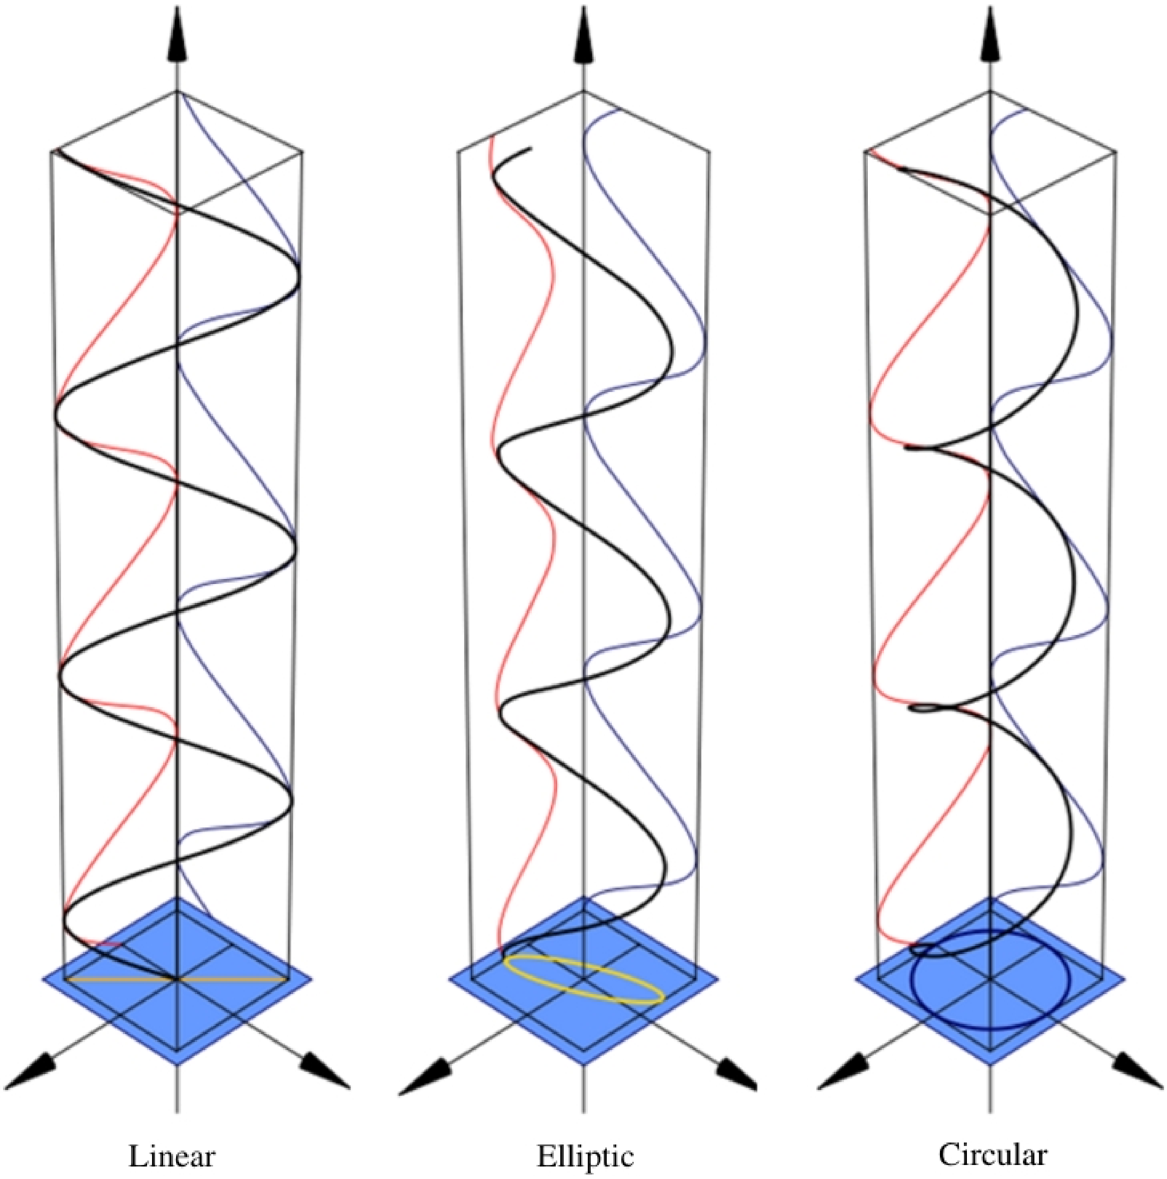

Figure 10.260: **Visual polarized wave principle summary as proposed by Wikipedia**

10.6.4.5 Malus' law

To polarize light, the physicist will use polarisers. We will not enter (because it is not part of the field of Wave Optics) in the details of atomic or molecular properties of matter that are the cause of the polarization of the transmitted light.

For our purposes, we will restrict ourselves to a polariser that polarizes incident light linearly along the x axis (the component E_y being therefore zero). We have therefore:

$$\vec{E}=\begin{pmatrix}E_x\\E_y\\E_z\end{pmatrix}=\Re\begin{pmatrix}\hat{E}\cos(\theta)e^{\mathrm{i}(\omega t-kz)}\\ \hat{E}\sin(\theta)e^{\mathrm{i}(\omega t-kz-\varphi)}\\ 0\end{pmatrix}=\Re\begin{pmatrix}\hat{E}\cos(\theta)e^{\mathrm{i}(\omega t-kz)}\\ 0\\ 0\end{pmatrix} \tag{10.6.286}$$

But, we have proved in the section of Electrodynamics during our study of Maxwell equations that:

$$I=\bar{S}=\frac{\hat{E}\hat{B}}{2\mu_0}=\frac{\hat{E}^2}{2\mu_0 c} \tag{10.6.287}$$

Therefore it comes for the maximum intensity (such that $e^{\mathrm{i}(\omega t-kz)}=1$):

$$\boxed{I=\frac{\hat{E}^2\cos^2(\theta)}{2\mu_0 c}=\frac{\hat{E}}{2\mu_0 c}\cos^2(\theta)=I_0\cos^2(\theta)} \tag{10.6.288}$$

relation that is the famous "Malus' law".

Here is a table with some famous values:

Angle θ	**Malus Law** $\cos^2(\theta)$ (I/I_0)
$0°$	100%
$22.5°$	$\sim 85.35\%$
$45°$	50%
$67.5°$	$\sim 14.64\%$
$95°$	0%

Some people are surprised in the above table that as $22.5°$ is half-way between $0°$ and $45°$ we have 83% rather than 75%.

We can rotate the second polarizer by intermediate angles to get more data points, and we can then rotate it the other way to get a set of data points for negative angles. Then you could plot a curve like this:

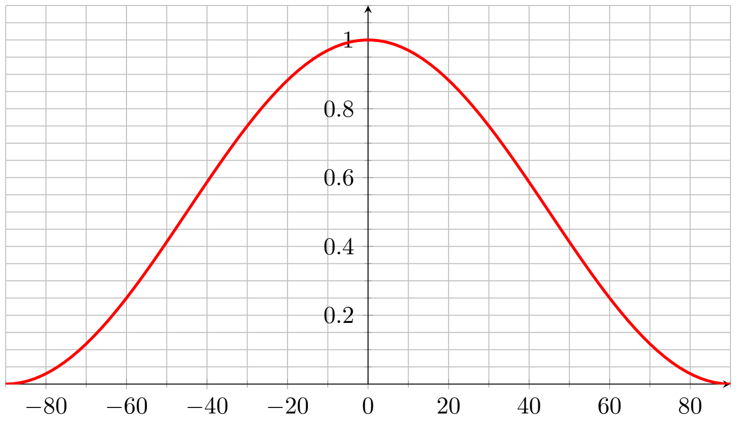

Figure 10.261: Malus' law plot for various angles

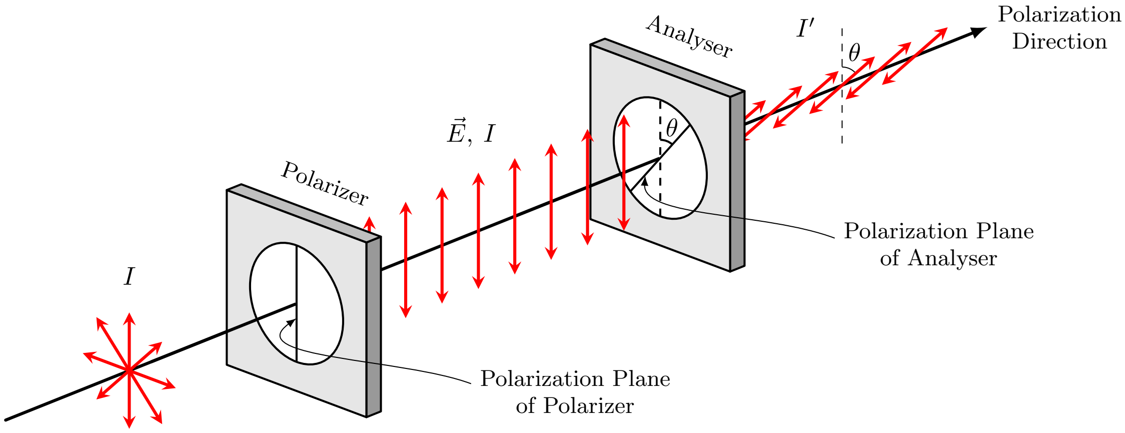
It's not a straight line, it's a cosine-like curve! As to why, it's because a polarizing filter isn't just a filter! It's simple physics. A polarizing filter doesn't just filter, it also rotates the light passing through it. When you have two polarizers at $90°$ to one another, none of the light gets through. But when you put a third polarizer between them at $45°$ to the first, it lets half the light through and rotates it. Then the third polarizer is at $45°$ to the second, and that lets half the light through again, and rotates it again.

To investigate quantitatively the polarization, we will use a polariser / analyser set a described below:



Analyser
I'
θ
Polarization
Direction
$\vec{E},\ I$
θ
Polarizer
Polarization Plane
of Analyser
I
Polarization Plane
of Polarizer

Figure 10.262: Simplified example of a polariser / analyser set (author: Alexandros Tsagkaropoulos)

We first let light pass through a polariser whose axis makes an angle θ with the x-axis, then pass through a second polariser, referred to as "analyser", whose axis makes an angle α with the same axis (see figure below) with:

$$\vec{n} = (\cos(\alpha), \sin(\alpha)) \qquad (10.6.289)$$

whose norm is equal to unity!

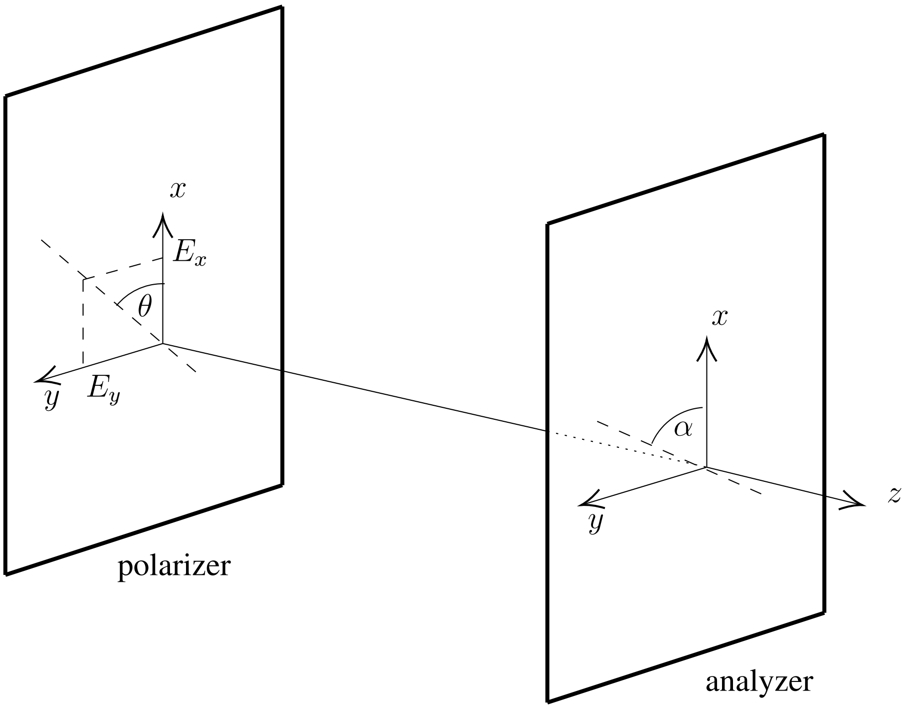


Figure 10.263: **Coordinates system used for our study**

At the exit of the analyser, the electric field $\vec{E}\,'$ is obtained by projecting the linear polarized light ($\varphi = 0$) obtained at the exit of polariser:

$$\vec{E} = \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix} = \begin{pmatrix} \hat{E}\cos(\theta)\cos(\omega t) \\ \hat{E}\sin(\theta)\cos(\omega t) \\ 0 \end{pmatrix} = \hat{E}\vec{p}\cos(\omega t) \qquad (10.6.290)$$

with:

$$\vec{p} = (\cos(\theta), \sin(\theta)) \qquad (10.6.291)$$

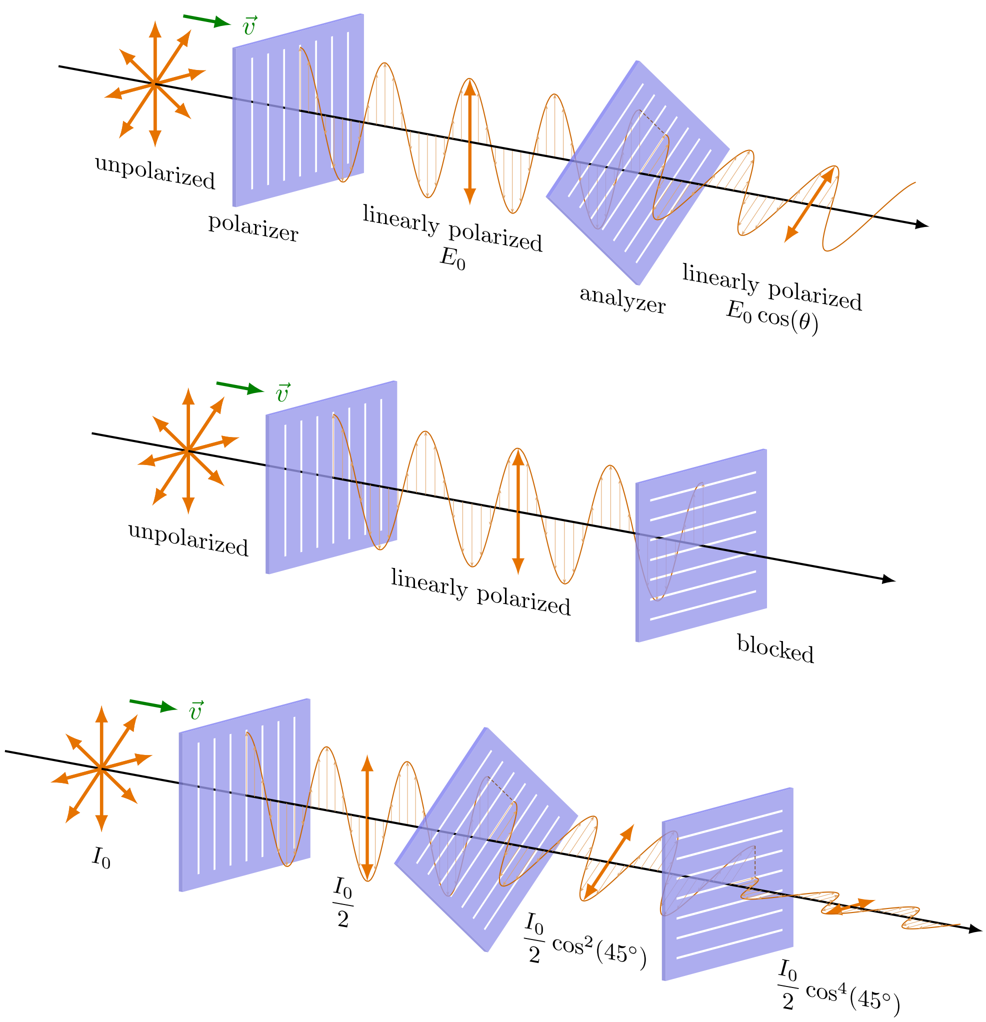
on $\vec{n}$ (which means: projection = dot product, to get a vector we multiply for recall by the vector on which we do the projection):

$$\begin{aligned}\vec{E}' &= (\vec{E}\circ\vec{n})\vec{n} = (E_0\cos(\omega t)(\vec{p}\circ\vec{n}))\vec{n} = E_0\cos(\omega t)(\cos(\theta)\cos(\alpha)+\sin(\theta)\sin(\alpha))\vec{n} \\ &= [E_0\cos(\omega t)\cos(\theta-\alpha)]\vec{n}\end{aligned} \qquad (10.6.292)$$

We the deduce the Malus law for the intensity:

$$\boxed{I' = I\cos^2(\theta-\alpha)} \qquad (10.6.293)$$

for the case of a linear polarization of course. We will reuse that result for our study of quantum cryptography (see section Cryptography page 7263).



$\vec{v}$

$\frac{I_0}{2}\cos^2(45°)$
$\frac{I_0}{2}\cos^4(45°)$

Figure 10.264: **Different configuration of linear polarizers (author: Izaak Neutelings)**

A polarizer does not work by transmitting one very specific polarization angle and blocking all other. The reason for this is that any incident polarization can always be seen as a linear superposition of the polarizer's polarization and the one orthogonal to it. The orthogonal polarization is completely blocked and the parallel polarization is completely transmitted - this is the definition of what a perfect polarizer does. Now, an incident electric field vector $\vec{E}$ at angle θ is:

$$\vec{E}_0 = \cos(\theta)E_{\parallel} + \sin(\theta)E_{\perp} \tag{10.6.294}$$

in terms of the field in the parallel direction $E_{\parallel}$and the field in the orthogonal direction $E_{\perp}$. After the polarizer, all that is left is $\vec{E}_1 = \cos(\theta)E_{\parallel\parallel}$. Therefore, the ratio of the intensities is:

$$\frac{I_1}{I_0} \propto \frac{\left(\vec{E}_1\right)^2}{\left(\vec{E}_0\right)^2} = \cos^2(\theta) \tag{10.6.295}$$

which shows Malus' law.

If the polarization angle of the the incident radiation is uniformly randomly distributed among the possible angles, then the average intensity will be:

$$\frac{1}{2\pi}\int_{0}^{2\pi}\cos^2(\theta)\mathrm{d}\theta=\frac{1}{2} \qquad (10.6.296)$$

i.e. "totally unpolarized" photons have, on average, an equal chance to be absorbed by or transmitted through the polarizer.

10.6.5 Coherence and interference (interferometry)

Interferometry is a technique which uses the interference of superimposed waves to extract information for various purposes. Interferometry typically uses electromagnetic waves and is an important investigative technique in the fields of astronomy, fiber optics, engineering, metrology, optical metrology, oceanography, seismology, spectroscopy (and its applications to chemistry), aeronautics, quantum mechanics, nuclear and particle physics, plasma physics, biomolecular interactions, surface profiling, microfluidics, mechanical stress/strain measurement, velocimetry, optometry, radiology, and making holograms.

Interferometers are devices that extract information from interference. They are widely used in science and industry for the measurement of microscopic displacements, refractive index changes and surface irregularities. In the case with most interferometers, light from a single source is split into two beams that travel in different optical paths, which are then combined again to produce interference; two incoherent sources can also be made to interfere under some circumstances. The resulting interference fringes give information about the difference in optical path lengths. In analytical science, interferometers are used to measure lengths and the shape of optical components with many times nanometer precision or even below (like for gravitational interferometers); they are the highest-precision length measuring instruments in existence. In Fourier transform spectroscopy they are used to analyze light containing features of absorption or emission associated with a substance or mixture. An astronomical interferometer consists of two or more separate dishes that correlates their signals, offering a resolution equivalent to that of a single-dish telescope of diameter equal to the largest separation between its individual elements.

Built by François Arago to measure refractive index differences, establishing early wave-theory applications.

First single-beam interferometer without a wavefront splitting aperture, simplifying atmospheric gas refractometry.

Two highly reflective parallel surfaces creating multiple-beam interference for ultra-high resolution laser cavities and spectroscopy.

Invented by Albert A. Michelson using a 50-50 beam splitter. Femuus for disproving the luminilurous asther and serving as the foundational architecture for modern FTIB spectroscopy and kilometer-scale gravitational wave detectors (LIGO).

Features two independent beam splittors in a single-pase geometry, ideal for fluid dynamics and optical modulators.

Routes counter-propagating beams around a closed path; phose shifie proportional to rotation rates, forming the core of ring laser and floer-optic gyroscopes.

Specialized Michelson variant using cokimated menochromatic light to text optical component quality (lenses, prisms).

Machined from a single highly perfect silicon crystal to unable phase-contrast imaging and latties struin measurements using hard X-rays.

Figure 10.265: Timeline of the most well-known interferometers

We will now see what are the conditions such that a plane waves interfere with each other. These developments help to explain well much about the vision of the world around us through our eye (especially why all the waves received by our retinas do not mix and so the colors either!).

Let us consider two plane waves Σ_1 and Σ_2 of pulsation ω_1 and ω_2 and of wave vectors $\vec{k}_1$ and $\vec{k}_2$ propagating both parallel to the z-axis.

We denote by Ψ_1 and $\Psi_2$the complex amplitudes of the two waves and we are interested in the average intensity observed at a point O taken as the coordinate origin:

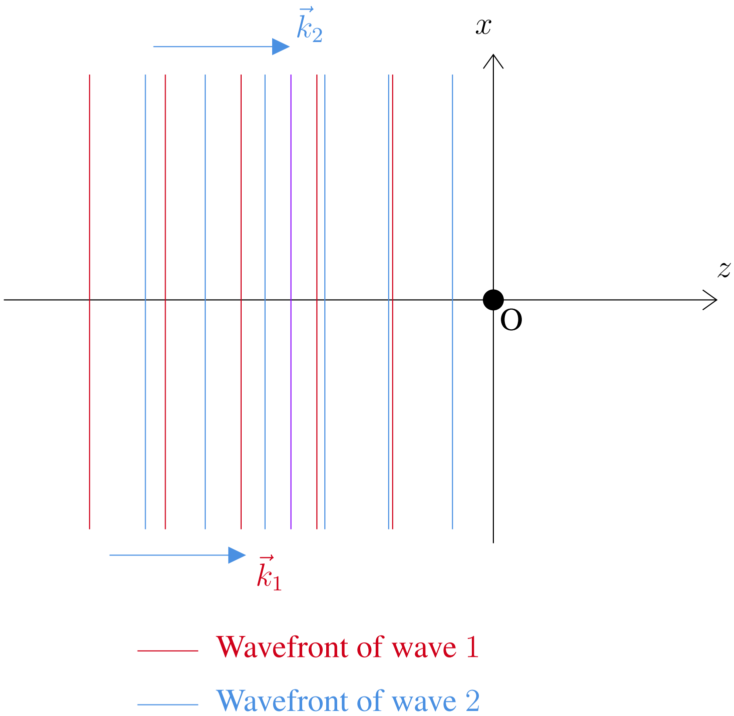

Figure 10.266: Representation of plane waves

We put:

$$\omega_0=\frac{\omega_1+\omega_2}{2} \tag{10.6.297}$$

and we will assume:

$$\delta\omega=\omega_2-\omega_1\ll 2\omega_0 \tag{10.6.298}$$

At the point O the complex amplitudes are written:

$$\begin{gathered}\Psi_1=\Psi_{01}e^{-\mathrm{i}\omega_1 t}=|\Psi_1|e^{\mathrm{i}\theta_1}e^{-\mathrm{i}\omega_1 t}\\ \Psi_2=\Psi_{02}e^{-\mathrm{i}\omega_2 t}=|\Psi_2|e^{\mathrm{i}\theta_2}e^{-\mathrm{i}\omega_2 t}\end{gathered} \tag{10.6.299}$$

where θ_1 and θ_2 represent the phases of Ψ_1 and Ψ_2.

Let us now calculate the instantaneous intensity at the point O will be denoted $J(t)$. As the average intensity I is proportional to the square of the amplitude, we assume it will be the same for the instantaneous intensity. Which brings us to calculate the sum of the real parts of the amplitudes of the two waves:

$$J(t)=\left(\Re(\Psi_1)+\Re(\Psi)\right)^2=\Re(\Psi_1)^2+\Re(\Psi_2)^2+2\Re(\Psi_1)\Re(\Psi_2) \tag{10.6.300}$$

What is written keeping in mind that (see section Numbers page 243):

$$\Re(\Psi)=\frac{1}{2}(\Psi+\bar{\Psi}) \tag{10.6.301}$$

Therefore:

$$\begin{aligned}\Re(\Psi_1)\Re(\Psi_2)&=\frac{1}{2}(\Psi_1+\bar{\Psi}_1)\frac{1}{2}(\Psi_2+\bar{\Psi}_2)=\frac{1}{4}(\Psi_1+\bar{\Psi}_1)(\Psi_2+\bar{\Psi}_2)\\&=\frac{1}{4}(\Psi_1\Psi_2+\Psi_1\bar{\Psi}_2+\bar{\Psi}_1\Psi_2+\bar{\Psi}_1\bar{\Psi}_2)=\frac{1}{4}(\Psi_1\Psi_1+\bar{\Psi}_1\bar{\Psi}_2)+\frac{1}{4}(\bar{\Psi}_1\Psi_2+\Psi_1\bar{\Psi}_2)\\&=\frac{1}{2}\Re(\Psi_1\Psi_2)+\frac{1}{2}\Re(\Psi_1\bar{\Psi}_2)\end{aligned} \tag{10.6.302}$$

And then we have:

$$J(t)=\Re(\Psi_1)^2+\Re(\Psi_2)^2+2\Re(\Psi_1)\Re(\Psi_2)=\Re(\Psi_1)^2+\Re(\Psi_2)^2+\Re(\Psi_1\Psi_1)+\Re(\Psi_1\bar{\Psi}_2) \tag{10.6.303}$$

It follows the sum of four terms:

$$\begin{aligned}J(t)=&|\Psi_1|^2\cos^2(\omega_1 t-\theta_1)+|\Psi_2|^2\cos^2(\omega_2 t-\theta_2)+|\Psi_1\Psi_2|\cos\left[(\omega_2+\omega_1)t-(\theta_1+\theta_2)\right]\\&+|\Psi_1\Psi_2|\cos\left[(\omega_2-\omega_1)t+(\theta_1-\theta_2)\right]\end{aligned} \tag{10.6.304}$$

To calculate the average intensity, we will choose an experimental approach:

The average intensity of the exposure time τ of the detector (electronic or biological) will be given by:

$$I=\frac{1}{\tau}\int\limits_0^{\tau}J(t)\mathrm{d}t=\langle J(t)\rangle_{\tau} \tag{10.6.305}$$

where I is then the sum of the averages of the four terms intervening in $J(t)$ given just above. For visible light (in the case of our eye), the frequencies are of the order of 10^{15} [Hz] and the exposure time of the detectors vary between the millisecond and the second. Then τ typically contains 10^{12} periods of Ψ_1 and Ψ_2!!

Figure 10.267: Example of the influence of various exposure times with a camera

Let us examinate the effect on the average value of each of the term of $J(t)$ by first recalling the relation (see section Wave Mechanics page 3480):

$$\omega=2\pi f=\frac{2\pi}{T} \tag{10.6.306}$$

1. We have using the usual integral proved in the section of Differential and Integral Calculus, the following valuation of the integrand on an important number of periods:

$$\begin{aligned}
I_1&=\frac{1}{nT_1}\int\limits_0^{nT_1}|\Psi_1|^2\cos^2(\omega_1 t-\theta)\mathrm{d}t=\frac{|\Psi_1|^2}{nT_1\omega_1}\int\limits_{-\theta_i}^{n2\pi-\theta_i}\cos^2(x)\mathrm{d}x\\
&=\frac{|\Psi_1|^2}{nT_1 2\pi f_1}\int\limits_{-\theta_1}^{n2\pi-\theta_i}\cos^2(x)\mathrm{d}x=\frac{|\Psi_1|^2}{n2\pi}\int\limits_{-\theta_i}^{n2\pi-\theta_i}\cos^2(x)\mathrm{d}x\\
&=\frac{|\Psi_1|^2}{2\pi n}\left[\frac{1}{2}\left(\int\limits_{-\theta_i}^{n2\pi-\theta_i}\mathrm{d}x+\sin(x)\cos(x)\Big|_{-\theta_i}^{n2\pi-\theta_i}\right)\right]\\
&=\frac{|\Psi_1|^2}{2\pi n}\left[\frac{1}{2}\left([(n2\pi-\theta_1)-(-\theta_1)]+(\sin(2n\pi-\theta_1)\cos(n2\pi-\theta_1)-\sin(-\theta_1)\cos(-\theta_1))\right)\right]\\
&=\frac{|\Psi_1|^2}{2\pi n}\left[\frac{1}{2}\left(n2\pi+(\sin(-\theta_1)\cos(-\theta_1)-\sin(-\theta_1)\cos(-\theta_1))\right)\right]\\
&=\frac{|\Psi_1|^2}{2\pi n}\left[\frac{1}{2}(n2\pi)\right]=\frac{|\Psi_1|^2}{2}
\end{aligned}$$

(10.6.307)

Calculation that is traditionally written and very abusively under the following condensed form:

$$I_1=\frac{1}{2\pi}\int\limits_0^{2\pi}|\Psi_1|^2\cos^2(\omega_1 t-\theta_1)\mathrm{d}t=\frac{|\Psi_1|^2}{2\pi}\int\limits_0^{2\pi}\cos^2(\omega_1 t-\theta_1)\mathrm{d}t=\frac{|\Psi_1|^2}{2\pi}\pi=\frac{|\Psi_1|^2}{2}$$

(10.6.308)

We can estimate that a large number of periods (opening time of the detector), it is this average that will be measured (in fact its really that latter!).

2. We have identically:

$$I_2=\frac{1}{2\pi}\int\limits_0^{2\pi}|\Psi_2|^2\cos^2(\omega_2 t-\theta_2)\mathrm{d}t=\frac{|\Psi|^2}{2\pi}\int\limits_0^{2\pi}\cos^2(\omega_2 t-\theta_2)\mathrm{d}t=\frac{|\Psi_2|^2}{2\pi}\pi=\frac{|\Psi_2|^2}{2}$$

(10.6.309)

with the same remarks as above regarding to the detector!

3. For the third term it is a bit different:

$$\begin{aligned}I_3&=\frac{1}{2\pi}\int\limits_0^{2\pi}|\Psi_1\Psi_2|\cos\left[(\omega_2+\omega_1)t-(\theta_1+\theta_2)\right]\mathrm{d}t=\frac{|\Psi_1\Psi_2|}{2\pi}\int\limits_0^{2\pi}\cos\left[(\omega_2+\omega_1)t-(\theta_1+\theta_2)\right]\mathrm{d}t\\&=\frac{|\Psi_1\Psi_2|}{2\pi}\left[\int\limits_0^{2\pi}\cos((\omega_2+\omega_1)t)\cos(\theta_1+\theta_2)\mathrm{d}t+\int\limits_0^{2\pi}\sin((\omega_2+\omega_1)t)\sin(\theta_1+\theta_2)\mathrm{d}t\right]\\&=\frac{|\Psi_1\Psi_2|}{2\pi}\left[\cos(\theta_1+\theta_2)\int\limits_0^{2\pi}\cos((\omega_2+\omega_1)t)\mathrm{d}t+\sin(\theta_1+\theta_2)\int\limits_0^{2\pi}\sin((\omega_2+\omega_1)t)\mathrm{d}t\right]\\&=\frac{|\Psi_1\Psi_2|}{2\pi}\left[\cos(\theta_1+\theta_2)\int\limits_0^{2\pi}\cos(2\omega_0t)\mathrm{d}t+\sin(\theta_1+\theta_2)\int\limits_0^{2\pi}\sin(2\omega_0t)\mathrm{d}t\right]\end{aligned}\tag{10.6.310}$$

However, the average of a cosine and a sine on a period is zero. So if the detector makes a measure on an exposure time above $1/2\omega_0$, that is on a large number of periods, we will have:

$$\begin{aligned}I_3&=\frac{|\Psi_1\Psi_2|}{2\pi}\left[\cos(\theta_1+\theta_2)\int\limits_0^{2\pi}\cos(2\omega_0t)\mathrm{d}t+\sin(\theta_1+\theta_2)\int\limits_0^{2\pi}\sin(2\omega_0t)\mathrm{d}t\right]\\&=\frac{|\Psi_1\Psi_2|}{2\pi}\left[\cos(\theta_1+\theta_2)\cdot0+\sin(\theta_1+\theta_2)\cdot0\right]=0\end{aligned}\tag{10.6.311}$$

4. For the fourth term it is still different in the experimental approximation. Indeed:

$$\begin{aligned}I_4&=\frac{1}{2\pi}\int\limits_0^{2\pi}|\Psi_1\Psi_2|\cos\left[\cos(\omega_2-\omega_1)t+(\theta_1-\theta_2)\right]\mathrm{d}t=\frac{|\Psi_1\Psi_2|}{2\pi}\int\limits_0^{2\pi}\int\cos\left[(\omega_2-\omega_1)t+(\theta_1-\theta_2)\right]\mathrm{d}t\\&=\frac{|\Psi_1\Psi_2|}{2\pi}\left[\int\limits_0^{2\pi}\cos((\omega_2-\omega_1)t)\cos(\theta_1-\theta_2)\mathrm{d}t-\int\limits_0^{2\pi}\sin((\omega_2-\omega_1)t)\sin(\theta_1-\theta_2)\mathrm{d}t\right]\\&=\frac{|\Psi_1\Psi_2|}{2\pi}\left[\cos(\theta_1-\theta_2)\int\limits_0^{2\pi}\cos((\omega_2-\omega_1)t)\mathrm{d}t-\sin(\theta_1-\theta_2)\int\limits_0^{2\pi}\sin((\omega_2-\omega_1)t)\mathrm{d}t\right]\\&=\frac{|\Psi_1\Psi_2|}{2\pi}\left[\cos(\theta_1+\theta_2)\int\limits_0^{2\pi}\cos(\delta\omega t)\mathrm{d}t-\sin(\theta_1+\theta_2)\int\limits_0^{2\pi}\sin(\delta\omega t)\mathrm{d}t\right]\end{aligned}\tag{10.6.312}$$

But, $\delta\omega\ll2\omega_0$. Therefore the detector does not have time to measure the average intensity over a whole period in first approximation since:

$$T=\frac{2\pi}{\delta\omega}\tag{10.6.313}$$

and that this value is much much greater in the visible spectrum that the opening / sampling time of the eye that it is 0.1 [s].

Thus, we will notice the average of the fourth term by:

$$I_4=\frac{|\Psi_1\Psi_2}{2\pi}\int\limits_0^{2\pi}\cos\left[(\omega_2-\omega_1)t+(\theta_1-\theta_2)\right]\mathrm{d}t=|\Psi_1\Psi_2|\langle\cos\left[\delta\omega t+(\theta_1-\theta_2)\right]\rangle_\tau=f(\tau)|\Psi_1\Psi_2| \tag{10.6.314}$$

The average intensity is therefore in an experimental context:

$$I=\frac{|\Psi_1|^2}{2}+\frac{|\Psi_2|^2}{2}+f(\tau)|\Psi_1\Psi_2| \tag{10.6.315}$$

or:

$$\boxed{I=I_1+I_2+f(\tau)\sqrt{I_1I_2}} \tag{10.6.316}$$

If the pulsations ω_1, ω_2 are equal (or almost equal), then it is the interference between two monochromatic plane waves. The average intensity is then written:

$$\begin{aligned}I&=I_1+I_2+2\sqrt{I_1I_2}f(\tau)=I_1+I_2+2\sqrt{I_1I_2}\langle\cos(\theta_1-\theta_2)\rangle_\tau\\&=I_1+I_2+2\sqrt{I_1I_2}\frac{1}{\tau}\int\limits_0^{\tau}\cos(\theta_1-\theta_2)\mathrm{d}t=I_1+I_2+2\sqrt{I_1I_2}\cos(\theta_1-\theta_2)\end{aligned} \tag{10.6.317}$$

When we know that the eye interprets the intensity to form perceptions of the objects we understand why two objects of two different colors are not a perception corresponding to a mixture of the two colors because even if in the visible spectrum, the pulses are almost equal, their phase is rarely at a given point in space zero such that:

$$I=I_1+I_2+2\sqrt{I_1I_2}\cos(0)=I_1+I_2+2\sqrt{I_1I_2} \tag{10.6.318}$$

There is therefore no interference and we have in reality:

$$I=I_1+I_2+2\sqrt{I_1I_2}\cos(\theta_2-\theta_1)\cong I_1+I_2 \tag{10.6.319}$$

Remark

During the composition of several waves, we can always consider that there is interference. However, we name "interference conditions" the conditions of observation of these interferences, i.e. conditions for the result of their composition to be stable enough to be observed. It is customary to speak of "visibility", which restricts to the single observation by the (human) eye.

We have seen for the eye that the sampling time frequency is $10\,[\mathrm{s}^{-1}]$. Knowing that the visible light has a frequency of $f\cong 10^{14}\,[s^{-1}]$, the frequency must then be stabilized by the source during:

$$\frac{10}{10^{14}}=10^{-13} \tag{10.6.320}$$

which is materially impossible except that the source is the same. We conclude that for interference to be visible to the eye, the sources must be synchronized at best at 10^{-13} which in practice leads to consider only sources absolutely synchronized on a single source.

In the previous model, we also have neglected the fact that a real wave is limited in time. A photon is represented by a limited wave packet. Given T, it will have a length $l_c = cT$ in a vacuum or in the air that we name "temporal coherence length".

A given radiation is thus a superposition of succession of wave trains whose average length is l_c, the successive wave trains have no phase relation between them: they can not interfere!

10.6.5.1 Michelson Interferometer

The "Michelson interferometer" is a very common and important configuration for optical interferometry[24] and was invented by the American physicist Albert Abraham Michelson in 11887 (holocene calendar) and at its time the setup was mounted on a stone slab that was floating in an annular trough of mercury (yellow light from a sodium flame (for alignment), or white light (for the actual observations).

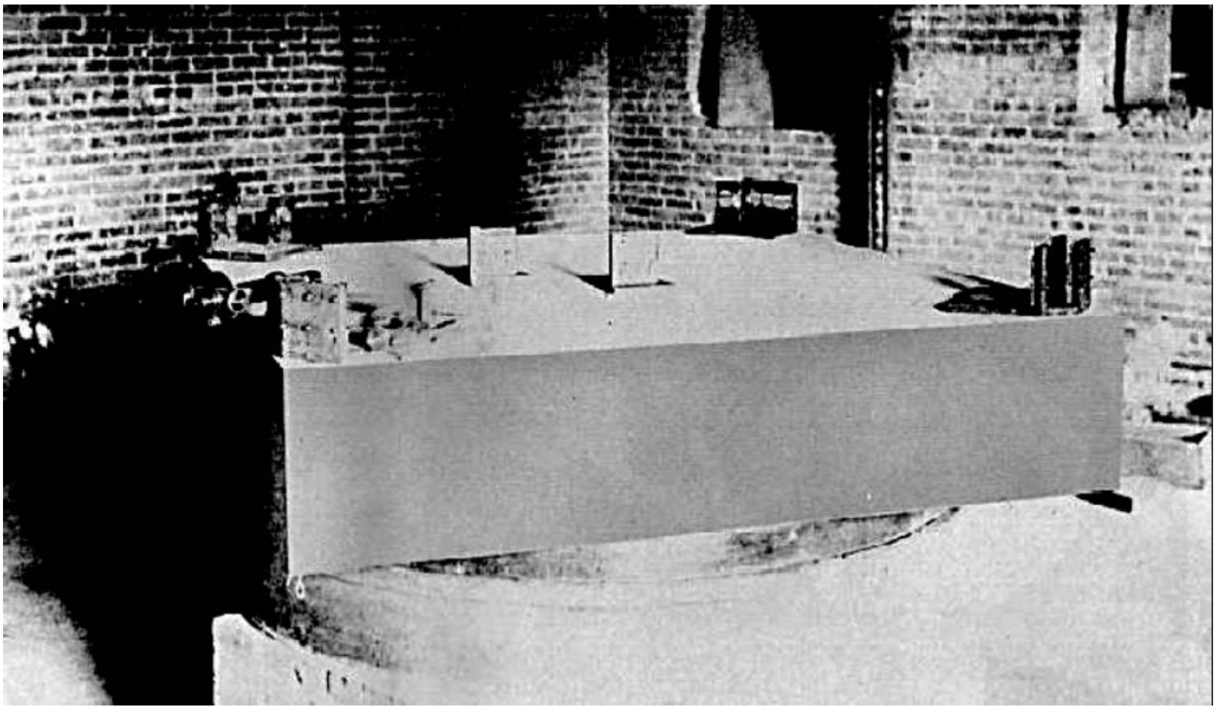

Figure 10.268: Setup of Michelson Morley experiment in 11887 at what is now Case Western Reserve University

It is considered as the single most important design in the history of precision measurement.

Using a beam splitter, a light source is split into two arms. Each of those light beams is reflected back toward the beamsplitter which then combines their amplitudes using the superposition principle. The resulting interference pattern that is not directed back toward the source is typically directed to some type of photoelectric detector or camera. For different applications of the interferometer, the two light paths can be with different lengths or incorporate optical elements or even materials under test.

The Michelson interferometer is employed in many scientific experiments and became well known for its use by Albert Abraham Michelson and Edward Morley in the famous Michelson-Morley experiment (11887 according to holocene calendar) in a configuration which would have detected the Earth's motion through the supposed luminiferous aether that most physicists at the time believed was the medium in which light waves propagated. The null result of that experiment essentially gave evidence against the existence of such an aether, leading eventually to the Special Relativity and the revolution in physics at the beginning of the twentieth century (see [390]). In 12015 (holocene calendar), another application of the Michelson interferometer, LIGO, made the first direct observation of gravitational waves. That observation confirmed an important prediction of General Relativity, validating the theory's prediction of space-time distortion in the context of large scale cosmic events (known as strong field tests).

---

[24] The underlying idea of this interferometer is use for the gravitational waves detectors.

Remark

The idea was that if Earth moves through the ether, light should travel faster in one direction than another (like swimming with vs. against a current). The interferometer would show this as a fringe shift when rotated. The result ? No fringe shift! None. The speed of light was the same in every direction, regardless of Earth's motion. This "null result" was one of the most important failed experiments in history.

A Michelson interferometer consists minimally of two mirrors M_1 and M_2 and a beam splitter M (although a diffraction grating is also used). In the figure below:

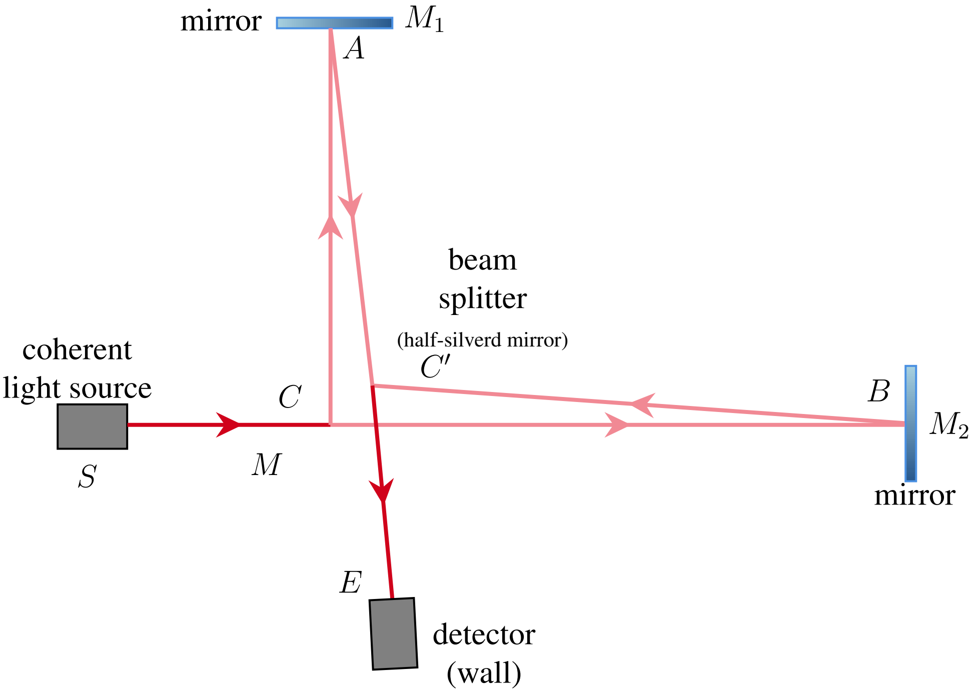

Figure 10.269: **Path of light in a simple Michelson interferometer**

A source S emits light that hits the beam splitter (in this case, a plate beamsplitter) surface M at point C. M is partially reflective, so part of the light is transmitted through to point B while some is reflected in the direction of A. Both beams recombine at point C' to produce an interference pattern incident on the detector at point E (or on the retina of a person's eye). If there is a slight angle between the two returning beams, for instance, then an imaging detector will record a sinusoidal fringe pattern - named "Haidinger fringes" - as shown in the figure below:

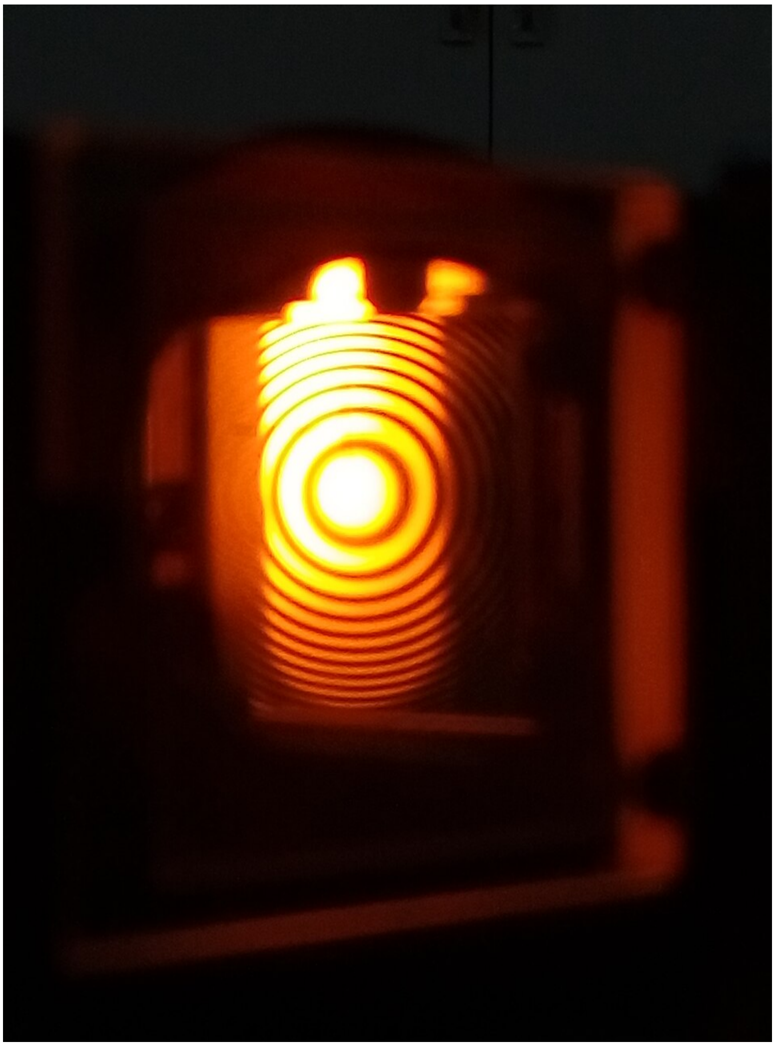

Figure 10.270: **Fringe pattern formed by the Michelson interferometer using monochromatic light - sodium D lines (source: Wikipedia, author: Warren Leywon)**

A typical Swiss PASCO® Scientific OS-925AA setup with a Helium/Neon $4\,[\text{mW}]$ LASER looks like this:

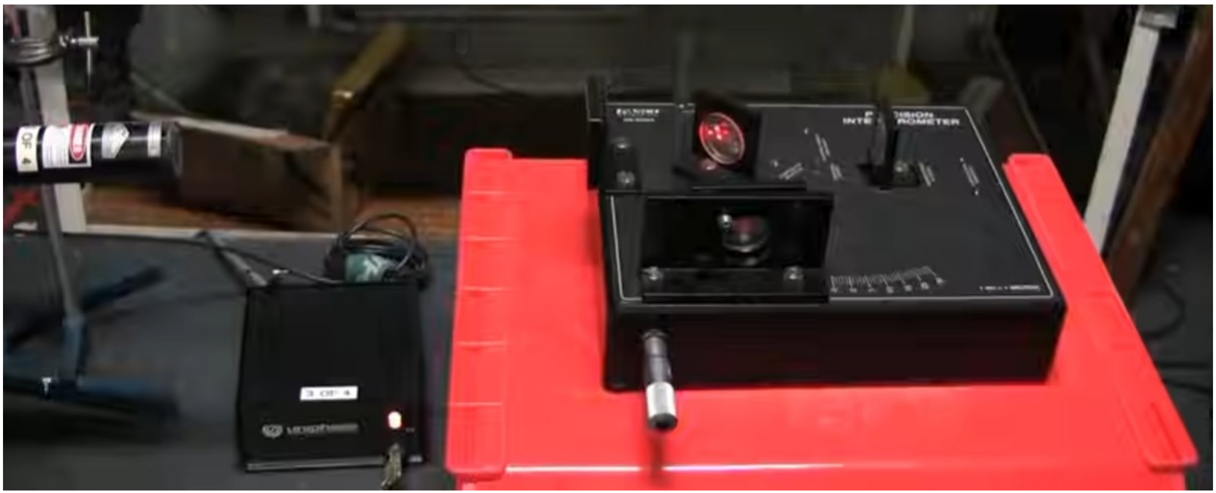

Figure 10.271: **Michelson interferometer typical setup (source: MIT)**

where we can see the beam splitter (the lens the multiple LASER dots) and at the bottom with the graduation a mirror ajustable with a micrometer knob.

From the top this is how it looks like if we draw in a childish way the LASER light wave (the LASER light enters from the left of the photo and the interference runs away from the top of the photo)

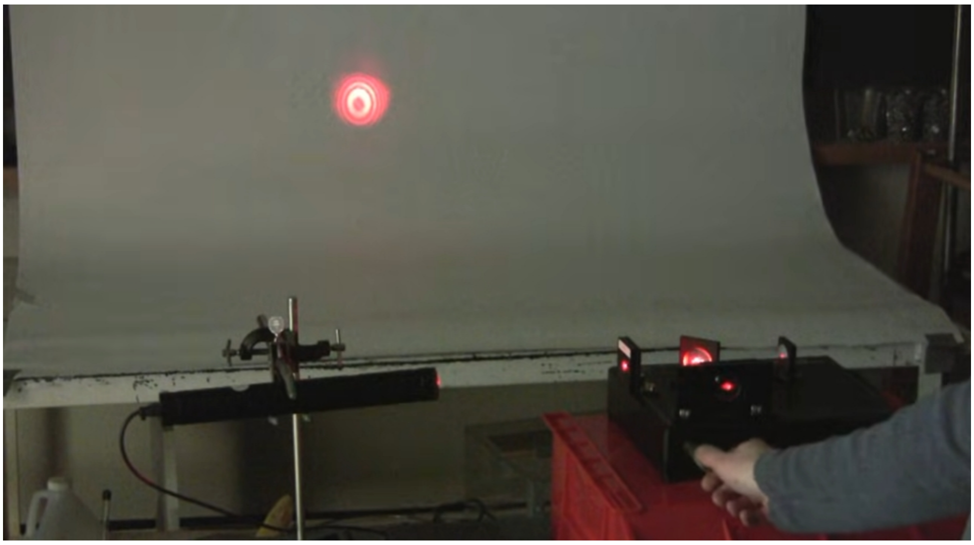
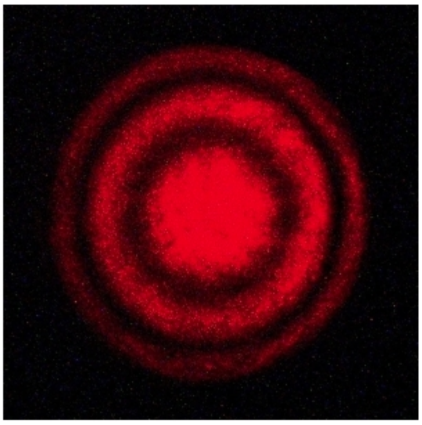
Figure 10.272: Michelson interferometer schematic constructive interference (source: MIT)

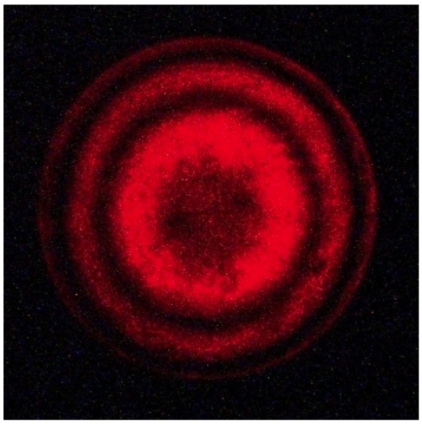
We have on the projection wall something typically that will look like this:



If the path lengths differ by exactly an integral number of wavelengths plus (or minus) a half wavelength, they undergo destructive interference to give an intensity minimum. One thus observes a pattern of fringes that appears to move as one adjusts the length of the variable arm.

When the two mirrors are "coplanar," that is, they are exactly perpendicular to the beam paths, one observes a symmetrical pattern such as those shown below:





The image on the left shows an interference maximum at the center, and the image at right shows an interference minimum at the center. In each photo you can see two fringes (and perhaps part of the next) surrounding the center spot. When the two arms are exactly the same length (i.e., they differ by exactly zero wavelengths!) and the mirrors are coplanar, the central maximum grows to fill the entire field.

When the mirrors are not coplanar, one can obtain so-called "hyperbolic" fringes (see proof further below), which appear as straight vertical lines. The fringes in the photograph at the top of this page indicate a mirror alignment somewhere between that which would give circular fringes and that which would give hyperbolic fringes.

After with stickers we mark the interference fringes to make them more easy to follow with our eyes when we change the micrometer knob:

Interference fringes are marked so that
cycles may be counted more easily

Remark

If there is perfect spatial alignment between the returning beams, then there will not be any such pattern but rather a constant intensity over the beam dependent on the differential pathlength; this is difficult, requiring very precise control of the beam paths.

Now we move the micrometer knob a at least for one cycle of constructive interference (one is enough but if we do it multiple times our calculation will give a smaller confidence interval according[25] to what we have seen in the section of Statistics page 855):

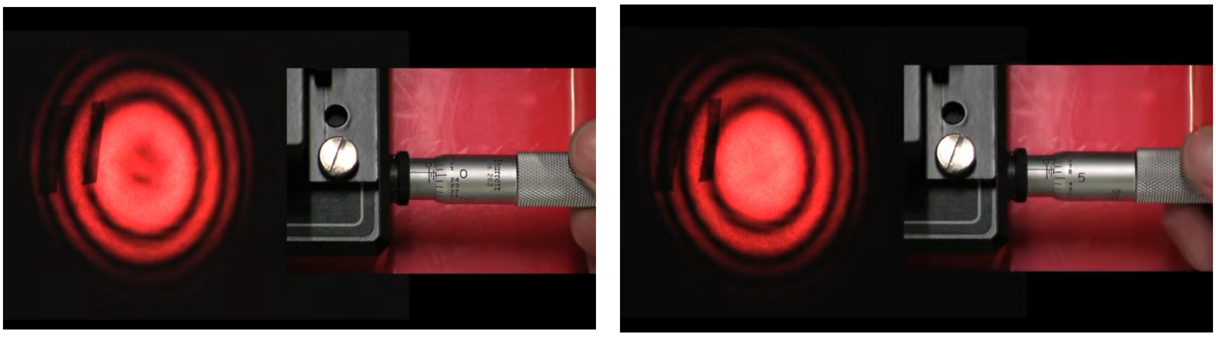


Figure 10.273: **Counting the interference fringe pattern when turning the micrometer**

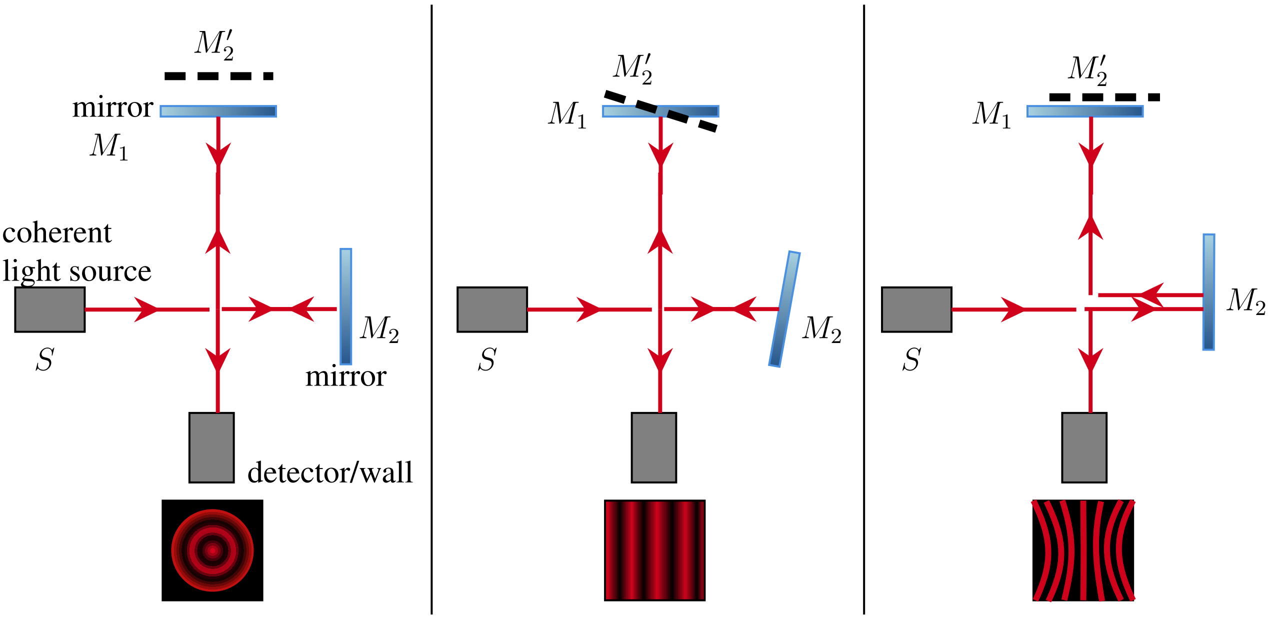
In the experiment above consider we have counted 20 times (it should be enough to have a quite small confidence interval) the crossing of the interference pattern between our stickers and that the micrometer knob shows that we have turned it from its initial position by $d \cong 6.5\,[\mu\text{m}]$.

Therefore:

$$\lambda = \frac{2d}{N} = \frac{2 \cdot 6.5\,[\mu\text{m}]}{20} \cong 0.65\,[\mu\text{m}] \tag{10.6.321}$$

and red has indeed a wavelength ranging from about 620 to 750 nanometers.

Now let us deal with the mathematical explanation. But keep in mind that in reality there can be three types of Haidinger fringes as illustrated below:



---

[25] Remember that the standard deviation does not become lower when the number of measurement grows but so do the confidence interval as it depends on $\sigma/\sqrt{n}$.

10.6.5.1.1 Case of circular Haidinger fringes

A point source produces a spherical wave. If the light from two point sources overlaps, the interference pattern maps out the way in which the phase difference between the two waves varies in space. This depends on the wavelength and on the separation of the point sources. The figure to the right shows interference between two spherical waves. The wavelength increases from top to bottom, and the distance between the sources increases from left to right.

Now remember that we have proven during our introduction of the homogeneous wave equation (see page **??**) that one possible solution in the Fresnel approximation (see page 4155) was:

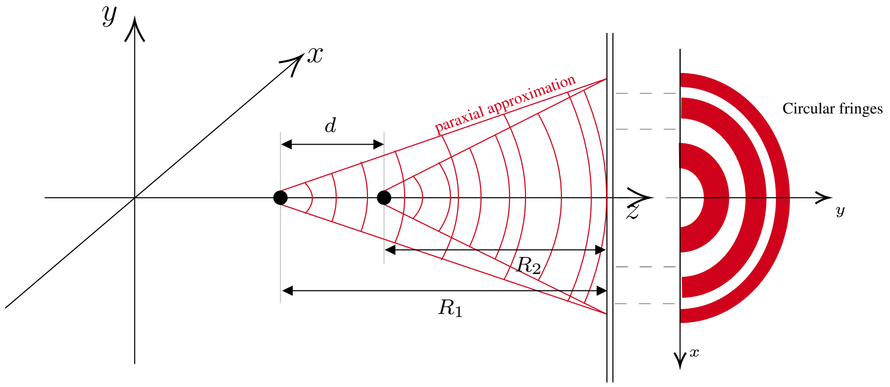
$$E_i(\rho,t)\cong\frac{A}{R}e^{\mathrm{i}\left(\omega t-k\left(R_i+\rho^2/2R_i\right)\right)} \tag{10.6.322}$$

here A is the amplitude, R is an average distance, ω is the angular frequency, $\boldsymbol{k}$ is the wave vector $k=2\pi/\lambda$, and $\rho=(x^2+y^2)^{1/2}$. The subscript i is specific to each source if there are multiple one.

Hence:

$$E_i(\rho,t)\cong\frac{A}{R}e^{\mathrm{i}\omega t}e^{-\mathrm{i}k\left(R_i+\rho^2/2R_i\right)} \tag{10.6.323}$$

Now let us consider two sources with different R_i aligned on the same axis as illustrated below (this is an equivalent to the Michelson interferometer):



Therefore the phase difference is:

$$\begin{aligned}\Delta\phi&=k\left(R_2+\frac{\rho^2}{2R_2}\right)-k\left(R_1+\frac{\rho^2}{2R_1}\right)=k(R_2-R_1)+\frac{\rho^2k}{2}\left(\frac{1}{R_2}-\frac{1}{R_1}\right)\\&=\frac{2\pi}{\lambda}(R_2-R_1)+\frac{\rho^22\pi}{2\lambda}\left(\frac{1}{R_2}-\frac{1}{R_1}\right)=\frac{2\pi}{\lambda}d+\frac{\rho^2\pi}{\lambda}\left(\frac{1}{R_2}-\frac{1}{R_1}\right)\\&=\frac{2\pi}{\lambda}d+\frac{\rho^2\pi}{\lambda}\frac{R_1-R_2}{R_1R_2}=\frac{2\pi}{\lambda}d-\frac{\rho^2\pi}{\lambda}\frac{d}{R_1R_2}\end{aligned} \tag{10.6.324}$$

Now let us consider common approximation that is $R_1R_2\cong R^2$, hence:

$$\Delta\phi=\frac{2\pi}{\lambda}d-\frac{\rho^2\pi}{\lambda}\frac{d}{R^2} \tag{10.6.325}$$

from the relation above where for reminder ρ is the distance from the optical axis in the observation plane, we see immediately that $\Delta\phi$ depends only on ρ!

Let the phase difference at the center ($\rho = 0$) be a reference state. The phase shift relative to the center, or the change in phase as you move outward radially by distance ρ, is governed by the second term:

$$\delta\phi(\rho) = \frac{\rho^2\pi}{\lambda}\frac{d}{R^2} \tag{10.6.326}$$

The fact that the phase difference above depends only on the radial distance ρ from the optical axis - not on the azimuthal angle, immediately tells you that curves of constant phase (i.e., fringes) must be circles centered on the axis, since any two points with the same ρ have identical $\delta\phi$ regardless of direction!

If we suppose can constructive or destructive interference may happen (suppose we don't already know the experimental result) then bright (or dark) rings occur wherever the total phase difference is an integer multiple of 2π :

$$\delta\phi = 2\pi m, \quad m \in \mathbb{Z} \tag{10.6.327}$$

Hence we can write:

$$2\pi m = \frac{\rho_m^2\pi}{\lambda}\frac{d}{R^2} \tag{10.6.328}$$

Rearranging:

$$\rho_m = \sqrt{m\left(\frac{2\lambda R^2}{d}\right)} \tag{10.6.329}$$

What is commonly denoted:

$$r_n = \sqrt{\frac{2\lambda n R^2}{d}}, \quad n \in \mathbb{Z}_+ \tag{10.6.330}$$

Remark

If both spherical source are not aligned the setup is therefore equivalent to the one of the double slit experiment (see section Wave Optics page 4509) and then we fall back - if the projection is made on a small finite horizontal screen - on a range of linear interference fringes.

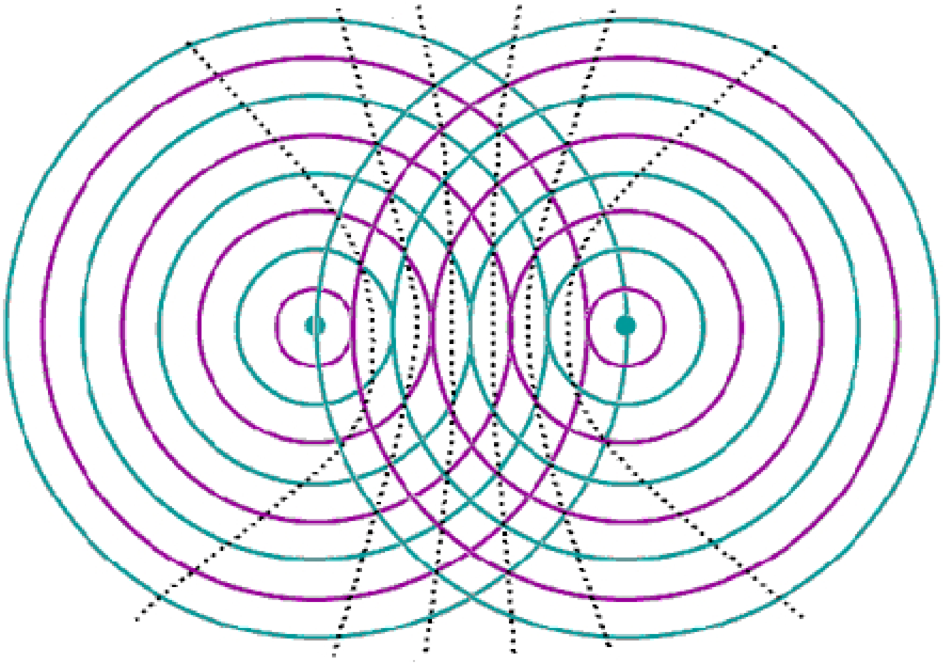
10.6.5.1.2 Case of hyperbolic Haidinger fringes

Haidinger fringes are interference fringes formed by the interference of monochromatic and coherent light to form visible dark and bright fringes. Fringe localization is the region of space where fringes with reasonably good contrast are observed.

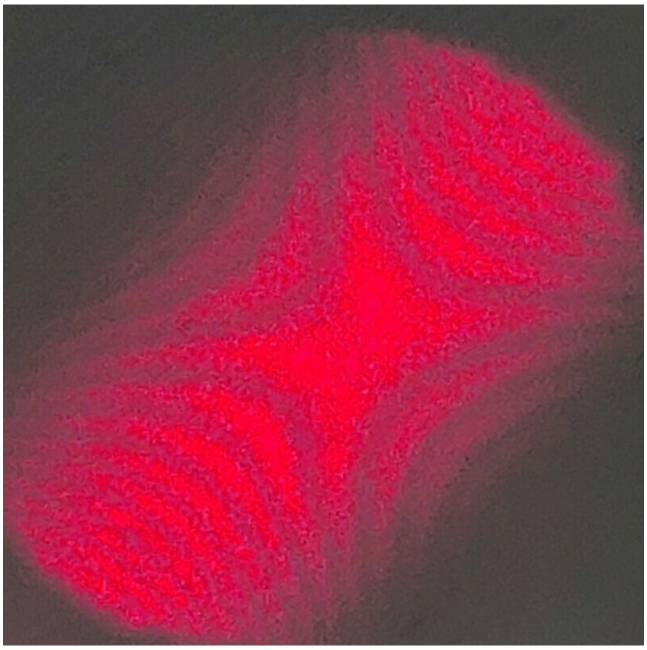
Haidinger fringes are fringes localized at infinity. Also known as fringes of equal inclination, these fringes result when light from an extended source falls on a thin film made of an optically denser medium. These fringes indicate the positions where light interferes, emerging from the medium at an equal angle.

There is almost no chance to apply two or even many independent sources to get interference patterns which are stable in time! Therefore, the interfering beams must have their origin in the same source.

Introducing the visibility or contrast (an interactive animation is available here: `https://www.walter-fendt.de/html5/phen/interference_en.htm`):



The hyperbolic interference pattern shown is typical of interferometers where there is a slight tilt of a mirror or a small angular difference between the interfering beams. Such patterns can be used to adjust interferometers, to analyze optical path length changes and to precisely measure surfaces or refractive index changes:



Consider two point sources, S_1 and S_2, separated by a distance d emitting spherical waves of wavelength λ.

At any arbitrary observation point $P(x, y, z)$ in 3D space, let r_1 and r_2 be the distances from S_1 and S_2 to P. Constructive interference (a bright fringe of order m) occurs when the path difference Δs is an integer multiple of the wavelength:

$$|r_1 - r_2| = k\lambda = C \quad (\text{ where } k \in \mathbb{Z} \text{ and } C \leq d) \tag{10.6.331}$$

For a given fringe order k, the path length difference C is a constant.

By definition, the locus of points P in space whose absolute difference in distances to two fixed points (foci) is a constant C forms a hyperboloid of revolution (see section Analytical Geometry page 2789).

Since the two sources S_1 and S_2 act as the foci:

- 3D Space: A fringe of constant phase difference forms a 3D hyperboloid of revolution around the axis containing S_1 and S_2.
- 2D Cross-section: The intersection of this 3D hyperboloid with a planar screen produces 2D hyperbolic curves.

Indeed, let us place S_1 and S_2 along the z-axis, centered symmetrically at the origin:

$$S_1 = \left(0, 0, -\frac{d}{2}\right) \qquad S_2 = \left(0, 0, \frac{d}{2}\right) \tag{10.6.332}$$

The distances from S_1 and S_2 to $P(x,y,z)$ are:

$$\begin{aligned}r_1&=\sqrt{x^2+y^2+\left(z+\frac{d}{2}\right)^2}\\r_2&=\sqrt{x^2+y^2+\left(z-\frac{d}{2}\right)^2}\end{aligned}\tag{10.6.333}$$

Setting $r_1-r_2=C$:

$$r_1=C+r_2\tag{10.6.334}$$

We square both sides:

$$r_1^2=C^2+2Cr_2+r_2^2\Longrightarrow r_1^2-r_2^2=C^2+2Cr_2\tag{10.6.335}$$

We calculate $r_1^2-r_2^2$:

$$r_1^2-r_2^2=\left[x^2+y^2+\left(z+\frac{d}{2}\right)^2\right]-\left[x^2+y^2+\left(z-\frac{d}{2}\right)^2\right]=2zd\tag{10.6.336}$$

We substitute this back into the squared equation:

$$2zd=C^2+2Cr_2\Longrightarrow r_2=\frac{zd}{C}-\frac{C}{2}\tag{10.6.337}$$

We square both sides again:

$$r_2^2=\left(\frac{zd}{C}-\frac{C}{2}\right)^2\tag{10.6.338}$$

But as :

$$r_2=\sqrt{x^2+y^2+\left(z-\frac{d}{2}\right)^2}\tag{10.6.339}$$

We have therefore:

$$x^2+y^2+\left(z-\frac{d}{2}\right)^2=\frac{z^2d^2}{C^2}-zd+\frac{C^2}{4}\tag{10.6.340}$$

Expand the left side and cancel $-zd$ from both sides:

$$x^2+y^2+z^2+\frac{d^2}{4}=\frac{z^2d^2}{C^2}+\frac{C^2}{4}\tag{10.6.341}$$

Rearrange terms to group z^2 :

$$\left(\frac{d^2}{C^2}-1\right)z^2-(x^2+y^2)=\frac{d^2-C^2}{4}\tag{10.6.342}$$

Hence:

$$\left(\frac{d^2-C^2}{C^2}\right)z^2-(x^2+y^2)=\frac{d^2-C^2}{4}\tag{10.6.343}$$

We divide through by $(d^2-C^2)/4$:

$$\frac{z^2}{\left(\frac{C}{2}\right)^2}-\frac{x^2+y^2}{\left(\frac{\sqrt{d^2-C^2}}{2}\right)^2}=1 \tag{10.6.344}$$

Let us put:

$$x=\frac{C}{2}=\frac{k\lambda}{2} \qquad b=\frac{\sqrt{d^2-C^2}}{2} \tag{10.6.345}$$

Therefore:

$$\frac{z^2}{a^2}-\frac{x^2+y^2}{b^2}=1 \tag{10.6.346}$$

This is the canonical equation of a two-sheeted circular hyperboloid of revolution symmetric about the z-axis (see section Analytical Geometry page 2841).

10.6.5.1.3 Case of straight Haidinger fringes

That's the original case of what Albert Abraham Michelson observed in his setup!

The key observation is that tilting one of the effective mirrors in a Michelson interferometer, produces two returning waves travelling in slightly different directions. Their phase difference varies linearly across the observation plane, giving straight interference fringes.

In a homogeneous medium, the scalar electric field $E(\vec{r},t)$ satisfies:

$$\nabla^2 E-\frac{1}{v^2}\frac{\partial^2 E}{\partial t^2}=0 \tag{10.6.347}$$

where $v=c/n$ is the speed of light in the medium.

For monochromatic light, let us write:

$$E(\vec{r},t)=\mathcal{R}\left\{\psi(\vec{r})e^{-\mathrm{i}\omega t}\right\} \tag{10.6.348}$$

Substitution gives the Helmholtz equation:

$$\nabla^2\psi+k^2\psi=0 \tag{10.6.349}$$

where $k=\omega/v=2\pi/\lambda$.

Its plane-wave solutions are:

$$\psi(\vec{r})=Ae^{\mathrm{i}\vec{k}\circ\vec{r}}, \quad |\vec{k}|=k \tag{10.6.350}$$

We will now derive the two returning wavevectors from the mirror geometry.

Consider, the two beams after recombination at the beam splitter. Choose z along the nominal direction of propagation toward the detector.

Suppose, the first effective mirror is perpendicular to the optical axis, while the second is tilted through a small angle α.

Reflection from a plane mirror transforms the incident wavevector according to:

$$\vec{k}_r = \vec{k}_i - 2\left(\vec{k}_i \circ \hat{\vec{n}}\right)\hat{\vec{n}} \tag{10.6.351}$$

where $\hat{\vec{n}}$ is the mirror's unit normal.

A mirror tilt of α therefore changes the reflected beam direction by 2α.

Indeed, let $\hat{\vec{n}}$ be the unit normal vector pointing outward from the surface of the mirror. Any vector, including the incident wavevector $\vec{k}_i$, can be resolved into components parallel ($\parallel$) and perpendicular $(\perp)$ to the surface normal:

$$\vec{k}_i = \vec{k}_{i,\parallel} + \vec{k}_{i,\perp} \tag{10.6.352}$$

The perpendicular component is given by the projection of $\vec{k}_i$ onto $\hat{\vec{n}}$:

$$\vec{k}_{i,\perp} = \left(\vec{k}_i \circ \hat{\vec{n}}\right)\hat{\vec{n}} \tag{10.6.353}$$

Consequently, the parallel component is whatever remains:

$$\vec{k}_{i,\parallel} = \vec{k}_i - \left(\vec{k}_i \circ \hat{\vec{n}}\right)\hat{\vec{n}} \tag{10.6.354}$$

For a wave to satisfy boundary conditions continuously across an infinite plane interface at all points along the surface, the spatial phase of the incident wave must match the spatial phase of the reflected wave along the boundary. This requires the parallel component of the wavevector to be invariant under reflection:

$$\vec{k}_{r,\parallel} = \vec{k}_{i,\parallel} = \left(\vec{k}_i \circ \hat{\vec{n}}\right)\hat{\vec{n}} \tag{10.6.355}$$

Because the reflection is elastic in a uniform medium, the magnitude of the wavevector is conserved:

$$||\vec{k}_r|| = ||\vec{k}_i|| \tag{10.6.356}$$

Since the total magnitude squared is the sum of the squares of its orthogonal components ($||\vec{k}||^2 = ||\vec{k}_\parallel||^2 + ||\vec{k}_\perp||^2$), and the parallel component $\vec{k}_\parallel$ is identical for both incident and reflected waves, the magnitude of the perpendicular component must also be identical:

$$||\vec{k}_{r,\perp}|| = ||\vec{k}_{i,\perp}|| \tag{10.6.357}$$

Physically, the normal component must reverse its direction (pointing into the opposite half-space away from the mirror):

$$\vec{k}_{r,\perp} = -\vec{k}_{i,\perp} = -\left(\vec{k}_i \circ \hat{\vec{n}}\right)\hat{\vec{n}} \tag{10.6.358}$$

The total reflected wavevector k_r is the sum of its parallel and perpendicular components:

$$\vec{k}_r = \vec{k}_{r,\parallel} + \vec{k}_{r,\perp} \tag{10.6.359}$$

Substituting from our previous expressions:

$$\vec{k}_r = \vec{k}_{r,\parallel} + \vec{k}_{r,\perp} = \left[\vec{k}_i - \left(\vec{k}_i \circ \hat{\vec{n}}\right)\hat{\vec{n}}\right] - \left(\vec{k}_i \circ \hat{\vec{n}}\right)\hat{\vec{n}} = \vec{k}_i - 2\left(\vec{k}_i \circ \hat{\vec{n}}\right)\hat{\vec{n}} \tag{10.6.360}$$

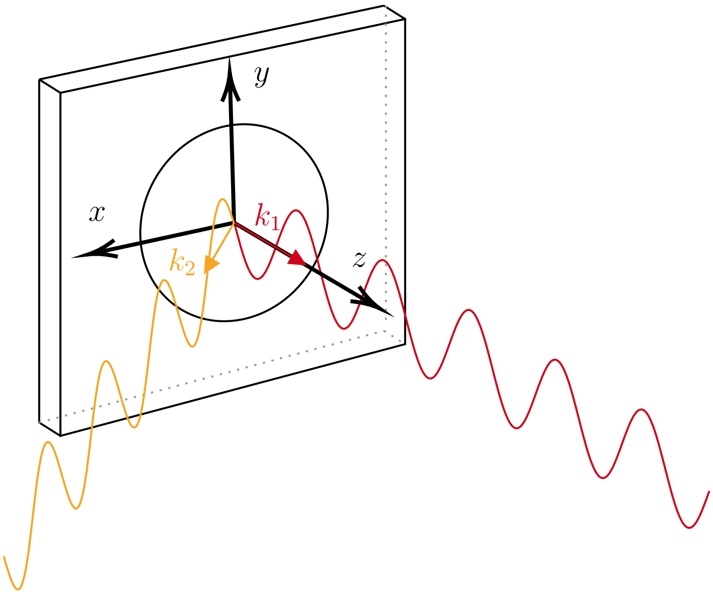
This reflection law follows by matching the phase of the incident and reflected solutions of the Helmholtz equation along the mirror surface.

After accounting for the beam splitter, we can choose coordinates such that the two recombined wavevectors are:

$$\vec{k}_1 = k(0,0,1) \tag{10.6.361}$$

and:

$$\vec{k}_2 = k(\sin(2\alpha), 0, \cos(2\alpha)) \tag{10.6.362}$$



Notice that we have not assumed anything about the shape of the fringes. We have obtained the wavevectors from the optical geometry.

The complex fields are:

$$\psi_1 = A_1 e^{\mathrm{i}kz} \tag{10.6.363}$$

and:

$$\psi_2 = A_2 e^{\mathrm{i}[kx\sin(2\alpha) + kz\cos(2\alpha) + \phi_0]} \tag{10.6.364}$$

Here ϕ_0 represents a constant phase difference arising from the optical path lengths and reflections.

The resultant field is:

$$\psi = \psi_1 + \psi_2 \tag{10.6.365}$$

The time-averaged intensity is proportional to:

$$\begin{aligned}I &= |\psi_1+\psi_2|^2 = |\psi_1+\psi_2|^2 = (\psi_1+\psi_2)\left(\bar{\psi}_1+\bar{\psi}_2\right) = \psi_1\bar{\psi}_1+\psi_2\bar{\psi}_2+\psi_1\bar{\psi}_2+\bar{\psi}_1\psi_2\\ &= \left(A_1e^{\mathrm{i}kz}\right)\left(A_1e^{-\mathrm{i}kz}\right)+\left(A_2e^{\mathrm{i}[kx\sin(2\alpha)+kz\cos(2\alpha)+\phi_0]}\right)\left(A_2e^{-\mathrm{i}[kx\sin(2\alpha)+kz\cos(2\alpha)+\phi_0]}\right)\\ &+\left(A_1e^{\mathrm{i}kz}\right)\left(A_2e^{-\mathrm{i}[kx\sin(2\alpha)+kz\cos(2\alpha)+\phi_0]}\right)+\left(A_1e^{-\mathrm{i}kz}\right)\left(A_2e^{\mathrm{i}[kx\sin(2\alpha)+kz\cos(2\alpha)+\phi_0]}\right)\\ &= A_1^2+A_2^2+A_1A_2\left(e^{\mathrm{i}kz-\mathrm{i}[kx\sin(2\alpha)+kz\cos(2\alpha)+\phi_0]}\right)\\ &+A_1A_2\left(e^{\mathrm{i}[kx\sin(2\alpha)+kz\cos(2\alpha)+\phi_0]--\mathrm{i}kz}\right)\\ &= A_1^2+A_2^2+A_1A_2\left(e^{\mathrm{i}kz-\mathrm{i}[kx\sin(2\alpha)+kz\cos(2\alpha)+\phi_0]}+e^{\mathrm{i}[kx\sin(2\alpha)+kz\cos(2\alpha)+\phi_0]-\mathrm{i}kz}\right)\end{aligned} \tag{10.6.366}$$

Using Euler's formula (see section Number page 251):

$$\cos(\phi) = \frac{e^{\mathrm{i}\phi}+e^{-\mathrm{i}\phi}}{2} \tag{10.6.367}$$

we get:

$$I = A_1^2+A_2^2+2A_1A_2\cos(\Delta\phi) \tag{10.6.368}$$

where:

$$\Delta\phi = kx\sin(2\alpha)+kz[\cos(2\alpha)-1]+\phi_0 \tag{10.6.369}$$

Now consider a detector in the plane $z=z_0$.

All terms involving z_0 are constants, so that we can write:

$$I(x,y) = A_1+A_2+2A_1A_2\cos[kx\sin(2\alpha)+\phi] \tag{10.6.370}$$

where ϕ is a constant.

This is the required intensity distribution, derived from the wave equation and mirror geometry.

Bright fringes occur when the phase difference is an integer multiple of 2π :

$$kx\sin(2\alpha)+\phi = 2\pi m \tag{10.6.371}$$

where m is an integer.

Therefore:

$$x_m = \frac{2\pi m-\phi}{k\sin(2\alpha)} \tag{10.6.372}$$

Since x_m is independent of y, every bright fringe is a straight line parallel to the y-axis.

The fringe spacing is:

$$\Delta x = \frac{2\pi}{k|\sin(2\alpha)|} \tag{10.6.373}$$

Using $k=2\pi/\lambda$:

$$\Delta x = \frac{\lambda}{|\sin(2\alpha)|} \tag{10.6.374}$$

For small angles, $\sin(2\alpha)\simeq 2\alpha$, so:

$$\Delta x \cong \frac{\lambda}{2|\alpha|} \tag{10.6.375}$$

10.6.5.1.4 Michelson interferometer and Special Relativity

At the origin this experiment was devised by Albert Abraham Michelson to measure the speed of light within its hypothesized medium (the ether), based on the classical law of the addition of velocities. It appeared that the Earth - moving in its orbit at a speed of approximately 30 $[\text{km}\cdot\text{s}^{-1}]$ relative to the Sun-provided an ideal laboratory for detecting variations in the speed of light over paths of equal length; such paths, however, were expected to require different amounts of time to traverse, depending on whether they were aligned with the direction of motion or oriented perpendicular to the "ether wind".

The apparatus is constructed in such a way that mirrors M_1 and M_2 are at an equal distance, d, from the beam splitter.

So, if the Earth is stationary relative to the ether, the two paths - in the two perpendicular directions - are equal (the same distance is traveled, and the travel time is the same).

If, on the other hand, the Earth is in motion relative to the ether - at a speed v in a certain direction (toward M_1, for example) - then the two journeys are not made at the same speed, and the time required is not the same in both directions:

- A round trip in the direction of the Earth's motion (toward M_1) requires a certain amount of time:

  $$t_1=\frac{d}{c-v}+\frac{d}{c+v}=\frac{2d\cdot c}{c^2-v^2}=\frac{2d}{c}\frac{1}{1-\frac{v^2}{c^2}}\cong\frac{2L}{c}\left(1+\frac{v^2}{c^2}\right) \tag{10.6.376}$$

  Michelson obtained this expression correctly in 11881 (holocene calendar), however, in transverse direction that we will derive now he obtained the incorrect expression (this was corrected by Alfred Potier on year later and Hendrik Lorentz five yers later).

- A round trip perpendicular to the Earth's motion (towards M_2) requires a certain amount of time t_2. This inclined travel path follows from the transformation from the interferometer rest frame to the aether rest frame. One direction path will have length using Pythagoras theorem:

  $$ct=\sqrt{d^2+(vt)^2} \tag{10.6.377}$$

  and consequently the one direction travel time is after rearranging:

  $$t=\frac{d}{\sqrt{c^2-v^2}} \tag{10.6.378}$$

  which is the same for the backward journey. The total travel time is therefore equal to:

  $$t_2=\frac{2d}{\sqrt{c^2-v^2}}=\frac{2d}{c}\frac{1}{\sqrt{1-\frac{v^2}{c^2}}}\cong\frac{2d}{c}\left(1+\frac{v^2}{2c^2}\right) \tag{10.6.379}$$

The time difference between t_1 and t_2 is given by:

$$t_1 - t_2 = \frac{2L}{c}\left(\frac{1}{1-\frac{v^2}{c^2}} - \frac{1}{\sqrt{1-\frac{v^2}{c^2}}}\right) \tag{10.6.380}$$

The expected time difference is too small to be measured directly: the speed of light was already known to be on the order of $3\cdot 10^8\,[\mathrm{m}\cdot\mathrm{s}^{-1}]$, the speed of the Earth relative to the Sun - and thus relative to the ether - on the order of $3\cdot 10^4\,[\mathrm{m}\cdot\mathrm{s}^{-1}]$, and the dimensions of the apparatus on the order of 10 [m]. This results in a measurement on the order of $10\cdot 10^9/10^{25}$, or 10^{-15} seconds.

Son instead we use the the path difference, simply by multiplying by c:

$$\Delta\lambda = 2L\left(\frac{1}{1-\frac{v^2}{c^2}} - \frac{1}{\sqrt{1-\frac{v^2}{c^2}}}\right) \tag{10.6.381}$$

The path difference is denoted by $\Delta\lambda$ because the beams are out of phase by a some number of wavelengths (λ). To visualise this, consider taking the two beam paths along the longitudinal and transverse plane, and lying them straight. One path will be longer than the other, this distance is $\Delta\lambda$.

If the relation $v^2/c^2 \ll 1$ is true (if the velocity of the aether is small relative to the speed of light), then the expression can be simplified using a first order binomial expansion:

$$(1-x)^n \cong 1 - nx \tag{10.6.382}$$

So, rewriting the above in terms of powers:

$$\Delta\lambda = 2d\left(\left(1-\frac{v^2}{c^2}\right)^{-1} - \left(1-\frac{v^2}{c^2}\right)^{-1/2}\right) \tag{10.6.383}$$

Applying binomial simplification:

$$\Delta\lambda \cong 2d\left(\left(1+\frac{v^2}{c^2}\right) - \left(1+\frac{v^2}{2c^2}\right)\right) = 2d\frac{v^2}{2c^2} = d\frac{v^2}{c^2} \tag{10.6.384}$$

The derivation above shows that the presence of an aether wind would produce a difference in optical path lengths between the two arms of the interferometer. This path difference depends on the orientation of the interferometer relative to the aether wind. Specifically, the derivation assumes that the longitudinal arm is aligned parallel to the presumed direction of the aether wind. If instead the longitudinal arm is oriented perpendicular to the aether wind, the resulting path difference would have the opposite sign.

The magnitude of the path difference can vary continuously and may represent any fraction of the wavelength, depending on both the angle between the apparatus and the aether wind and the wind's speed.

In fact, this is related to a whole series of experiments conducted between 11881 (by Michelson alone) and 11887 (by both of them together). By the latter date, it was definitively accepted - a conclusion that has been consistently reaffirmed whenever the experiment is repeated with the benefit of technical advancements allowing for greater precision - that the speed of light is constant.

The negative result led Michelson to the conclusion that there is no measurable aether drift. However, he never accepted this on a personal level, and the negative result haunted him for the rest of his life.

The interpretation of this result led physicists to question the existence of the ether (hypothesized to be the material medium for the vibrations of electromagnetic waves, such as light) - or, at the very least, to question its motion. It also demonstrated that the speed of light is the same in all directions, up to the second order in (v/c), which was the level of precision of the experiment.

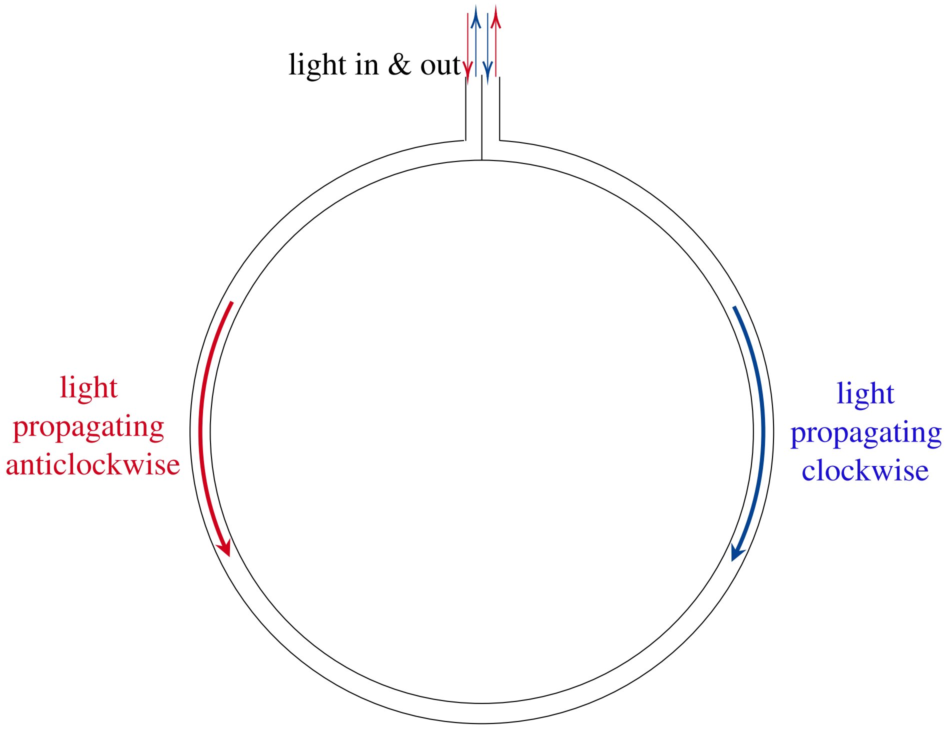
Remark

The extent to which the null result of the Michelson-Morley experiment influenced Albert Einstein is disputed. Alluding to some statements of Albert Einstein, many historians argue that it played no significant role in his path to special relativity, while other statements of Einstein probably suggest that he was influenced by it. In any case, the null result of the Michelson-Morley experiment helped the notion of the constancy of the speed of light gain widespread and rapid acceptance.

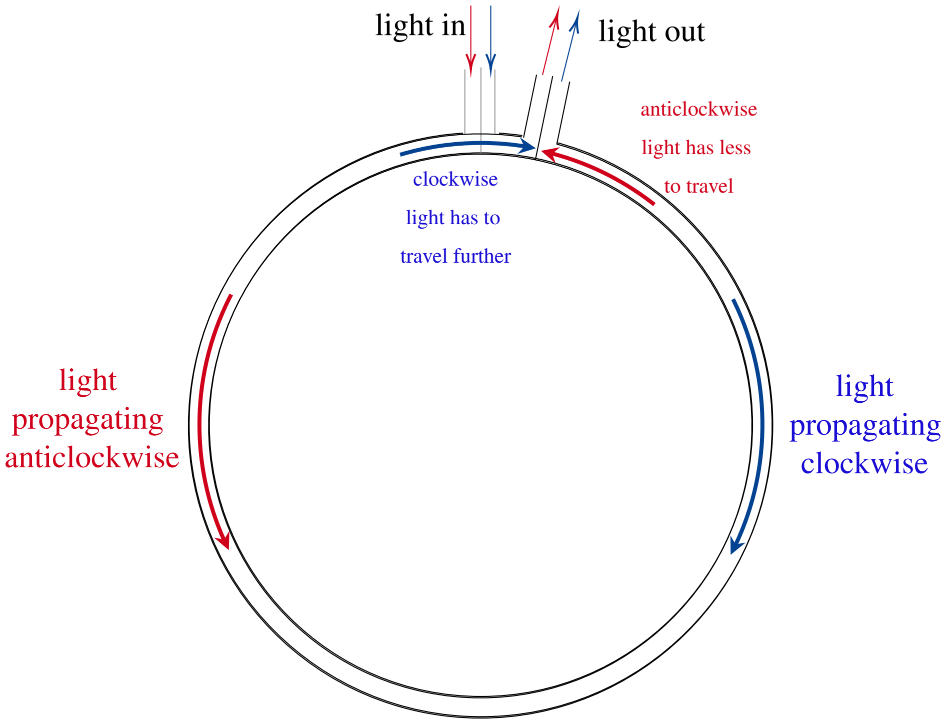
10.6.5.2 Sagnac interferometer (Sagnac effect)

The "Sagnac effect", also named "Sagnac interference", named after French physicist Georges Sagnac, is a phenomenon encountered in interferometry that is elicited by rotation. The Sagnac effect manifests itself in a setup called a ring interferometer or Sagnac interferometer. A beam of light is split and the two beams are made to follow the same path but in opposite directions. On return to the point of entry the two light beams are allowed to exit the ring and undergo interference. The relative phases of the two exiting beams, and thus the position of the interference fringes, are shifted according to the angular velocity of the apparatus. In other words, when the interferometer is at rest with respect to a nonrotating frame, the light takes the same amount of time to traverse the ring in either direction. However, when the interferometer system is spun, one beam of light has a longer path to travel than the other in order to complete one circuit of the mechanical frame, and so takes longer, resulting in a phase difference between the two beams. Georges Sagnac set up this experiment in 11913 (holocene calendar) in an attempt to prove the existence of the aether that Einstein's theory of special relativity makes superfluous.

Imagine beams of light coming from an emitter and travelling around a circular path in both directions, until they arrive back at the source. Such an arrangement can be constructed by using an optic fibre in a circular loop, injecting light at both ends. The distance travelled by the clockwise beam is the same as the distance travelled by the anticlockwise beam, and the speed of light in both directions is the same, so the time taken for each beam to travel from the source back to the origin is the same. So far, so good:



Now imagine the whole thing is rotating - let's say clockwise. For reference we will use the numbers on a clock face and the finer divisions into 60 minutes. The optic fibre ring runs around the edge of the clock, with the light source and a detector at 12. Now imagine that the clock rotates fast enough that by the time the clockwise-going light reaches the original 12 position, the clock has rotated so that 12 is now located at the original 1 minute past 12 position. The light has to travel an extra 60th of the circle to reach its starting position (actually a tiny bit more than that because the clock is still rotating and will have gone a tiny bit further by the time the light beam catches up). But the light going anticlockwise reaches the source early, only needing to travel a tiny bit more than 59/60 of the circle. The travel times of the two beams of light around the circle are different!



This is a very simplified explanation, and figuring out the mathematics of exactly what happens involves using special relativity, since the speed of light is involved, but it can be shown that there is indeed a time difference between the travel times of beams of light heading in opposite directions around a rotating loop. The time difference is proportional to the speed of rotation and to the area of the loop (and to the cosine of the angle between the rotation axis and the perpendicular to the loop, for those who enjoy vector mathematics).

The shift in interference fringes in a ring interferometer can be viewed intuitively and naively as a consequence of the different distances that light travels due to the rotation of the ring. The simplest derivation is for a circular ring of radius R, with a refractive $n = 1$, rotating at an angular velocity of ω, but the result is general for loop geometries with other shapes. If a light source emits in both directions from one point on the rotating ring, light travelling in the same direction as the rotation direction needs to travel more than one circumference around the ring before it catches up with the light source from behind. The time t_1 that it takes to catch up with the light source is given by:

$$t_1 = \frac{2\pi R + \Delta L}{c} \qquad (10.6.385)$$

where ΔL is the distance that the mirror has moved in that same time:

$$\Delta L = R\omega t_1 \qquad (10.6.386)$$

Eliminating ΔL from the two equations above we get:

$$t_1 = \frac{2\pi R}{c - R\omega} \qquad (10.6.387)$$

Likewise, the light travelling in the opposite direction of the rotation will travel less than one circumference before hitting the light source on the front side. So the time for this direction of light to reach the moving source again is:

$$t_2=\frac{2\pi R}{c+R\omega} \tag{10.6.388}$$

The time difference is therefore:

$$\Delta T=t_1-t_2=\frac{4\pi R^2\omega}{c^2-R^2\omega^2} \tag{10.6.389}$$

For $R\omega=v\ll c$, this reduces to the "Sagnac Newtonian formula":

$$\Delta T\cong\frac{4\pi R^2\omega}{c^2}=\frac{4A\omega}{c^2} \tag{10.6.390}$$

where A is the area of the ring. Hence the phase shift[26]:

$$\boxed{\Delta\phi=c\Delta T\frac{1}{\lambda}\cdot 2\pi\cong\frac{8\pi\omega}{c\lambda}} \tag{10.6.391}$$

Although this simple derivation is for a circular ring with an index of refraction of one, the result holds true for any shape of rotating loop with area A.

We see that this result has been achieved at the cost of introducing an anisotropy in the velocity of light and of actually allowing velocities higher than the velocity of light (the $c+R\omega$). This anisotropy contradicts the relativistic law for adding velocities (even in first order), and it contradicts the constancy of the velocity of light. In other words, although these ideas do generate a prediction which agrees (in a first approximation) with the correct prediction, it is internally untenable.

Remark

Since emitter and detector are travelling at the same speeds, Doppler effects cancel out, so the Sagnac effect does not involve the Doppler effect. In the case of ring LASER interferometry, it is important to be aware of this. When the ring LASER setup is rotating, the counterpropagating beams undergo frequency shifts in opposite directions.

Let us see now the relativist approach version!

Consider a ring interferometer where two counter-propagating light beams share a common optical path determined by a loop of an optical fiber. The loop may have an arbitrary shape, and can move arbitrarily in space. The only restriction is that it is not allowed to stretch.

Consider a small segment of the fiber, whose length in its rest frame is $d\ell'$. The time intervals, $dt'_\pm$, it takes the left and right moving light rays to traverse the segment in the rest frame coincide and are given by (n is the index of refraction):

$$\mathrm{d}t'_\pm=\frac{n}{c}\mathrm{d}\ell' \tag{10.6.392}$$

---

[26] For reminder the $c\Delta T$ give obviously the distance shift, but as the phase shift is by definition in radian in fraction of the wavelength that why divide by λ and to get the result in radian we multiply by 2π.

Let $\mathrm{d}\ell=|\mathrm{d}\vec{x}|$ be the length of this small segment in the lab frame. By the relativistic length contraction formula (see section Special Relativity page 5654)), $\mathrm{d}\ell'=\gamma\mathrm{d}\ell\cong\mathrm{d}\ell$ correct to first order in the velocity $\vec{v}$ of the segment. The time intervals $\mathrm{d}t_{\pm}$for traversing the segment in the lab frame are given by Lorentz transformation as:

$$\mathrm{d}t_{\pm}=\gamma\left(\mathrm{d}t'\pm\frac{\vec{v}\circ d\vec{x}'}{c^2}\right)\cong\frac{n}{c}\mathrm{d}\ell\pm\frac{\vec{v}}{c^2}\circ\mathrm{d}\vec{x}\tag{10.6.393}$$

correct to first order in the velocity $\vec{v}$. In general, the two beams will visit a given segment at slightly different times, but, in the absence of stretching, the length $\mathrm{d}\ell$ is the same for both beams.

It follows that the time difference for completing a cycle for the two beams is:

$$\Delta T=\int(\mathrm{d}t_{+}-\mathrm{d}t_{-})\cong\frac{2}{c^2}\oint\vec{v}\circ\mathrm{d}\vec{x}\tag{10.6.394}$$

Imagine a screen for viewing fringes placed at the light source (alternatively, use a beamsplitter to send light from the source point to the screen). Given a steady light source, interference fringes will form on the screen with a fringe displacement given by $\Delta\phi\approx\frac{2\pi c}{\lambda}\Delta T$ where the first factor is the frequency of light. This gives the generalized Sagnac formula:

$$\Delta\phi\cong\frac{4\pi}{\lambda c}\oint\vec{v}\circ\mathrm{d}\vec{x}\tag{10.6.395}$$

In the special case that the fiber moves like a rigid body with angular frequency $\vec{\omega}$, the velocity is $\vec{v}=\vec{\omega}\times\vec{x}$ and the line integral can be computed in terms of the area of the loop (we have us the property of the dot and cross product as give at page 1836):

$$\oint\vec{v}\circ\mathrm{d}\vec{x}=\oint\vec{\omega}\times\vec{x}\circ\mathrm{d}\vec{x}=\oint\vec{\omega}\circ\vec{x}\times\mathrm{d}\vec{x}=2\oint\vec{\omega}\circ\mathrm{d}\vec{A}=2\vec{\omega}\circ\vec{A}\tag{10.6.396}$$

This gives the "Sagnac formula for ring interferometers" of arbitrary shape and geometry:

$$\boxed{\Delta\phi\cong\frac{8\pi}{\lambda c}\vec{\omega}\circ\vec{A}}\tag{10.6.397}$$

Caution! According to the ether hypothesis, light is a disturbance similar to sound. It takes place in a substance called luminiferous ether. When we assume the interferometer is placed in an inertial system that is stationary with respect to the ether, then the result given by (see proof above):

$$\Delta\phi\cong\frac{8\pi\omega}{\lambda c}\tag{10.6.398}$$

is correct if the rotating platform does not drag the ether along with its motion.

On the other hand, it was already noticed by Max von Laue that relativity predicts, to first order approximation, the same kind of result as an ether theory for a Sagnac type experiment (see proof also just above):

$$\Delta\phi \cong \frac{8\pi}{\lambda c}\vec{\omega}\circ\vec{A} \qquad (10.6.399)$$

Since the Sagnac effect is compatible either with relativity or the ether hypothesis, the conclusion is that the Sagnac experiment cannot discriminate between the two models.

However, the famous 11887 (holocene calendar) Michelson-Morley experiment (see page 4562) can be explained only if the ether is fully dragged with the earth's motion. On the other hand, in 11925 (holocene calendar), Michelson and Gale confirmed the Sagnac effect using the earth as a rotating platform. This experiment can only be explained if the ether is not dragged with the earth's rotation.

Thus, neither the Michelson-Morley nor the Michelson-Gale experiments, taken separately, are evidence against the ether. However, when considered jointly, they are incompatible with the existence of the luminiferous ether since it cannot be consistently assumed the ether is fully dragged with the earth translation and, at the same time, remains unperturbed by its rotation. Nonetheless, both experiments can be explained by relativity.

The first relativistic proofs of the effect were presented by Max von Laue in 11920 (holocene calendar) and with a different approach by Paul Langevin in 11921 (holocene calendar). Presumably, it took so long to find relativistic explanations because, at the time, the experiment was not widely known.

In this early 121st century (holocene calendar), the relativistic nature of the Sagnac effect is, of course, beyond reasonable doubt. There exists a vast literature with an exhaustive analysis of the phenomenon. Its applications range from GPS, fiber optic and ring LASER gyroscopes, navigation systems to geodesic and seismology. There are even derivations based on the mathematics of General Relativity that leads to the same result (see [**lambare2024sagnac**] or [**logunov1988special**]).

Measuring the minuscule time difference between the propagation of the light beams is not difficult, due to the wave nature of light itself. The wavelength of visible light is just a few hundred nanometres, so even a time difference of the order of 10^{-16} seconds can be observed because it moves the wave crests and troughs of the two beams relative to one another, causing visible interference patterns as they shift out of synchronisation. This makes the device an interferometer that is very sensitive to rotational speed.

Remark

A gimbal mounted mechanical gyroscope remains pointing in the same direction after spinning up, and thus can be used as a rotational reference for an inertial navigation system. With the development of so-called LASER gyroscopes and fiber optic gyroscopes based on the Sagnac effect, bulky mechanical gyroscopes can be replaced by those with no moving parts in many modern inertial navigation systems. A conventional gyroscope relies on the principle of conservation of angular momentum whereas the sensitivity of the ring interferometer to rotation arises from the invariance of the speed of light for all inertial frames of reference.

As the Earth moves through space, it wobbles. Researchers in Germany have now directly observed this wobble with the highest precision yet thanks to a large ring LASER gyroscope they developed for this purpose (other have also measured the rotation of Earth long time before but with less precision: see [391] and [18]). The instrument, which is located in southern Germany and operates continuously, represents an important advance in the development of super-sensitive rotation sensors. If further improved, such sensors could help us better understand the interior of our planet and test predictions of relativistic effects, including the distortion of space-time due to Earth's rotation. The instrument can sense the Earth's rotation to within an accuracy of 48 parts per billion (ppb), which corresponds to picoradians per second.

10.6.6 LASER

The conceptual contribution of Albert Einstein to light-matter interaction is essential. His approach, which was to introduce the concept of absorption and stimulated emission of radiation, is the origin of the LASER emission process (Light Amplification by Stimulated Emission of Radiation) used in many areas such as: read / write optical discs, satellite data transmission, conferences pointers, precision measuring devices (telemetry, anemometry), surgery (eye, hair removal, gyrometry, cutting or industrial welding, micromachining, priming nuclear reactions (megajoule LASER) prototyping (3D printers), cleaning surfaces (ablation / LASER etching), structure analysis, cooling, etc.

By analysing the thermal equilibrium conditions in the interaction of electromagnetic radiation with matter, Albert Einstein understood that taking into account the spontaneous emission permits only to find the Wien's distribution law (see section Thermodynamics page 3727). However Planck's law (see section Thermodynamics page 3719) can not be obtained if we assume the existence of a stimulated emission process. This is where Einstein's work germ contain the development of coherent electromagnetic radiation sources.

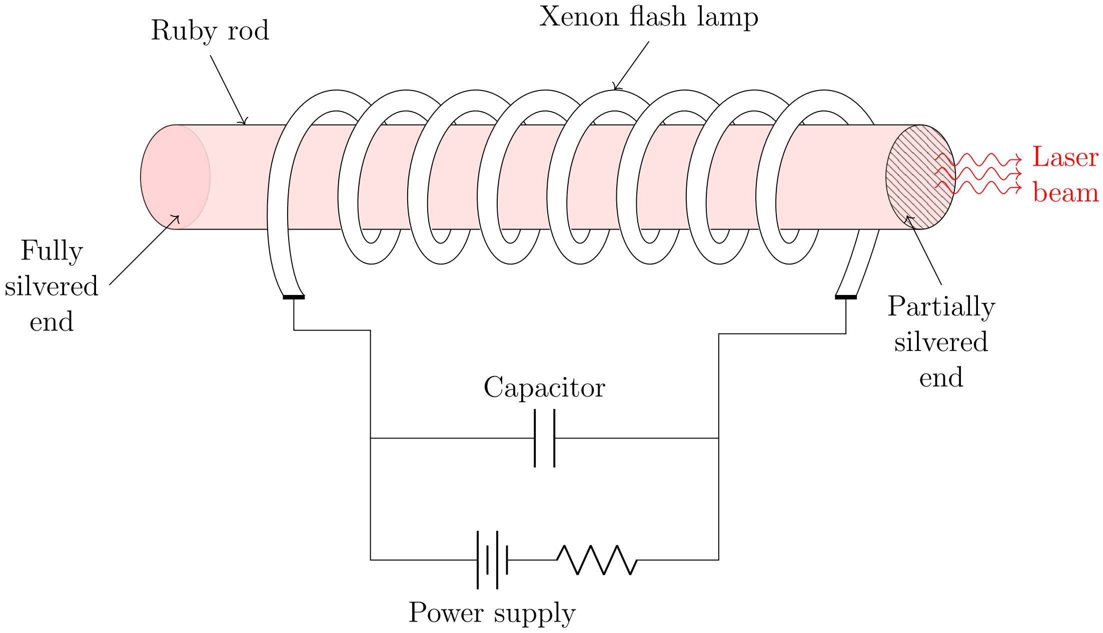

Figure 10.276: **Schematic principle of a ruby LASER (solid-state LASER)**

Indeed, the first proofs of a coherent emission of radiation have involved specialists in atomic physics to those of electromagnetism. This gave birth to the MASER (Microwave Amplification by Stimulated Emission of Radiation).

It is the evolution of this multifaceted tool and the response that it has be able to bring to problems that contributed to the development of optoelectronics, optronics and biophotonics.

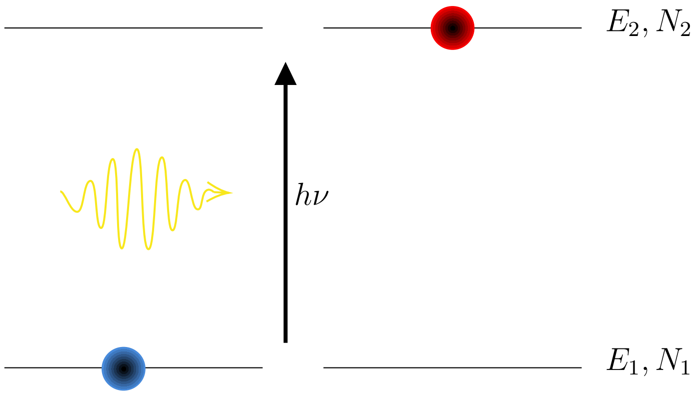
I have hesitated during a long time to put the basic developments of the LASER in the section of Statistical Mechanics, or Thermodynamics or Electrodynamics. As in my private circle the majority of people (not scientific) associated the LASER with optics, I thought it was more appropriate to present the below developments in this section of Wave Optics.

We will, as did Albert Einstein, show by contradiction that consider only stimulated absorption and spontaneous emission are insufficient to fall back on the law Planck proved in the section Thermodynamics (law which describes the radiation density at equilibrium in a cavity of finite dimension):

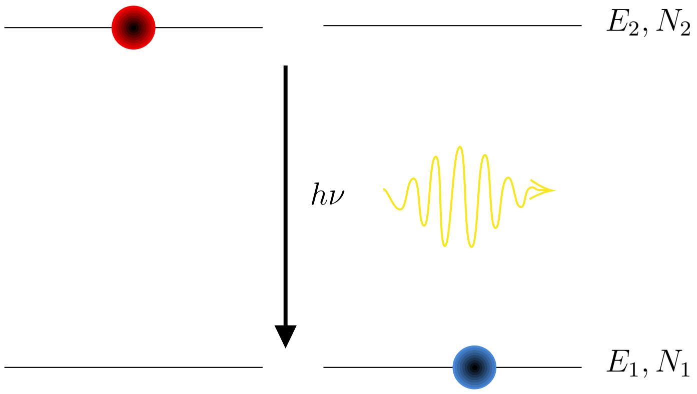
$$R(\nu,T)=\frac{8\pi h\nu^3}{c^3}\frac{1}{e^{\frac{h\nu}{kT}}-1} \tag{10.6.400}$$

Let us represent schematically what are stimulated absorption and spontaneous emission disregarding the notations of energy levels as used in the sections of Corpuscular Quantum Physics, Wave Quantum Physics and Quantum Chemistry:

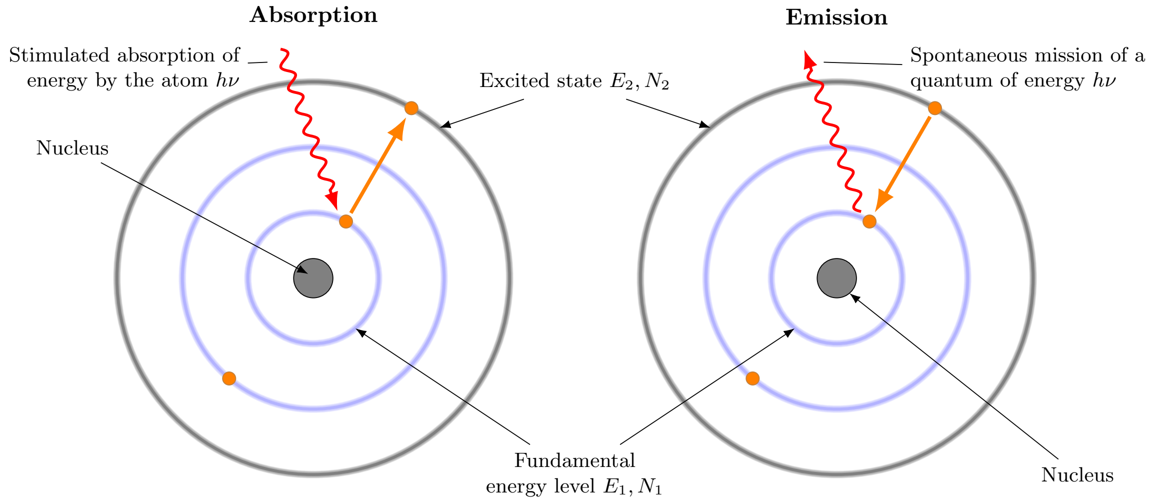
stimulated absorption



spontaneous emmission



Or seen from a naive atomistic level point of view (the old Bohr model...):



Absorption
Stimulated absorption of energy by the atom $h\nu$
Nucleus
Excited state E_2, N_2
Emission
Spontaneous mission of a quantum of energy $h\nu$
Fundamental energy level E_1, N_1
Nucleus

In our gedankenexperiment, N_{tot} atoms are divided into the populations N_1 and N_2 respectively on two energy levels E_1 and E_2.

We observe a resonant absorption of electromagnetic radiation when the frequency ν of the radiation is equal to the energy difference between the two considered levels. The energy emitted or absorbed is then linked to the relation:

$$E_2 - E_1 = h\nu \tag{10.6.401}$$

The absorption rate obviously depends on the spectral energy density of the incident electromagnetic field $R(\nu, T)$, of the population N_1 of the lower level and finally it is probably proportional to a factor B_{12} that would give the properties of the atomic system. Under these assumptions, we are led to write naturally:

$$\left.\frac{\mathrm{d}N_2}{\mathrm{d}t}\right|_{\text{absorption}} = N_1 R(\nu, T) B_{12} = -\frac{\mathrm{d}N_1}{\mathrm{d}t}_{\text{absorption}} \tag{10.6.402}$$

The phenomenon of stimulated resonant absorption is superimposed the fact that an excited system returns to its initial state with a characteristic time: the lifetime of the excited state. The de-excitation rate is proportional to the population of the upper level of the transition such as this brings us to write:

$$\left.\frac{\mathrm{d}N_2}{\mathrm{d}t}\right|_{\text{spontaneous}} = -N_2 A_{21} = \frac{\mathrm{d}N_1}{\mathrm{d}t}_{\text{spontaneous}} \tag{10.6.403}$$

The conservation of the total number of atoms:

$$N_1(t) + N_2(t) = N_{\text{tot}} \tag{10.6.404}$$

interacting with the radiation is reflected by the kinetic condition (it is just the derivative with respect to time of the preceding expression):

$$\frac{\mathrm{d}N_1(t)}{\mathrm{d}t} + \frac{\mathrm{d}N_2(t)}{\mathrm{d}t} = N_{\text{tot}} \tag{10.6.405}$$

By injecting previous relations wisely, we get:

$$-N_2 A_{21} + N_1 R(\nu, T) B_{12} = 0 \tag{10.6.406}$$

Therefore (if we fall back on Planck's law, our assumptions for the gendankenexperiment will then be checked!):

$$R(\nu,T)=\frac{N_2}{N_1}A_{21}B_{12} \tag{10.6.407}$$

The population of levels at thermodynamic equilibrium following a Maxwell-Boltzmann distribution law (see section Statistical Mechanics page 3554):

$$n_i=g_i e^{\frac{\nu-E_i}{kT}} \tag{10.6.408}$$

We therefore have:

$$R(\nu,T)=\frac{g_2 e^{\frac{\nu-E_2}{kT}}}{g_1 e^{\frac{\nu-E_1}{kT}}}\frac{A_{21}}{A_{12}}=\frac{g_2}{g_1}\frac{A_{21}}{B_{12}}e^{\frac{\nu-E_2}{kT}-\frac{\nu-E_1}{kT}} \tag{10.6.409}$$

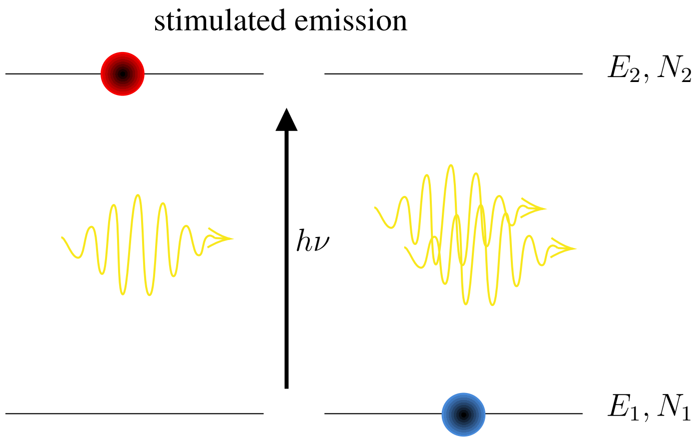
So we see well that we will never be able to fall back on Planck's law given for reminder by:

$$R(\nu,T)=\frac{8\pi h\nu^3}{c^3}\frac{1}{e^{\frac{n\nu}{kT}}-1} \tag{10.6.410}$$

with our assumptions. Of course, by choosing the constant well, we fall back on the Wien's law (see section Thermodynamics page 3727) but it has since the problems we already know.

So to get the Planck's law we must have missed something or the approach is totally false! To keep it simple ... if we observe a long time the result we just get, we find that we could possibly reach our goal if the relation arising from the conservation of the number of atoms had one more term (actually, simply from the Planck's law and to developments in reverse: reverse engineering). This is the brilliant idea that had Albert Einstein and allowed the creation of the theoretical concept of LASER.

Let us assume therefore that in addition to the spontaneous emission and absorption, we have the concept of "stimulated emission" that is really not intuitive (but that appears when the developments are done in reverse):



Therefore, in the spontaneous emission, the photon can be emitted in any direction. In the stimulated emission, we recognize (figure) two photons in the same direction, the incident photon causing the emission and the emitted photon. By filtering processes, it is then possible to obtain a monochromatic beam which can be used for power transmission, information or measurement.

Therefore in the presence of radiation of the same frequency as that of the transition, the system has a certain probability of being desexcited to regain its fundamental or initial state:

$$\left.\frac{\mathrm{d}N_2}{\mathrm{d}t}\right|_{\text{stimulated}}=-N_2B_{21}R(\nu,T)=-\frac{\mathrm{d}N_1}{\mathrm{d}t}_{\text{spontaneous}} \tag{10.6.411}$$

We therefore have the following kinetic equation:

$$\frac{\mathrm{d}N_1(t)}{\mathrm{d}t}+\frac{\mathrm{d}N_2(t)}{\mathrm{d}t}=0 \tag{10.6.412}$$

becomes:

$$(-N_2A_{21}-N_2B_{21}R(\nu,T))+N_1R(\nu,T)B_{12}=0 \tag{10.6.413}$$

Therefore:

$$R(\nu,T)(N_1B_{12}-N_2B_{21})=N_2A_{21} \tag{10.6.414}$$

Which brings us to:

$$R(\nu,T)=\frac{N_2A_{21}}{N_1B_{12}-N_2B_{21}}=\frac{N_2A_{21}}{N_2\left(\dfrac{N_1}{N_2}B_{12}-B_{21}\right)}=\frac{A_{21}}{\dfrac{N_1}{N_2}B_{12}-B_{21}} \tag{10.6.415}$$

and as:

$$\frac{N_1}{N_2}=\frac{g_1e^{\frac{\mu-E_1}{kt}}}{g_2e^{\frac{\mu-E_2}{T}}}=\frac{g_1}{g_2}e^{\frac{-E_1+E_2}{kT}}=\frac{g_1}{g_2}e^{\frac{h\nu}{kT}} \tag{10.6.416}$$

then it comes:

$$R(\nu,T)=\frac{A_{21}}{\dfrac{g_1}{g_2}e^{\frac{h\nu}{kT}}B_{12}-B_{21}}=A_{21}\frac{1}{B_{12}\left(\dfrac{B_{12}}{B_{21}}\dfrac{g_1}{g_2}e^{\frac{h\nu}{kT}}-1\right)} \tag{10.6.417}$$

and then we see that to get the Planck's law:

$$R(\nu,T)=\frac{8\pi h\nu^3}{c^3}\frac{1}{e^{\frac{h\nu}{kT}}-1} \tag{10.6.418}$$

We just have to put:

$$\frac{B_{12}}{B_{21}}=1\qquad\text{and}\qquad\frac{A_{21}}{B_{21}}=\frac{8\pi h\nu^3}{c^3} \tag{10.6.419}$$

Bingo! The coefficients are named by tribute: "Einstein coefficients".

For a system in thermal equilibrium, the lowest level of a transition is always more populated than the upper level. Accordingly, the medium behaves as an absorbent in the presence of incident radiation of the same frequency as that of the transition between the two states. However, if this equilibrium is changed so that the upper level is significantly more populated than the lower level, the system facilitates the stimulated emission process. We thus obtain an optical amplifying mechanism, which is associated with the population inversion produced through a technique named "optical pumping".

It must be indicate that the LASER may be made of gas mixtures, liquids doped with rare earths, semiconductor materials (LASER diodes), crystals or glasses doped with active ions.

Also let us mention that through this model, Albert Einstein was the first to introduce the probabilities in quantum physics in 11916 (holocene calendar). This led Max Born ten years later to advance a probabilistic interpretation of the Schrödinger's wave function (see section Wave Quantum Physics page 4758).

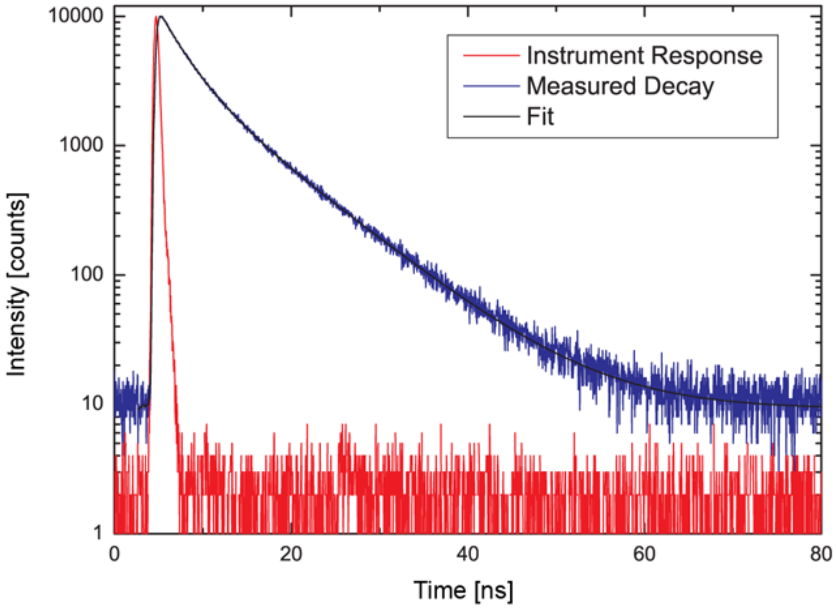
If the number of light sources in the excited state at time t is given by $N(t)$, the rate at which N decays is (see section Nuclear Physics page 5029):

$$\frac{\mathrm{d}N(t)}{\mathrm{d}t}=-A_{21}N(t) \tag{10.6.420}$$

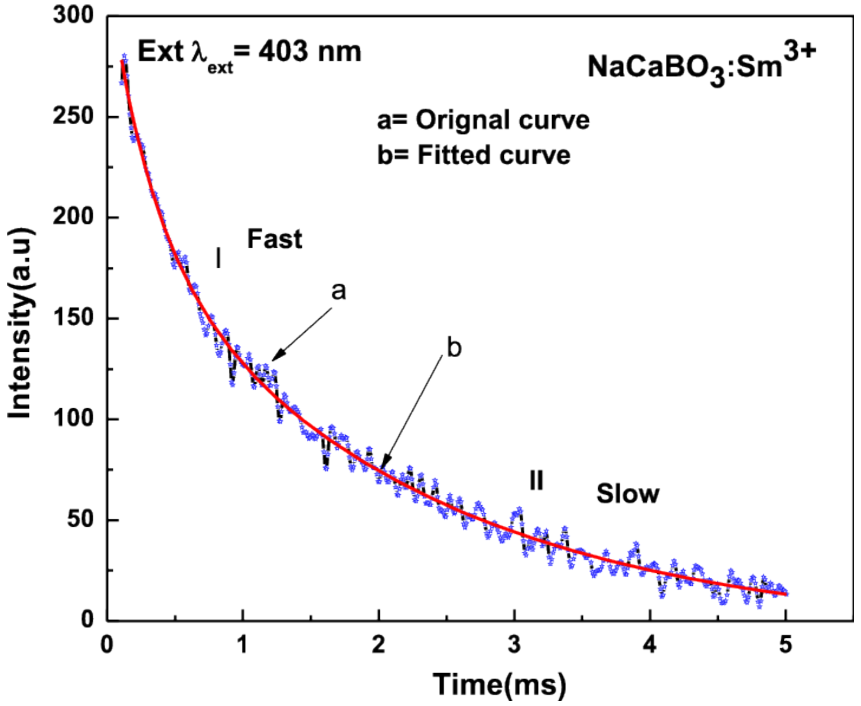
where A_{21} is the rate of spontaneous emission. In the above rate equation A_{21} is a proportionality constant for this particular transition in this particular light source. The constant is referred to as the Einstein A_{ki} coefficient, and has units s^{-1}. The above equation can be solved to give:

$$\boxed{N(t)=N(0)e^{-A_{21}t}=N(0)e^{-\Gamma_{\text{rad}}t}} \tag{10.6.421}$$

where $N(0)$ is the initial number of light sources in the excited state, t is the time and Γ_{rad} is the radiative decay rate of the transition. The number of excited states N thus decays exponentially with time, similar to radioactive decay.



and the figure below represents the decay rate of phosphoresence decay of $\mathrm{NaCaBO_3:Sm^{3+}}$ (notice again the inverse exponential shape):



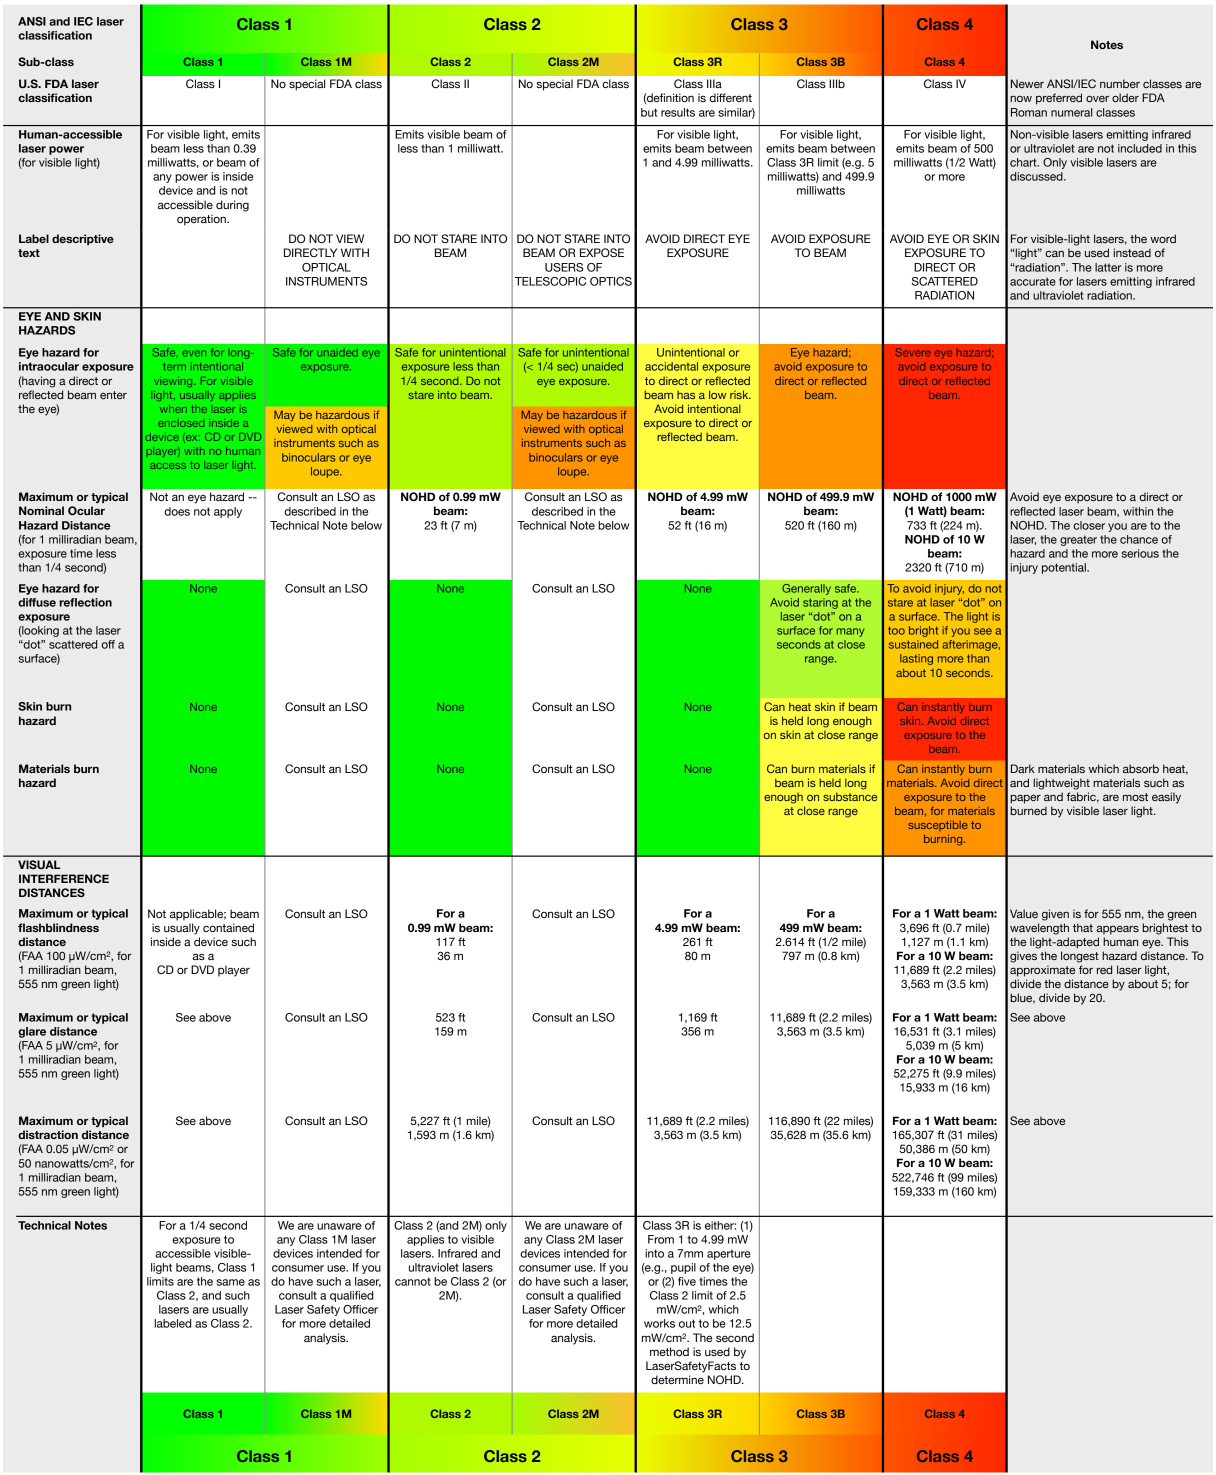
After one lifetime, the number of excited states decays to 36.8% of its original value ($1/e$-time). The radiative decay rate Γ_{rad} is inversely proportional to the lifetime τ_{21}:

$$A_{21} = \Gamma_{21} = \frac{1}{\tau_{21}} \tag{10.6.422}$$

The NIST (National Institute of Standards and Technology) website has a huge database of Einstein coefficients available at the adresse https://physics.nist.gov/PhysRefData/Handbook/element_name.htm. The reader just have to first pick up an atomic element and aftwards click on the button "Persistent Lines". Here are some examples:

Element	**Wavelength** 10^{-10} [m]	**Transition**	A_{ki} [s^{-1}]	**Half-life** [s]
Hydrogen	949.743	$1s \to 5p$	$3.44 \cdot 10^7$	$2.91 \cdot 10^{-8}$
Oxygen	1302.168	$2s^22p^4 \to 2s^22p^3(4S^\circ)3s$	$3.15 \cdot 10^7$	$3.17 \cdot 10^{-8}$
Carbon	1277.5497	$2s^22p^2 \to 2s^22p(^2p^\circ)3d$	$2.31 \cdot 10^8$	$4.33 \cdot 10^{-9}$
Iron	2382.0376	$3d^6(5D)4s \to 3d^6(^5D)4p$	$3.13 \cdot 10^8$	$3.19 \cdot 10^{-9}$
Neon	460.7284	$2s^22p^5 \to 2s2p^6$	$5.39 \cdot 10^9$	$1.86 \cdot 10^{-10}$
Silver	3280.68	$4d^{10}(^1s)5s \to 4d^{10}(1S)5p$	$1.47 \cdot 10^8$	$6.80 \cdot 10^{-9}$
Sodium	5889.95	$3s \to 3p$	$6.16 \cdot 10^7$	$1.62 \cdot 10^{-8}$
Xenon	1295.5878	$5p^6 \to 5p^5(^2P^\circ_{3/2})5d$	$2.53 \cdot 10^8$	$3.95 \cdot 10^{-9}$

Table 10.13: **Some Einstein coefficients A_{ki} for various elements and transitions (source: NIST)**



ANSI and IEC laser classification	**Class 1**		**Class 2**		**Class 3**		**Class 4**	**Notes**
Sub-class	**Class 1**	**Class 1M**	**Class 2**	**Class 2M**	**Class 3R**	**Class 3B**	**Class 4**	
U.S. FDA laser classification	Class I	No special FDA class	Class II	No special FDA class	Class IIIa (definition is different but results are similar)	Class IIIb	Class IV	Newer ANSI/IEC number classes are now preferred over older FDA Roman numeral classes
Human-accessible laser power (for visible light)	For visible light, emits beam less than 0.39 milliwatts, or beam of any power is inside device and is not accessible during operation.		Emits visible beam of less than 1 milliwatt.		For visible light, emits beam between 1 and 4.99 milliwatts.	For visible light, emits beam between Class 3R limit (e.g. 5 milliwatts) and 499.9 milliwatts	For visible light, emits beam of 500 milliwatts (1/2 Watt) or more	Non-visible lasers emitting infrared or ultraviolet are not included in this chart. Only visible lasers are discussed.
Label descriptive text		DO NOT VIEW DIRECTLY WITH OPTICAL INSTRUMENTS	DO NOT STARE INTO BEAM	DO NOT STARE INTO BEAM OR EXPOSE USERS OF TELESCOPIC OPTICS	AVOID DIRECT EYE EXPOSURE	AVOID EXPOSURE TO BEAM	AVOID EYE OR SKIN EXPOSURE TO DIRECT OR SCATTERED RADIATION	For visible-light lasers, the word “light” can be used instead of “radiation”. The latter is more accurate for lasers emitting infrared and ultraviolet radiation.
EYE AND SKIN HAZARDS								
Eye hazard for intraocular exposure (having a direct or reflected beam enter the eye)	Safe, even for long-term intentional viewing. For visible light, usually applies when the laser is enclosed inside a device (ex: CD or DVD player) with no human access to laser light.	Safe for unaided eye exposure. May be hazardous if viewed with optical instruments such as binoculars or eye loupe.	Safe for unintentional exposure less than 1/4 second. Do not stare into beam.	Safe for unintentional (< 1/4 sec) unaided eye exposure. May be hazardous if viewed with optical instruments such as binoculars or eye loupe.	Unintentional or accidental exposure to direct or reflected beam has a low risk. Avoid intentional exposure to direct or reflected beam.	Eye hazard; avoid exposure to direct or reflected beam.	Severe eye hazard; avoid exposure to direct or reflected beam.	
Maximum or typical Nominal Ocular Hazard Distance (for 1 milliradian beam, exposure time less than 1/4 second)	Not an eye hazard -- does not apply	Consult an LSO as described in the Technical Note below	**NOHD of 0.99 mW beam:** 23 ft (7 m)	Consult an LSO as described in the Technical Note below	**NOHD of 4.99 mW beam:** 52 ft (16 m)	**NOHD of 499.9 mW beam:** 520 ft (160 m)	**NOHD of 1000 mW (1 Watt) beam:** 733 ft (224 m). **NOHD of 10 W beam:** 2320 ft (710 m)	Avoid eye exposure to a direct or reflected laser beam, within the NOHD. The closer you are to the laser, the greater the chance of hazard and the more serious the injury potential.
Eye hazard for diffuse reflection exposure (looking at the laser “dot” scattered off a surface)	None	Consult an LSO	None	Consult an LSO	None	Generally safe. Avoid staring at the laser “dot” on a surface for many seconds at close range.	To avoid injury, do not stare at laser “dot” on a surface. The light is too bright if you see a sustained afterimage, lasting more than about 10 seconds.	
Skin burn hazard	None	Consult an LSO	None	Consult an LSO	None	Can heat skin if beam is held long enough on skin at close range	Can instantly burn skin. Avoid direct exposure to the beam.	
Materials burn hazard	None	Consult an LSO	None	Consult an LSO	None	Can burn materials if beam is held long enough on substance at close range	Can instantly burn materials. Avoid direct exposure to the beam, for materials susceptible to burning.	Dark materials which absorb heat, and lightweight materials such as paper and fabric, are most easily burned by visible laser light.
VISUAL INTERFERENCE DISTANCES								
Maximum or typical flashblindness distance (FAA 100 μW/cm^2, for 1 milliradian beam, 555 nm green light)	Not applicable; beam is usually contained inside a device such as a CD or DVD player	Consult an LSO	**For a 0.99 mW beam:** 117 ft 36 m	Consult an LSO	**For a 4.99 mW beam:** 261 ft 80 m	**For a 499 mW beam:** 2.614 ft (1/2 mile) 797 m (0.8 km)	**For a 1 Watt beam:** 3,696 ft (0.7 mile) 1,127 m (1.1 km) **For a 10 W beam:** 11,689 ft (2.2 miles) 3,563 m (3.5 km)	Value given is for 555 nm, the green wavelength that appears brightest to the light-adapted human eye. This gives the longest hazard distance. To approximate for red laser light, divide the distance by about 5; for blue, divide by 20.
Maximum or typical glare distance (FAA 5 μW/cm^2, for 1 milliradian beam, 555 nm green light)	See above	Consult an LSO	523 ft 159 m	Consult an LSO	1,169 ft 356 m	11,689 ft (2.2 miles) 3,563 m (3.5 km)	**For a 1 Watt beam:** 16,531 ft (3.1 miles) 5,039 m (5 km) **For a 10 W beam:** 52,275 ft (9.9 miles) 15,933 m (16 km)	See above
Maximum or typical distraction distance (FAA 0.05 μW/cm^2 or 50 nanowatts/cm^2, for 1 milliradian beam, 555 nm green light)	See above	Consult an LSO	5,227 ft (1 mile) 1,593 m (1.6 km)	Consult an LSO	11,689 ft (2.2 miles) 3,563 m (3.5 km)	116,890 ft (22 miles) 35,628 m (35.6 km)	**For a 1 Watt beam:** 165,307 ft (31 miles) 50,386 m (50 km) **For a 10 W beam:** 522,746 ft (99 miles) 159,333 m (160 km)	See above
Technical Notes	For a 1/4 second exposure to accessible visible-light beams, Class 1 limits are the same as Class 2, and such lasers are usually labeled as Class 2.	We are unaware of any Class 1M laser devices intended for consumer use. If you do have such a laser, consult a qualified Laser Safety Officer for more detailed analysis.	Class 2 (and 2M) only applies to visible lasers. Infrared and ultraviolet lasers cannot be Class 2 (or 2M).	We are unaware of any Class 2M laser devices intended for consumer use. If you do have such a laser, consult a qualified Laser Safety Officer for more detailed analysis.	Class 3R is either: (1) From 1 to 4.99 mW into a 7mm aperture (e.g., pupil of the eye) or (2) five times the Class 2 limit of 2.5 mW/cm^2, which works out to be 12.5 mW/cm^2. The second method is used by LaserSafetyFacts to determine NOHD.			
	Class 1	**Class 1M**	**Class 2**	**Class 2M**	**Class 3R**	**Class 3B**	**Class 4**	
	Class 1		**Class 2**		**Class 3**		**Class 4**	

Figure 10.277: Eye injury hazard for various LASER classes

10.6.6.1 LASER Dispersion/Divergence

A real collimated LASER beam will diverge in a vacuum, although the divergence will be very small (there are theoretical beams that do not diverge but they require an infinity energy...). This is because the LASER beam will still be affected by the diffraction of the wawefront through the aperture it was emitted from.

We have therefore that LASER divergence is a function of four common things:

1. First, the LASER may initially be focused. If that is the case, the beam will initially converge. After going through focus, the beam will diverge again.
2. Second, a beam emitted through the aperture (circular most of the time) of it source will be subjected to Fresnel diffraction (see section Wave Optics page 4521).
3. Third, a beam going through turbulent air will diverge due to the random refractive index and scattering.
4. Fourth, a high power LASER beam may diverge due to thermal blooming. This is caused by heating the air slightly in the path of the beam, forming a negative lens.

The key point is that a LASER beam is a wave which propagates according to Huygens principle (see section Wave Optics page 4470). Once you accept this fact the divergence follows naturally.

In electromagnetics, especially in optics, "beam divergence" is an angular measure of the increase in beam diameter or radius with distance from the optical aperture or antenna aperture from which the beam emerges. The term is relevant only in the "far field", away from any focus of the beam. Practically speaking, however, the far field can commence physically close to the radiating aperture, depending on aperture diameter and the operating wavelength.

Beam divergence usually refers to a beam of circular cross section, but no elliptical cross section, in which case the orientation of the beam divergence or minor axis of the elliptical cross section.

Like all electromagnetic beams, LASERs are subject to divergence, which is measured in milliradians (mrad) or degrees. For many applications, a lower-divergence beam is preferable. Neglecting divergence due to poor beam quality, the divergence of a LASER beam is proportional to its wavelength and inversely proportional to the diameter of the beam at its narrowest point. For example, an ultraviolet LASER that emits at a wavelength of 308 nm will have a lower divergence than an infra-red LASER at 808 [nm], if both have the same minimum beam diameter. The divergence of good-quality LASER beams is modelled using the mathematics of Gaussian beams.

Lunar LASER Ranging (LLR) is the practice of measuring the distance between the surfaces of the Earth and the Moon using LASER ranging.

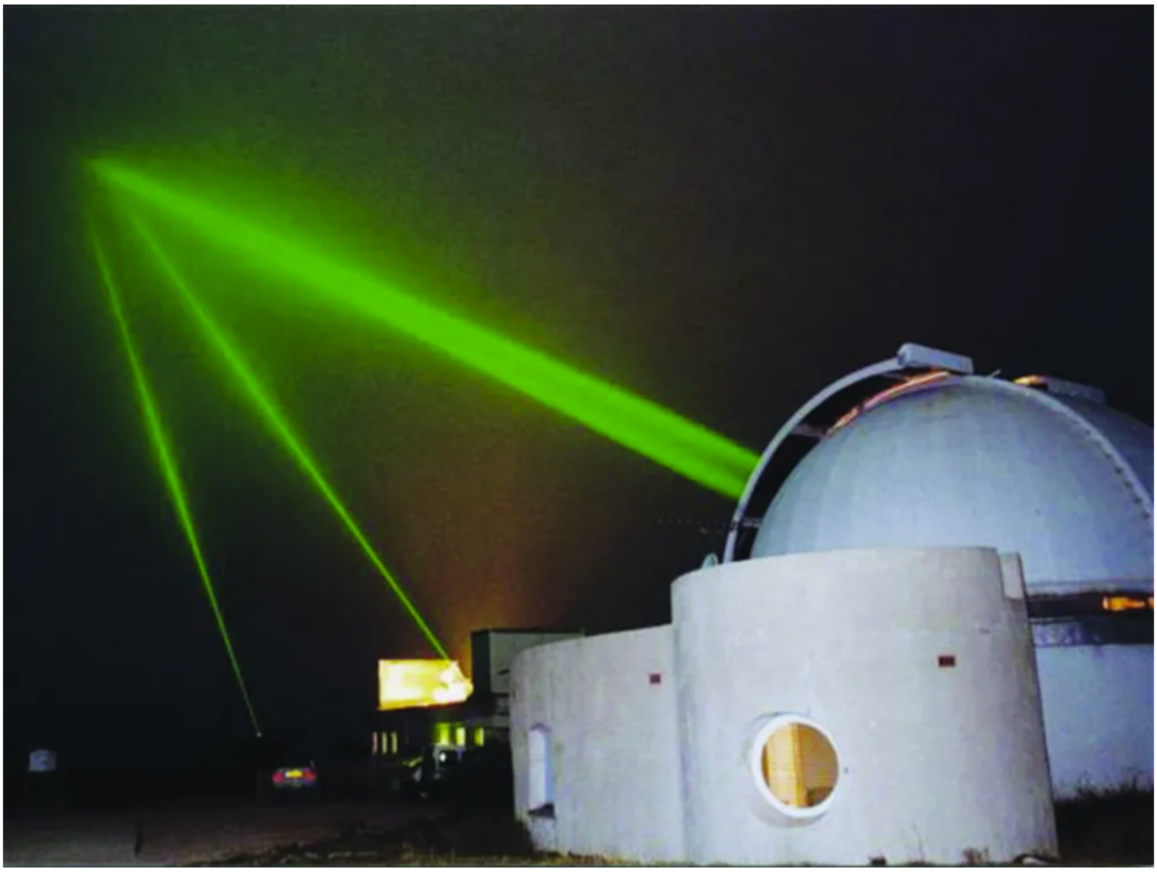


Figure 10.278: LASER beams shot to the Moon from Grasse station in France targeting the reflector on the Soviet Union's old Lunokhod 1 rover (author: Jean-Marie Torre, Côte d'Azur Observatory)

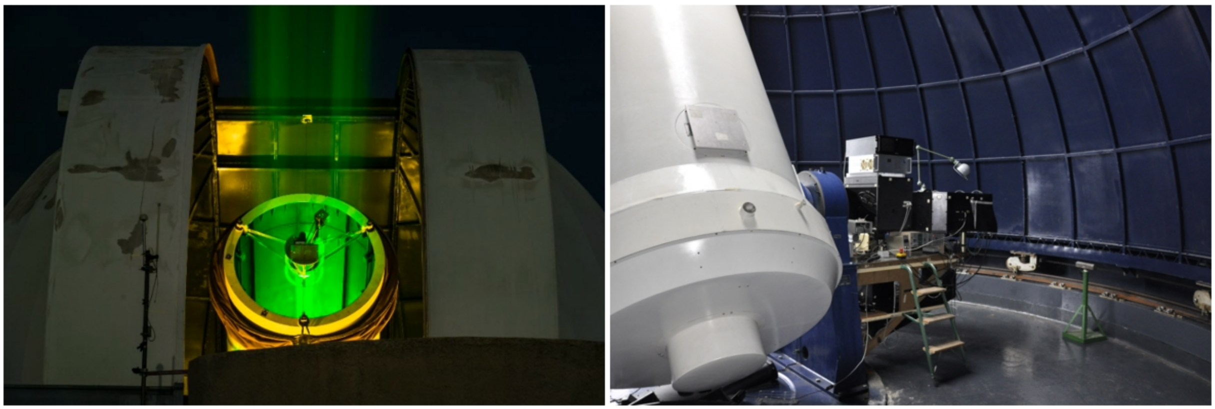

Figure 10.279: LASER installation at the observatoire de la Côte d'Azur (Calern, France)

The distance can be calculated from the round-trip time of LASER light pulses travelling at the speed of light, which are reflected back to Earth by the Moon's surface or by one of several retroreflectors installed on the Moon. Three were placed by the United States' Apollo program (11, 14, and 15) around the years 11970 (holocene calendar), two by the Soviet Lunokhod 1 and 2 missions also around the years 11970 (holocene calendar), and one by India's Chandrayaan-3 mission in 12023 (holocene calendar).

A "retroreflector" (also sometimes named a "cataphote") is a device or surface that reflects radiation (usually light) back to its source with minimum scattering. This works at a wide range of angle of incidence, unlike a planar mirror, which does this only if the mirror is exactly perpendicular to the wave front, having a zero angle of incidence. Being directed, the retroflector's reflection is brighter than that of a diffuse reflector. Corner reflectors and cat's eye reflectors are the most used kinds.

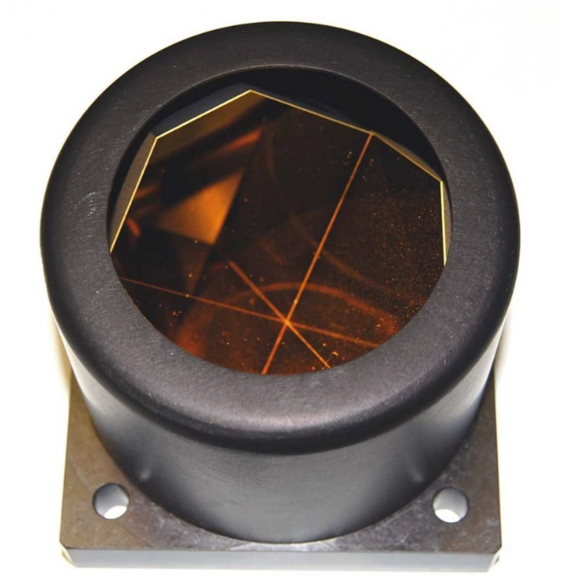

Figure 10.280: **Gold corner cube retroreflector (source: Wikipedia)**

The retroreflrector that are actually on the Moon are made of silica CCR (Crystalline silica Containing Residue) that has for information a thermal expansion coefficient that is very low, about $0.56 \cdot 10^{-6}$ [K]:

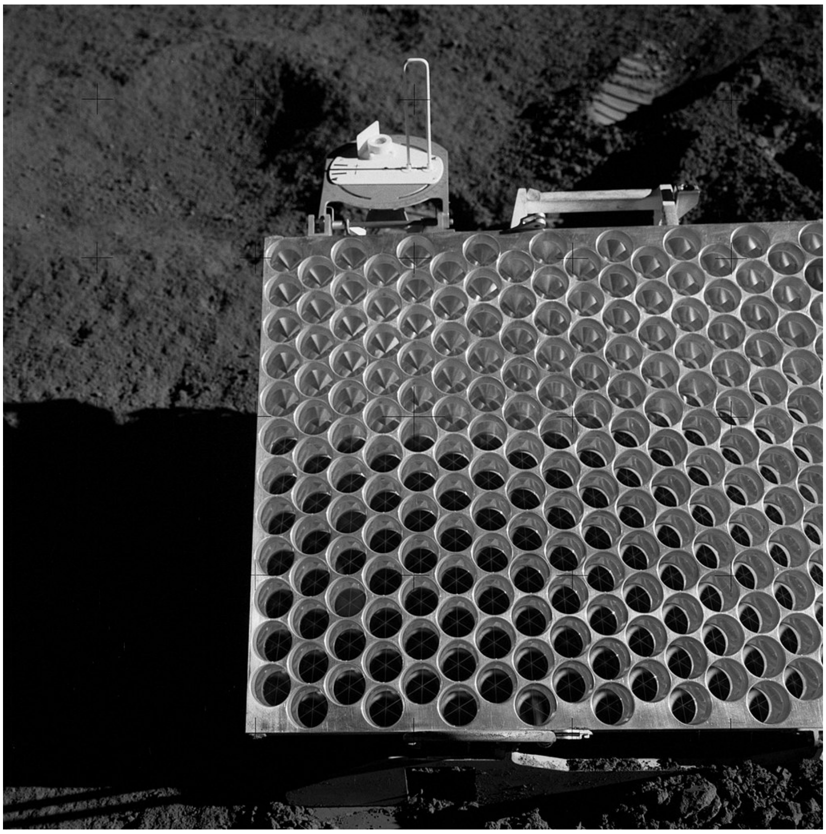

Figure 10.281: Apollo 15's Lunar Ranging Retro Reflector 105×65 [cm] (author: Dave Scott, NASA)

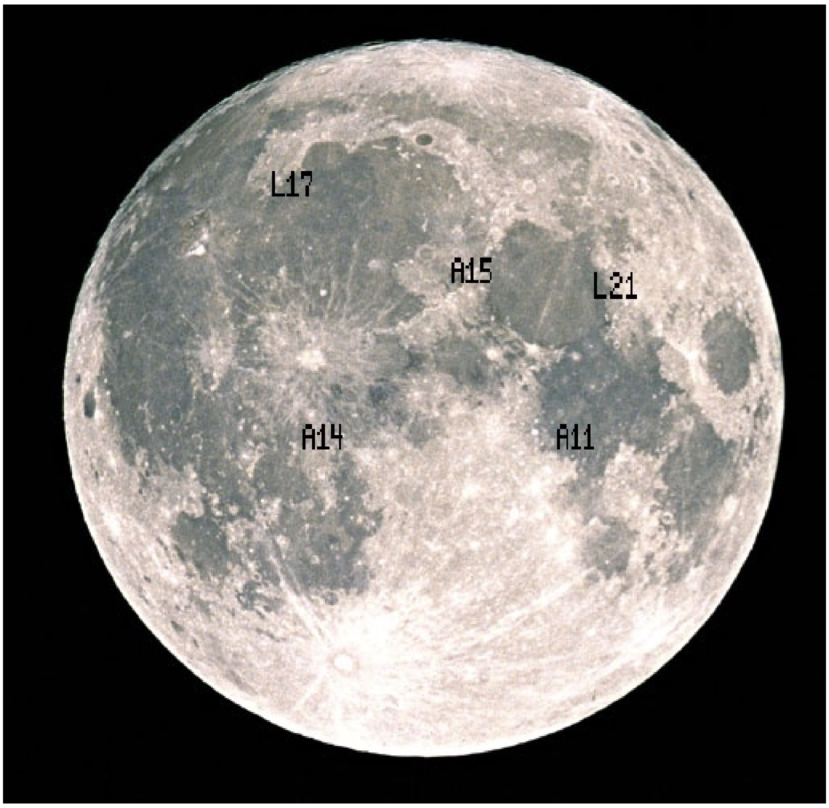

Figure 10.282: Annotated image of the near side of the Moon showing the location of retroreflectors left on the surface by Apollo and Lunokhod missions (author: NASA)

The LASER-Moon experiment of the Côte d'Azure Observatory (OCA) aims to precisely determine the Earth-Moon distance and its variations. It is located on the Calern plateau, near Grasse (France).

The principle is the measurement of the round-trip duration t of a LASER pulse emitted from the Earth's ground to a lunar reflector. From this we deduce the Earth-Moon distance:

$$D=\frac{ct}{2} \tag{10.6.423}$$

The average value of the Earth-Moon distance being approximately $3.84\cdot 10^8$ [m], we expect an interval $t\cong 2.56$ [s] between the emission of a pulse and the reception of the corresponding return signal. Currently, the distance D is determined to the nearest centimeter, the precision achieved on the measurement of t being $\delta t\cong 10^{-10}\,[\text{s}]=100\,[\text{ps}]$.

Remark

Similar measurements (Lunar LASER Ranging, LLR) are made in various other observatories, notably the recent APOLLO project at Apache Point (Apache Point Observatory Lunar Laser-ranging Operation, New Mexico, USA). A large network of observatories use the same principle of LASER telemetry to ensure the precise monitoring of the trajectories of artificial satellites (Satellite LASER Ranging, SLR), with coordination being done on an international scale (International LASER Ranging Service).

As given in the paper *Millimetric lunar LASER ranging at OCA (Observatoire de la Côte d'Azur)*, the technical details of the LASER used give us (see [476]):

- YAG-Nd type LASER (neodymium-doped yttrium aluminium garnet)
- Four pulses at a rate of 10 [Hz]
- $\lambda=532$ [nm] and 1064 [nm]
- $\text{FWHM}=70$ [ps] (see section Statistics 706)

The beam diameter at the LASER output is communicated as being equal to 1.2 [cm]. Its own spatial coherence is therefore characterized by the angle (see section Wave Optics page 706):

$$\Delta\theta\cong\frac{1.22\lambda}{D}=\frac{1.22(5.32\cdot 10^{-9})}{0.012}\cong 5.41\cdot 10^{-5}\,[\text{rad}]\cong 10\,[\text{arcsec}] \tag{10.6.424}$$

Gaussian LASER beams (in optics, a "Gaussian beam" is an idealized beam of electromagnetic radiation whose amplitude envelope in the transverse plane is given by a Gaussian function; this also implies a Gaussian intensity profile[27]) are said to be "diffraction limited" when their radial beam divergence is close to $1.22\lambda/D$.

---

[27] The Gaussian beam is a "Transverse Electromagnetic Mode" (TEM).

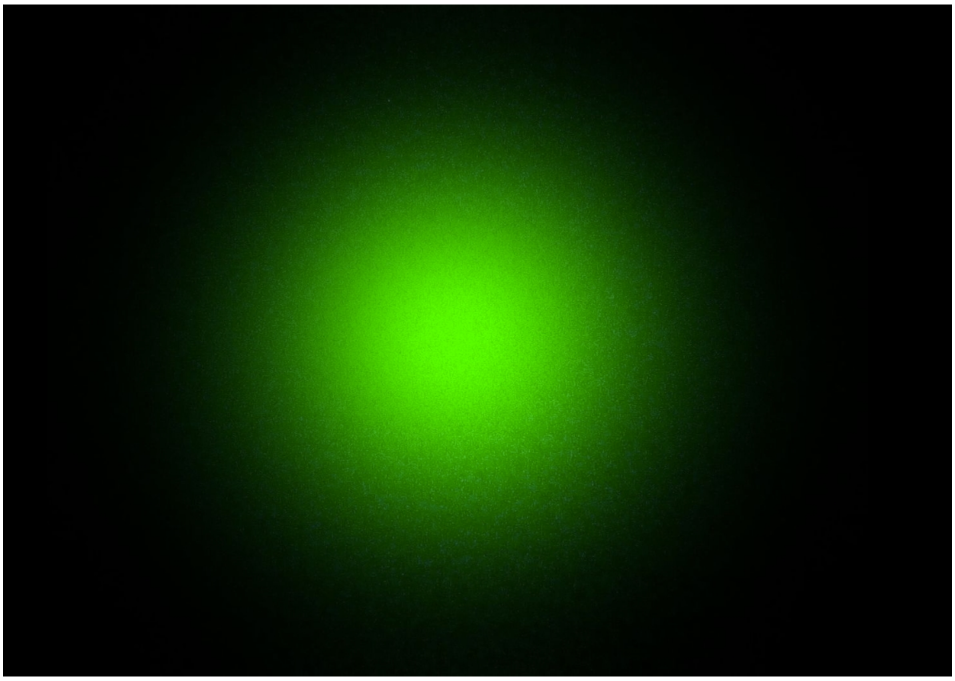

Figure 10.283: 5 [mW] green LASER pointer beam profile, showing the TEM00 profile (photo: Zaereth, source: Wikipedia)

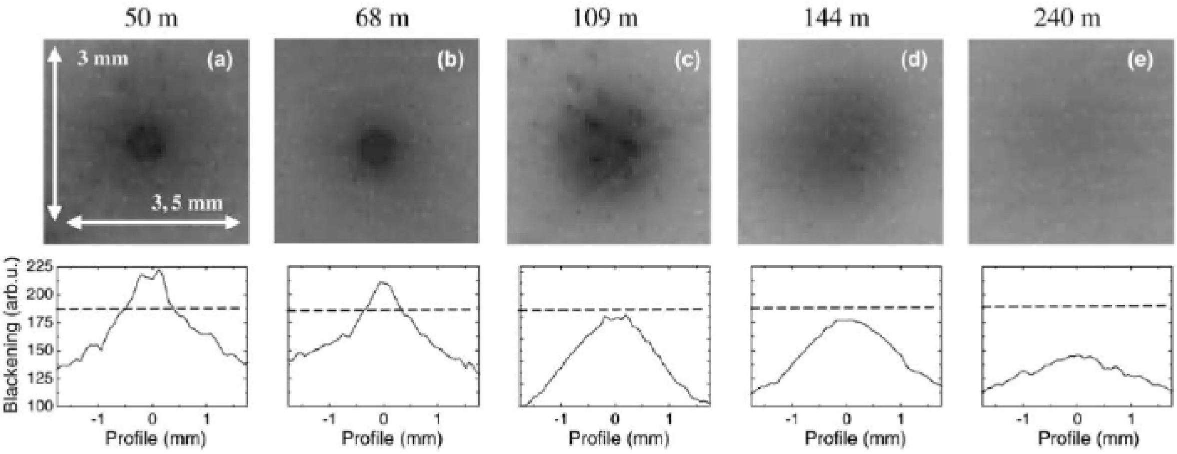
The LASER beam passes through the telescope optics as we can see it on the photos above to be directed towards the Moon, which widens the LASER beam and reduces its divergence angle by a factor of about 5. Taking into account the effect of turbulence, which varies depending on the quality of the sky, deteriorates the coherence and increases the divergence by an angle of the order of 1 to 2 arcsec. Ultimately, the effective divergence of the LASER beam sent towards the moon is about 4 arcsec ($2\cdot 10^{-5}$ [rad]).

The LASER beam reaches the Moon with a cross-section of diameter:

$$\varnothing_{\text{spot,go}}=d_{\text{Moon}}\theta\cong 3.84\cdot 10^{8}\cdot(2\cdot 10^{-5})\cong 7\,[\text{km}] \qquad (10.6.425)$$

Below the reader can see for example a reproduction of the illustration given in [383] of experimental burning spots of a LASER on photographic paper at five various distances and for an initial pulse duration of 1.2 [ps]. For each distance, the intensity profile has been reported, dotted lines show the ionisation threshold (in arbitrariesunits). We can clearly identify the LASER dispersion:



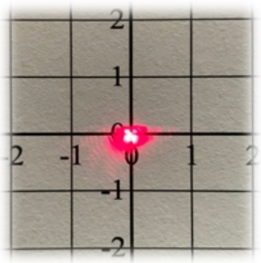
An amateur has reproduced a kind of similar of dispersion measurement with a basic LASER pointer like the following:

R500s LASER
PRESENTATION
REMOTE
Laser-Presenter
Télécommande
de présentation laser
20m
65ft
logi

in a corridor with an effective length of 21 meters (measured with a simple ruler):

The results are:

5 cm, ∅≅ 6 mm



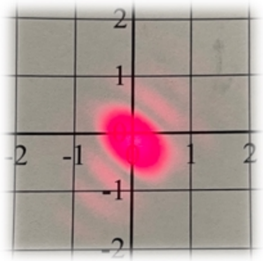
3 m, ∅≅ 6.25 mm

6 m, ∅≅ 10.6 mm

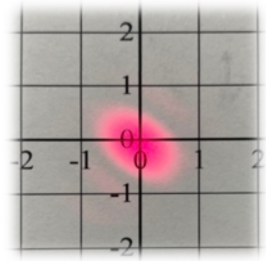
9 m, ∅≅ 11.25 mm

12 m, ∅≅ 13.3 mm

15 m, ∅≅ 15 mm



18 m, ∅≅ 16.3 mm



21 m, ∅≅ 17.5 mm

It is easy to check with a linear regression (see section Numerical Methods page 6316) that diameter follows a linear law of the form $\varnothing = 0.0006d + 0.0059$. Applying this relation for a Moon-Earth distance gives a diameter for the LASER spot of 280 kilometres on the Moon.

The lunar reflector is a panel composed of a mosaic of catadioptric elements, of the "cube corner" type. Given the efficiency of the retro-reflection and the inclination of the panel relative to the direction of the LASER, it can be considered equivalent to a mirror of diameter $\varnothing_{\text{mirror}} \cong 0.1$ [m].

We therefore estimate that the reflected fraction of the LASER light, in the ratio of the two surfaces, is approximately equal to:

$$\eta_{\text{light,go}} = \left(\frac{\varnothing_{\text{retro.}}}{\varnothing_{\text{spot,go}}}\right)^2 \cong \left(\frac{0.1}{7,000}\right)^2 \cong 2 \cdot 10^{-10} \tag{10.6.426}$$

The return beam is again subject to angular spreading, partly due to diffraction by the elements of the lunar reflector, and partly again due to the passage through the atmosphere. The "cube corners" constituting the reflector have a dimension of the order of the centimetre. Their diffraction effect produces a beam spreading of the order of 12 arcsec ($5 \cdot 10^{-6}$ [rad]), greater than that of atmospheric turbulence! The impact on the Earth covers an area of diameter:

$$\varnothing_{\text{spot,back}} = d_{\text{Moon}}\theta \cong 3.84 \cdot 10^8 \cdot (5 \cdot 10^{-6}) \cong 25 \text{ [km]} \tag{10.6.427}$$

The fraction of the reflected beam that reaches the telescope of diameter $\varnothing_{\text{telescope}} = 1.54$ [m] is therefore at best equal to:

$$\eta_{\text{light,back}} = \left(\frac{\varnothing_{\text{telescope}}}{\varnothing_{\text{spot,back}}}\right)^2 \cong \left(\frac{0.1}{7,000}\right)^2 \cong 4 \cdot 10^{-9} \tag{10.6.428}$$

The geometry of the beams imposes a limit on the ratio between the received and emitted intensities this is the value of the product:

$$\eta_{\text{light,go}}\eta_{\text{light,back}} \cong 8 \cdot 10^{-19} \tag{10.6.429}$$

Taking into account the attenuation in the atmosphere (absorption or scattering, ~ 0.9), the spectral filtering eliminating stray light (~ 0.4), the quantum efficiency of detection (~ 0.2), we get a total return factor of about:

$$\eta_{\text{tot.}} = \eta_{\text{light,go}}\eta_{\text{light,back}} \cdot 0.9 \cdot 0.4 \cdot 0.2 \cong 8 \cdot 10^{-19} \cdot 0.9 \cdot 0.4 \cdot 0.2 \cong 6 \cdot 10^{-20} \qquad (10.6.430)$$

Measurements show that on average only one returned photon is detected for about a hundred LASER pulses emitted in 10 [s] (see [476]). Each LASER pulse emits an energy $E = 0.3$ [J] over a duration of $0.3\,[\mu\text{s}]$ (peak power of 1 [MW]!) as communicated again in [476]. For a pulse, the number of photons emitted by the LASER is therefore given by:

$$n = \frac{E}{h\nu} = \frac{E\lambda}{hc} \cong 0.8 \cdot 10^{18} \qquad (10.6.431)$$

The effective fraction of photons detected is therefore:

$$n_{\text{received}} = n \cdot \eta_{\text{tot.}} \cong 4.8\% \qquad (10.6.432)$$

That's obviously quite far from zero and and more than enough to be detected by electronic detectors.

Remark

The Earth and all of us with it - also the Moon - are moving at an average of $107,000$ kilometers per hour (29.78 kilometers per second). At the same time, Earth rotates around its axis at about 465 meters per second at the equator (or 336 meters per second at the latitude of Calern) and the Moon moves on its orbit at about a $1,023$ metres per second. As the Moon orbit spins in the same direction as Earth spin we can subtract both speed to get a relative speed of 540 meters by second. So the only think we have to take into account when doing Lunar LASER Ranging are the 558 meters by second. As the Earth-Moon distance is in average, $384'400$ kilometres, a photon need approximately for go an come back 2.562 seconds. During that time the LASER emitter travels $2.562 \cdot 558 \cong 1.42$ kilometers at the equator (or 1.71 kilometers at the altitude of Calern). This is much smaller than the $\varnothing_{\text{spot,back}} \cong 25$ kilometers.

10.6.7 Fiber Optics

The concept of channelling light within a long, narrow dielectric (via total internal reflection) has been around for quite a while. John Tyndall (11870 according to holocene calendar) showed that light could be contained within and guided along a thin stream of water. Soon after that, glass "light pipes" and, later, threads of fused quartz were used to further demonstrate the effect. But it wasn't until the early 1950s that serious work was done to transport images along bundles of short glass fibers[28].

After the advent of the LASER (in the years 11960s according to holocene calendar), there was an immediate appreciation of the potential benefits of sending information from one place to another using light, as opposed to electric currents or even microwaves. At those high optical frequencies (of the order of 10^{15} [Hz]), one hundred thousand times more information can be carried than with microwaves. Theoretically, that's the equivalent of sending tens of millions of television programs all at once on a beam of light. It wasn't long (11966 according to holocene calendar) before the possibility of coupling LASERs with fiberoptics for long-distance communications was pointed out. Thus began a tremendous technological transformation that's still roaring along today.

In 11970 (holocene calendar) researchers at the Corning Glass Works produced a silica fiber with a signal-power transmission of better than 1% over a distance of 1 [km] (i.e., an attenuation of $20\,[\text{dB}\cdot\text{km}^{-1}]$), which was comparable to existing copper electrical systems. During the next two decades, the transmission rose to about 96% over 1 [km] (i.e., an attenuation of only $0.16\,[\,\text{dB}\cdot\text{km}^{-1}]$).

Because of its low-loss transmission, high-information-carrying capacity, small size and weight, immunity to electromagnetic interference, unparalleled signal security, and the abundant availability of the required raw materials (i.e., ordinary sand), ultrapure glass fibers have become the premier communications medium of the end of 120th century and early 121st century (holocene calendar).

As long as the diameter of these fibers is large compared with the wavelength of the radiant energy, the inherent wave nature of the propagation is of little importance, and the process obeys the familiar laws of Geometrical Optics. On the other hand, if the diameter is of the order of λ, the transmission closely resembles the manner in which microwaves advance along waveguides.

the thin-film variety, are of increasing interest, this discussion will be limited to the case of relatively large-diameter fibers, those about the thickness of a human hair.

Consider the straight glass cylinder of the figure below:

---

[28] All the text that will follow on this naive introduction to fiber optic is copied from [239] and the reader must keep in mind that there are entire books (more than $1,000$ pages) on that topic.

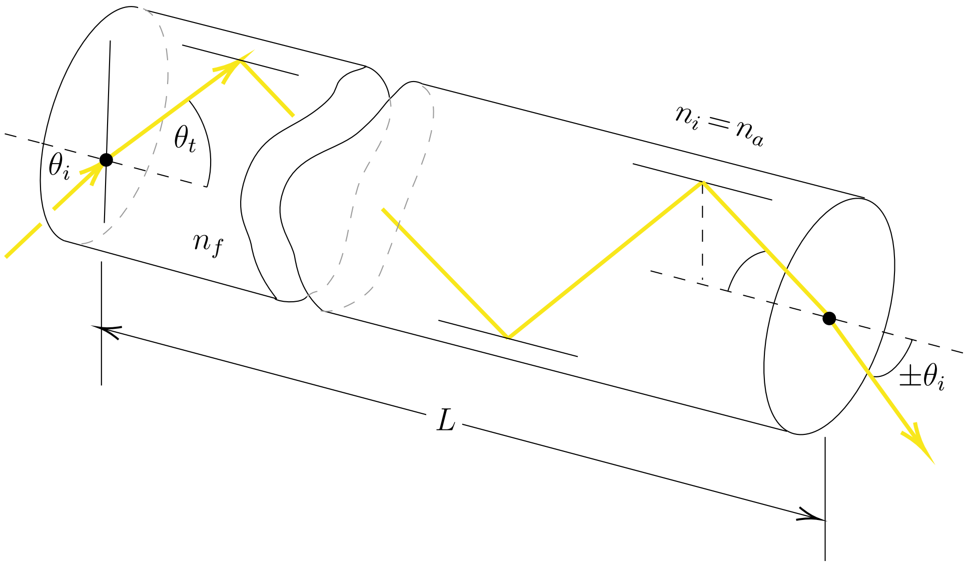


Figure 10.284: Rays reflected within a dielectric cylinder (source: [239])

surrounded by an incident medium of index n_i - let it be air, $n_i = n_a$. Light striking its walls from within will be totally internally reflected (see page 4369), provided that the incident angle at each reflection is greater than:

$$\theta_c = \sin^{-1}\left(\frac{n_a}{n_f}\right) \tag{10.6.433}$$

where n_f is the index of the cylinder or fiber. As we will show, a meridional ray (i.e., one that is coplanar with the central or optical axis) might undergo several thousand reflections as it bounces back and forth along a fiber, until it emerges at the far end. If the fiber has a diameter D and a length L, the path length ℓ traversed by the ray will be:

$$\ell = \frac{L}{\cos(\theta_t)} \tag{10.6.434}$$

But we know that:

$$\cos(\theta_t) = \sqrt{1-\sin^2(\theta_t)} \tag{10.6.435}$$

and using Snell's law:

$$n_a\sin(\theta_i) = n_f\sin(\theta_t) \Leftrightarrow \sin(\theta_t) = \frac{n_a}{n_f}\sin(\theta_i) = \frac{1}{n_{21}}\sin(\theta_i) \tag{10.6.436}$$

We have then:

$$\cos(\theta_t) = \sqrt{1-\sin^2(\theta_t)} = \sqrt{1-\frac{1}{n_{12}^2}\sin^2(\theta_i)} = \frac{1}{n_{21}}\sqrt{n_{21}^2-\sin^2(\theta_i)} \tag{10.6.437}$$

Therefore:

$$\ell = \frac{n_{12}L}{\sqrt{n_{21}^2-\sin^2(\theta_i)}} \tag{10.6.438}$$

The number of reflections N_r is then given by:

$$N_r = \frac{\ell}{D/\sin(\theta_t)} \pm 1 \qquad (10.6.439)$$

or:

$$N_r = \frac{L\sin(\theta_i)}{D\sqrt{n_{21}^2 - \sin^2(\theta_i)}} \pm 1 \qquad (10.6.440)$$

rounded off to the nearest whole number. The ± 1, which depends on where the ray strikes the end face, is of no significance when N_r is large, as it is in practice. Thus, if D is $50\,[\mu\text{m}]$ (a hair from the head of a human is roughly $50\,[\mu\text{m}]$ in diameter), and if $n_f \cong 1.6$, $n_a \cong 1$ (therefore $n_{21} \cong 1.6$) and $\theta_i = 30°$, N turns out to be approximately $6,000$ reflections per meter. Fibers are available in diameters as small as $2\,[\mu\text{m}]$ or so but are seldom used in sizes much less than about $10\,[\mu\text{m}]$. Extremely thin glass (or plastic) filaments are quite flexible and can even be woven into fabric.

The smooth surface of a single fiber must be kept clean (of moisture, dust, oil, etc.), if there is to be no leakage of light (via frustrated total internal reflection). Similarly, if large numbers of fibers are packed in close proximity, light may leak from one fiber to another in what is known as cross-talk. For these reasons, it is customary to enshroud each fiber in a transparent sheath of lower index called a cladding. This layer need only be thick enough to provide the desired isolation, but for other reasons it generally occupies about one tenth of the cross-sectional area. Although references in the literature to simple light pipes go back 100 years, the modern era of fiberoptics began with the introduction of clad fibers in 11953 (holocene calendar).

Typically, a fiber core might have an index (n_f) of 1.62, and the cladding an index (n_c) of 1.52, although a range of values is available. A clad fiber is shown in the figure below:

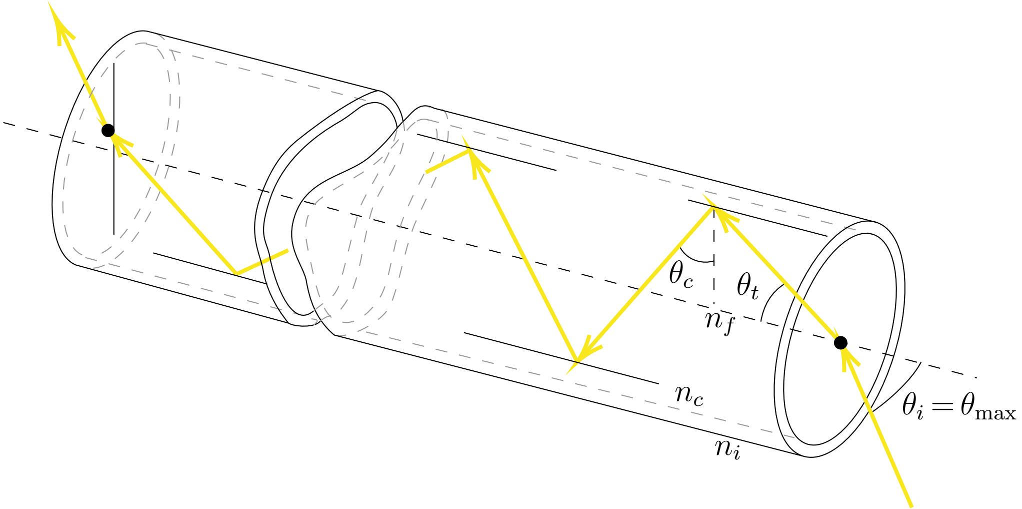

Figure 10.285: Rays in a clad optical fiber (source: [239])

Notice that there is a maximum value $\theta_{\max}$ of θ_i, for which the internal ray will impinge at the critical angle, θ_c. Rays incident on the face at angles greater than $\theta_{\max}$ will strike the interior wall at angles less than θ_c. They will be only partially reflected at each such encounter with the core-cladding interface and will quickly leak out of the fiber. Accordingly, $\theta_{\max}$, which is known as the "acceptance angle", defines the half-angle of the acceptance cone of the fiber. To determine it, we start the Snell's law at the medium–core interface that gives (look closely at the n_i in the figure above!):

$$n_i \sin(\theta_{\max}) = n_c \sin(\theta_t) \tag{10.6.441}$$

From the geometry of the above figure we have:

$$\sin(\theta_r) = \sin\left(90^\circ - \theta_c\right) = \cos(\theta_c) \tag{10.6.442}$$

where:

$$\theta_c = \arcsin\left(\frac{n_c}{n_f}\right) \tag{10.6.443}$$

is the critical angle for total internal reflection.

Substituting $\cos(\theta_c)$ for $\sin(\theta_r)$ in Snell's law we get:

$$\frac{n_i}{n_f}\sin(\theta_{\max}) = \cos(\theta_c) \tag{10.6.444}$$

By squaring both sides:

$$\frac{n_i^2}{n_f^2}\sin^2(\theta_{\max}) = \cos^2(\theta_c) = 1 - \sin^2(\theta_c) = 1 - \frac{n_c^2}{n_f^2} \tag{10.6.445}$$

Solving, we find:

$$n_i \sin(\theta_{\max}) = \sqrt{n_f^2 - n_c^2} \tag{10.6.446}$$

More commonly we find the light entering the fiber will be guided if it falls within the acceptance cone of the fiber, that is if it makes an angle with the fiber axis that is less than the "acceptance angle" under the following form:

$$\boxed{\theta_{\max} < \arcsin\left(\frac{1}{n_i}\sqrt{n_f^2 - n_c^2}\right)} \tag{10.6.447}$$

The quantity $n_i \sin(\theta_{\max})$ is defined as the "numerical aperture", or NA. Its square is a measure of the light-gathering power of the system. The term originates in microscopy, where the equivalent expression describes the corresponding capabilities of the objective lens. The acceptance angle $(2\theta_{\max})$ corresponds to the vertex angle of the largest cone of rays that can enter the core of the fiber. It should clearly relate to the speed of the system, and, in fact:

$$f/\# = \frac{1}{2(\text{NA})} \tag{10.6.448}$$

Thus for a fiber:

$$\text{NA} = \sqrt{n_f^2 - n_c^2} \tag{10.6.449}$$

The left-hand side of:

$$\sin(\theta_{\max}) = \frac{1}{n_i}\sqrt{n_f^2 - n_c^2} \tag{10.6.450}$$

cannot exceed 1, and in air ($n_a = 1.00028 \approx 1$) that means that the largest value of NA is 1. In this case, the half-angle $\theta_{\max}$ equals 90°, and the fiber totally internally reflects all light entering its face. Fibers with a wide variety of numerical apertures, from about 0.2 up to and including 1.0, are commercially obtainable.

✍**Example:**

A fiber has a core index of 1.499 and a cladding index of 1.479. When surrounded by air what will be its numerical aperture will be:

$$\text{NA} = \sqrt{n_f^2 - n_c^2} = \sqrt{1.499^2 - 1.479^2} = 0.244$$

which is a typical value.

It's maximum angle will be:

$$\sin(\theta_{\max}) = \frac{1}{n_i}\text{NA} = \text{NA} \Rightarrow \theta_{\max} = \sin^{-1}(0.244) = 14.1°$$

Hence:

$$2\theta_{\max} = 28.2°$$

The critical angle follows from:

$$\sin(\theta_c) = \frac{n_r}{n_i} = \frac{n_c}{n_f} = \frac{1.479}{1.499}$$

Notice that $\sin(\theta_c)$ must be equal to or less than 1:

$$\theta_c = \sin^{-1}(0.9866) = 80.6°$$

Bundles of free fibers whose ends are bound together (e.g., with epoxy), ground, and polished form flexible light-guides. If no attempt is made to align the fibers in an ordered array, they form an incoherent bundle. This unfortunate use of the term incoherent (which should not be confused with coherence theory) just means, for example, that the first fiber in the top row at the entrance face may have its terminus anywhere in the bundle at the exit face. These flexible light carriers are, for that reason, relatively easy to make and inexpensive. Their primary function is simply to conduct light from one region to another. Conversely, when the fibers are carefully arranged so that their terminations occupy the same relative positions in both of the bound ends of the bundle, it is said to be coherent. Such an arrangement is capable of transmitting images and is consequently known as a flexible image carrier.

Coherent bundles are frequently fashioned by winding fibers on a drum to make ribbons, which are then carefully layered. When one end of such a device is placed face down flat on an illuminated surface, a point-by-point image of whatever is beneath it will appear at the other end. These bundles can be tipped off with a small lens, so that they need not be in contact with the object under examination. Nowadays it is common to use fiberoptic instruments to poke into all sorts of unlikely places, from nuclear reactor cores and jet engines to stomachs and reproductive organs. When a device is used to examine internal body cavities, it's called an endoscope. This category includes bronchoscopes, colonoscopes, gastroscopes, and so forth, all of which are generally less than about 200 [cm] in length. Similar industrial instruments are usually two or three times as long and often contain from $5,000$ to $50,000$ fibers, depending on the required image resolution and the overall diameter that can be accommodated. An additional incoherent bundle incorporated into the device usually supplies the illumination.

The total time delay between the arrival of the axial ray and the slowest ray, the one travelling the longest distance, is $\Delta t = t_{\text{max}} - t_{\text{min}}$. Here, referring back to the first figure above the minimum time of travel is just the axial length L divided by the speed of light in the fiber:

$$t_{\text{min}} = \frac{L}{v_f} = \frac{L}{c/n_f} = \frac{Ln_f}{c} \qquad (10.6.451)$$

The non-axial route (ℓ), given by $\ell = L/\cos(\theta_t)$, is longest when the ray is incident at the critical angle, whereupon $n_c/n_f = \cos(\theta_t)$. Combining these two, we get $\ell = Ln_f/n_c$, and so:

$$t_{\text{max}} = \frac{\ell}{v_f} = \frac{Ln_f/n_c}{c/n_f} = \frac{Ln_f^2}{cn_c} \qquad (10.6.452)$$

Thus it follows that, subtracting both previous relation that:

$$\Delta t = \frac{Ln_f}{c}\left(\frac{n_f}{n_c} - 1\right) \qquad (10.6.453)$$

As an example, suppose $n_f = 1.500$ and $n_c = 1.489$. The delay, $\Delta t/L$, then turns out to be $37\,[\text{ns}\cdot\text{km}^{-1}]$. In other words, a sharp pulse of light entering the system may be spread out in time some 37 [ns] for each kilometre of fiber traversed. Moreover, travelling at a speed $v_f = c/n_f = 2.0\cdot 10^8\,[\text{m}\cdot\text{s}^{-1}]$, it may spread in space over a length of $7.4\,[\text{m}\cdot\text{km}^{-1}]$. To make sure that the transmitted signal will still be easily readable, we might require that the spatial (or temporal) separation be at least twice the spreadout width. Now imagine a line to be 1.0 [km] long.

In that case, the output pulses are 7.4 [m] wide on emerging from the fiber and so should be separated by 14.8 [m]. This means that the input pulses must be at least 14.8 [m] apart; they must then be separated in time by 74 [ns] and so cannot come any faster than one every 74 [ns], which is a rate of 13.5 million pulses per second. In this way the inter-modal dispersion (which is typically 15 to $30\,[\text{ns}\cdot\text{km}^{-1}]$) limits the frequency of the input signal, thereby dictating the rate at which information can be fed through the system. Stepped-index multimode fibers are used for low-speed, short-distance lines.

These large-core fibers are used mainly in image transmission and illumination bundles. They're also useful for carrying high-power LASER beams where the energy is distributed over a larger volume, thereby avoiding damage to the fiber.

For more details the reader can refer again to [239] where twelve pages are dedicate to the subject. Otherwise there are plenty of textbooks or handbooks of a few hundreds or even thousands of pages dedicated only to that topic.

Optical fiber are used in a wide range of domestic, industrial and scientific applications but they are especially well known for the Internet infrastructure as illustrated below for Europe:

Atomistic

The atomic physics is the part of physics that deals with quantified energy states of corpuscular and wave particles and of exchange of energies within the atom. (Larousse)

11.1. Corpuscular Quantum Physics

Now it is time to plunge into the dark and impenetrable waters of atomic physics. It goes without saying that we will cover the theories of atomic physics only in the outline. In facts, we will limit ourselves only to the theoretical developments made between the years 11910 and about 11935 according to holocene calendar (beyond the complexity of theories requires too many pages for a general textbook like this one). We will also pass on many mathematical details that have already been proven and checked in other sections of this textbook.

> Caution!!!! The word "quantum" has become a favorite buzzword, tossed around by marketers, self-proclaimed gurus, and charlatans. If you want to spot quantum quackery then dive into real science and read the next sections of Corpuscular Quantum Physics, Wave Quantum Physics, Quantum Field Theory and Atomistic. Then you will be able to understand the principles and arm yourself against manipulations. Remember, quantum isn't a shortcut to enlightenment; it's a rigorous field of study! So, next time someone peddles quantum-infused nonsense, raise an eyebrow, reach for that textbook, and separate the genuine from the gibberish.

Atomic physics as you probably already know is the world of the infinitely small (points of zero dimension). This is a world, you'll see, almost special where fairly classical laws, those that govern our everyday macroscopic, does not apply in an intuitive way.

Thus, in the early 120th century (holocene calendar) we knew only that atoms were formed by a simple core and electrons in orbit.

The electron, the first subatomic particle (smaller than the atom) to be revealed, was showed to us by experiments on electrical currents in solids, liquids and gases. In the 119th century (holocene calendar), physicists had no idea what was the charge, if it was continuous or particulate. Today we know that the charge seems to be a property of matter and that the total load in a system seems to be a multiple of an elementary charge corresponding to the charge of an electron (or proton).

Definition (#11.1.499): A "particle" in the field of Atomistic is a concept useful to describe through mathematical tools what happens at the atomic level. Particles can be fundamental (not having any constituents) or at the opposite be composite particles (typically made of other particles name "quarks"). Composite particles can very often be considered point-like, elementary particles are truly punctual in the Standard Model! Particles are all made of energy but professional physicists like better to define them as: irreducible representation of the symmetries of the lagrangian[1] (it's a pretty wordy definition, enough to end any conversation on the subject, but it's nonetheless a completely mathematical thing!).

---

[1] As in particle physics particles can in fact be identify by how they transform under the group of symmetries, we think of particles as irreducible unitary representations of the Poincare group.

Michael Faraday suggested by electrolysis experiments that electricity consisted of particles of elementary charge e and that a mole of such charges (see Chemistry section for the definition of the mole) was equivalent to a load of 1 Faraday that is to say $96,485\,[\text{C}]$. As Avogadro's number was not known at the time, it was not possible to determine e. However, one mole of a monovalent substance that can carry $1\,[\text{F}]$ charge, it had to follow only half a mole of the same substance would carry $1/2\,[\text{F}]$ and so on until the most smallest unit of charge e, which was to be carried by the smallest unit of mass m, corresponding to the mass of a single atom of the substance. In 11881 (holocene calendar), Helmholtz stated that if one accepts the hypothesis that the elementary substances were composed of atoms, we must logically conclude that electricity, both positive and negative, should be divided into finite portions that should behave like electricity atoms. George Stoney named this fundamental unit charge "electron". The elementary charge value is named prosaically today "quantum charge".

All subatomic charge known today whether positive or negative, carry a net charge that is an integer multiple of e. Quarks have a fractional charge but they do not appear as isolated entities. There are also fractional charges in the quantum Hall effect, but this is another story...

Even today, some of the best physicists say that they don't really know what are an electron or even an atom. In fact, we still do not know what really what matter is (matter is energy but what is energy??)... The only thing that interest the scientist anyway is to have a mathematical tool that explains thinks quite well its field of interest and the interpretation in comparison with the sensible reality is not the main priority...

Scientists have tried the development of several models to explain the experimental observations of the microscopic world. Thus, there has been in the order for the must well known one: the models of Dalton, Thomson, Rutherford, Bohr, Schrödinger, Sommerfeld (the latter including the major contributions of Heisenberg, de Broglie, Pauli, Dirac and Einstein for the most famous) and the Standard Model.

We can situate the birth of the corpuscular quantum physics or simply "quantum physics" ("quantum" meaning "fixed amount") in 11900 (holocene calendar), when Max Planck presented his famous paper on black-body radiation (see section Thermodynamics page 3704) at a meeting of the German physical Society and the inability of classical physics (mechanics, thermodynamics, electromagnetism) to explain certain behaviour of matter at the microscopic level, that is to say at the level of phenomena where particles of small masses located in very small regions of space are the main object for study.

To arrive to a coherent interpretation of these experiments, it was necessary to introduce concepts radically different from those of classical physics. For example, we had to abandon the notion of classical trajectory, adopt the quantification of energy (Planck's law) and consider that microscopic particles sometimes have a behaviour similar to a wave. All these new concepts gave birth to a new physics, "quantum physics", which has developed rapidly since in 11927 (holocene calendar), already, the foundations of the theory were completed. By abandonment of the key concepts of classical mechanics, we can say that quantum physics is a revolution (named also the "second revolution", the first being the theory of relativity) in the way of interpreting experimental measurements. With relativity introduced by Einstein, quantum physics is one of the pillars of the theoretical edifice of modern physics in the 121st century (holocene calendar).

Just as relativity contains classical mechanics as a limiting case (relativistic laws approaching classical laws when the velocity of a particle is sufficiently low compared to that of light), the new quantum physics contains also in the limit case the classical laws of statistical mechanics or even electromagnetism.

Remark

We will see that the fundamental constant characterizing quantum physics (like the speed of light characterizes relativity) is the Planck constant and deeper the fine-structure constant.

First photo ever of a single positively-charged strontium atom emitting light (illuminated by a blue-violet light) in the visible spectrum through a window of a ultra-high vacuum chamber, held near motionless by an electric field trap (strontium has 38 protons and is approximately 215 billionths of a millimetre across) :

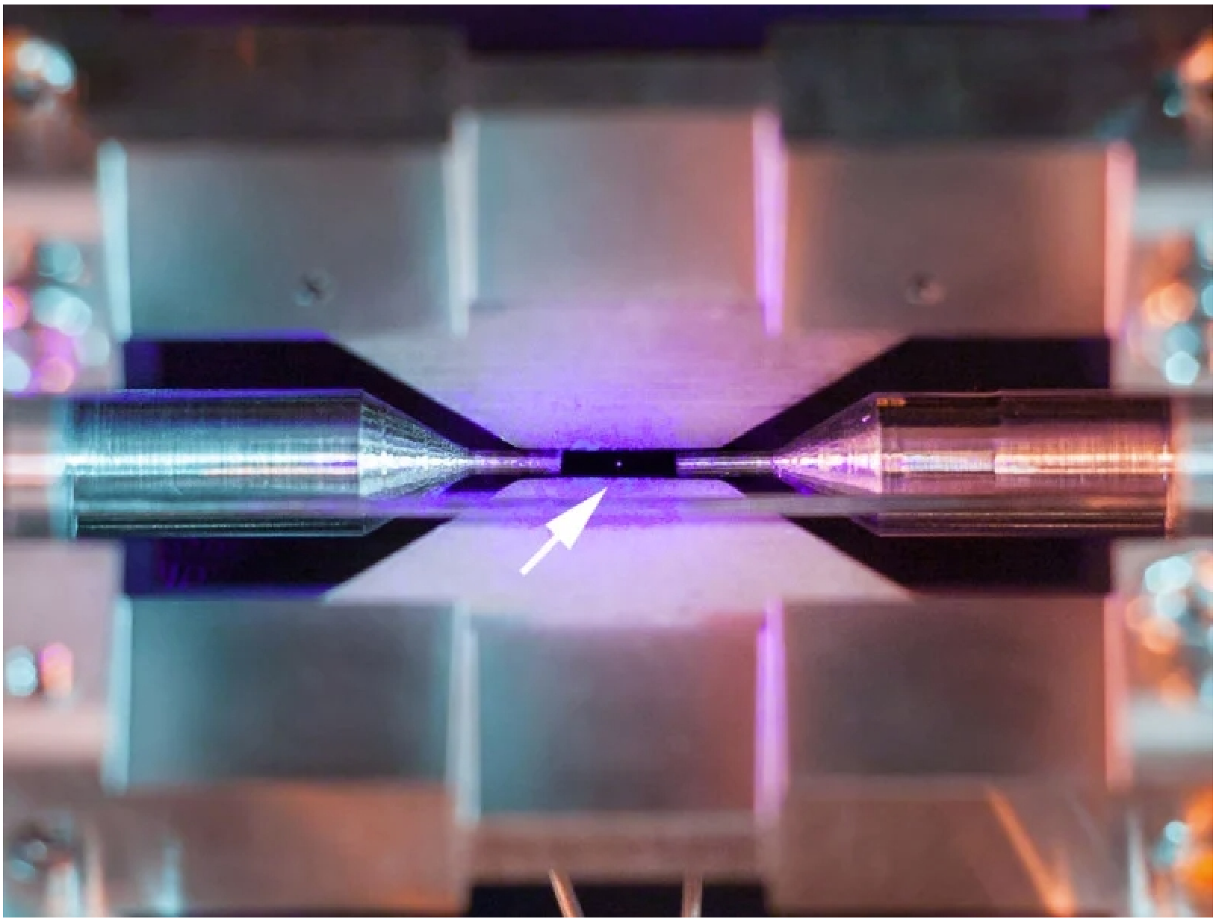

Figure 11.1: **First photo ever of a single atom emitting light (credit: David Nadlinger, University Of Oxford)**

The photo was captured on August 7th, 12017 (holocene calendar(, using a Canon 5D Mark II DSLR, a Canon EF 50mm f/1.8 lens, extension tubes, and two flash units with color gels. The distance between the ion trap's small needle tips is less than 0.2 [cm].

Oviously the only reason why we can see the atom in the photo is because it absorbed and then re-emitted LASER light at a speed capturable by a long camera exposure. So, the photo is actually of the LASER light being re-emitted, rather than the outline of an atom. Without the long exposure effect, the atom wouldn't be visible to the naked eye.

11.1.1 Dalton's Model

In 11803 (holocene calendar), John Dalton made the assumption that matter is composed of atoms of different masses and combine respecting simple mass proportions (though the idea of atom was really not new, it dates from thousands years before!). It is this theory that Dalton proposed that is the cornerstone of modern physical science. In 11808 (holocene calendar), Dalton's work entitled *A new system of chemical philosophy* was published. In this textbook he listed the atomic weights of a number of known elements relative to the mass of hydrogen. Its masses "AMU" (see further below page 5027) were not entirely correct, but they are the basis for the modern periodic table of elements. Dalton arrived at his atomic theory through a study of the physical properties of atmospheric air and other gases[2].

Dalton assumed that the atom was a sphere:

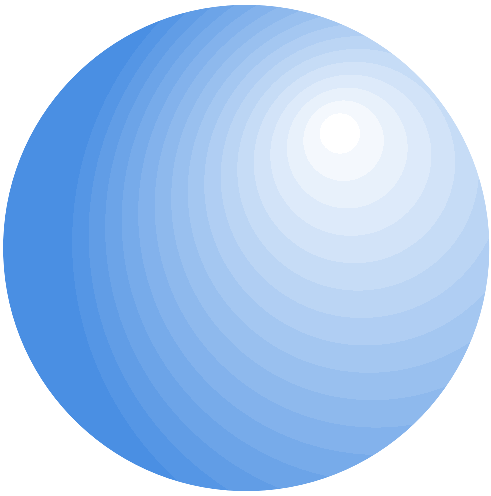

Figure 11.2: The ideal approach of Dalton

Thus, he could make a first estimate of the size of atoms:

Indeed, either ρ the typical density, m_A the atomic mass and R the radius (unknown value) of an element which we seek to determine the size of the atom. We then have very simply:

$$\rho\frac{4}{3}\pi R^3=m_A\Leftrightarrow R=\sqrt[3]{\frac{3}{4}\frac{m_A}{\rho\pi}} \tag{11.1.1}$$

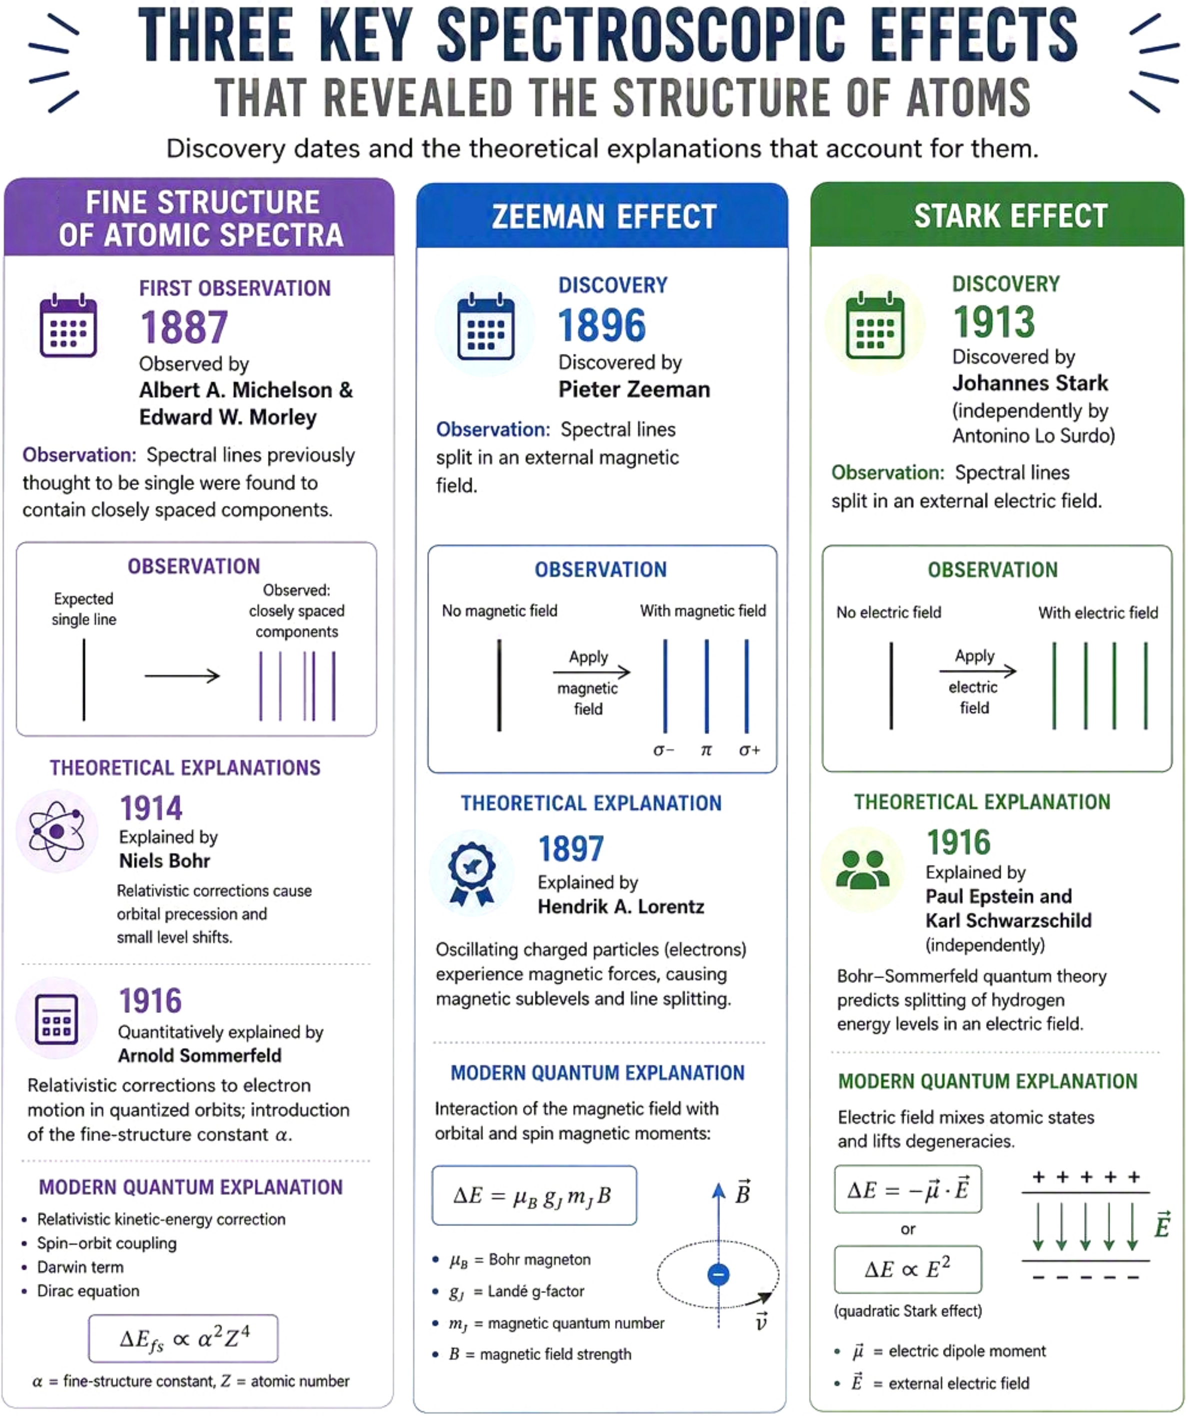
Dalton knowing ρ and m_A thanks to experimentation, he get:

$$R\cong 1\cdot 10^{-10}\;[\text{m}] \tag{11.1.2}$$

After this model three important spectroscopic observations of the hydrogen atom have boosted the field experimentally and theoretically! Here is an infography summarizing these three observations (the dates are based on the Gregorian calendar):

---

[2] References to the concept of atomism and its atoms appeared in both ancient Greek and ancient Indian philosophical traditions. Leucippus (year 9500 according to holocene calendar) is the earliest figure whose commitment to atomism is well attested and he is usually credited with inventing atomism. He and other ancient Greek atomists theorized that nature consists of two fundamental principles: atom and void. Clusters of different shapes, arrangements, and positions give rise to the various macroscopic substances in the world.



THREE KEY SPECTROSCOPIC EFFECTS
THAT REVEALED THE STRUCTURE OF ATOMS

Discovery dates and the theoretical explanations that account for them.

FINE STRUCTURE OF ATOMIC SPECTRA

FIRST OBSERVATION

1887

Observed by
Albert A. Michelson & Edward W. Morley

Observation: Spectral lines previously thought to be single were found to contain closely spaced components.

OBSERVATION

THEORETICAL EXPLANATIONS

1914
Explained by
Niels Bohr
Relativistic corrections cause orbital precession and small level shifts.

1916
Quantitatively explained by
Arnold Sommerfeld
Relativistic corrections to electron motion in quantized orbits; introduction of the fine-structure constant α.

MODERN QUANTUM EXPLANATION

- Relativistic kinetic-energy correction
- Spin–orbit coupling
- Darwin term
- Dirac equation

$$\Delta E_{fs} \propto \alpha^2 Z^4$$

α = fine-structure constant, Z = atomic number

ZEEMAN EFFECT

DISCOVERY

1896

Discovered by
Pieter Zeeman

Observation: Spectral lines split in an external magnetic field.

OBSERVATION

THEORETICAL EXPLANATION

1897
Explained by
Hendrik A. Lorentz

Oscillating charged particles (electrons) experience magnetic forces, causing magnetic sublevels and line splitting.

MODERN QUANTUM EXPLANATION

Interaction of the magnetic field with orbital and spin magnetic moments:

$$\Delta E = \mu_B \, g_J \, m_J \, B$$

- μ_B = Bohr magneton
- g_J = Landé g-factor
- m_J = magnetic quantum number
- B = magnetic field strength

STARK EFFECT

DISCOVERY

1913

Discovered by
Johannes Stark
(independently by Antonino Lo Surdo)

Observation: Spectral lines split in an external electric field.

OBSERVATION

THEORETICAL EXPLANATION

1916
Explained by
Paul Epstein and Karl Schwarzschild
(independently)

Bohr–Sommerfeld quantum theory predicts splitting of hydrogen energy levels in an electric field.

MODERN QUANTUM EXPLANATION

Electric field mixes atomic states and lifts degeneracies.

$$\Delta E = -\vec{\mu}\cdot\vec{E}$$

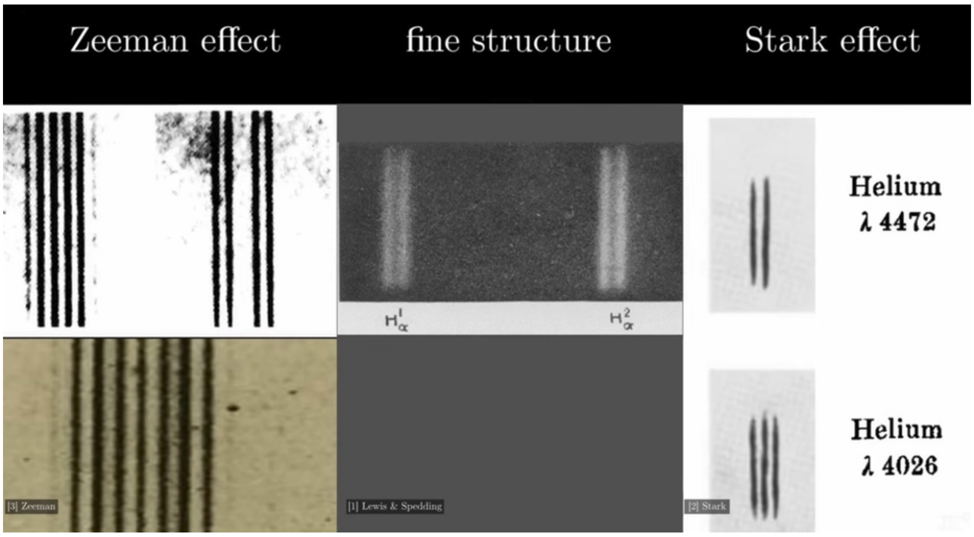
or

$$\Delta E \propto E^2$$

(quadratic Stark effect)

- $\vec{\mu}$ = electric dipole moment
- $\vec{E}$ = external electric field

And here are some of the early observations for each of the effect:



Zeeman effect
fine structure
Stark effect
Helium
λ 4472
Helium
λ 4026
H$_\alpha^1$
H$_\alpha^2$

[1] Lewis & Spedding
[2] Stark

11.1.2 Thomson's Model

Thomson is at the origin of the discovery of the electron by his experiments on the flow of particles (electrons) generated by cathode rays. Theoretician and experimenter, Thomson advanced in 11898 (holocene calendar) the "raisin bread theory" (see [539]) of atomic structure, in which the electrons are considered negative grapes pressed into a loaf of positive material. His model of the atom is represented by the figure below:

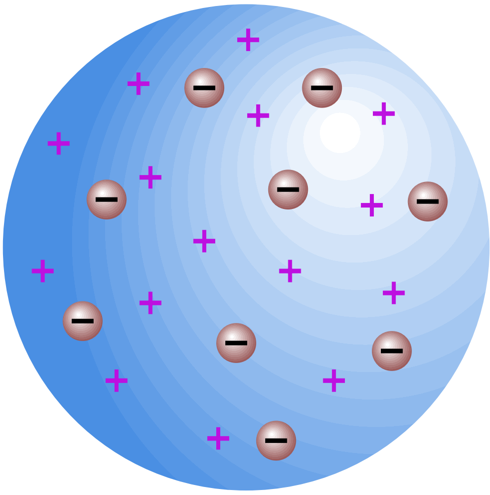

Figure 11.3: **Thomson's Gourmet approach...**

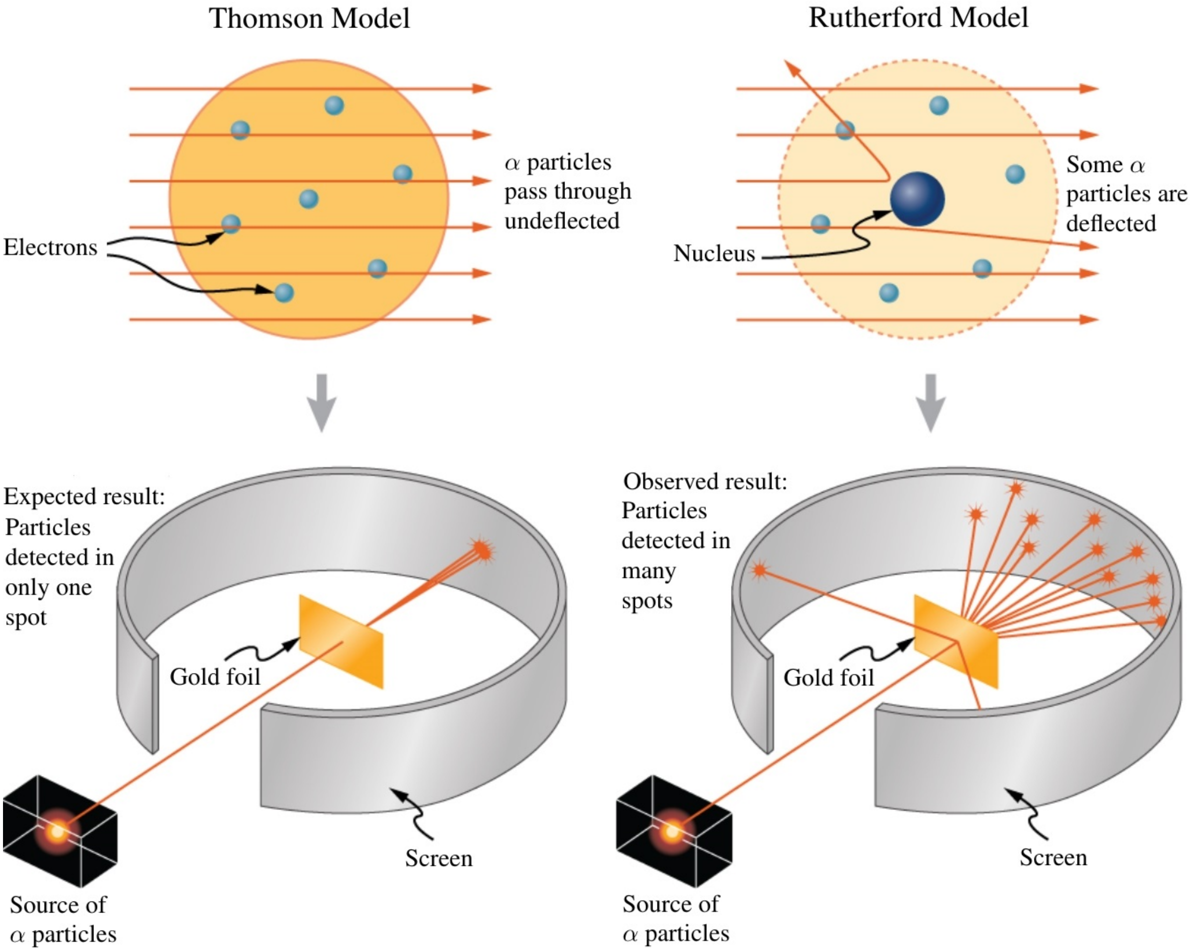
But, we know (the physicists of the 119th century also knew it) that no arrangement of static charges is stable if these charges are under the influence of the Coulomb force:

$$\vec{F}=q\left(\frac{1}{4\pi\varepsilon}\sum_i\frac{Q_i}{\|\vec{r}-\vec{r}_i\|^3}(\vec{r}-\vec{r}_i)\right) \tag{11.1.3}$$

that we had studied in detail in the section of Electrostatic. Thus that this requires that the particles that make up the atom are in motion which leads us to develop another model: the following "Rutherford model".

11.1.3 Rutherford's Model

Thus Ernest Rutherford assimilated intuitively by this theoretical fact, a few years after the discovery of Thomson, the atom to a planetary system whose center was occupied by a nucleus of positive charge, which contained almost the entire mass of the atom. The core was a hundred thousand times smaller than the atom and thus occupied a very small volume. The assumptions was more adapted to experimental results (11909 according to holocene calendar, see [471]):



Thomson Model
Rutherford Model
α particles pass through undeflected
Electrons
Nucleus
Some α particles are deflected
Expected result: Particles detected in only one spot
Observed result: Particles detected in many spots
Gold foil
Gold foil
Screen
Screen
Source of α particles
Source of α particles

Figure 11.4: Rutherford experiment (source: OpenStax)

Therefore here is a pictorial representation of how should looks like an atom in this model (the distances are not at scale for obvious reasons...):

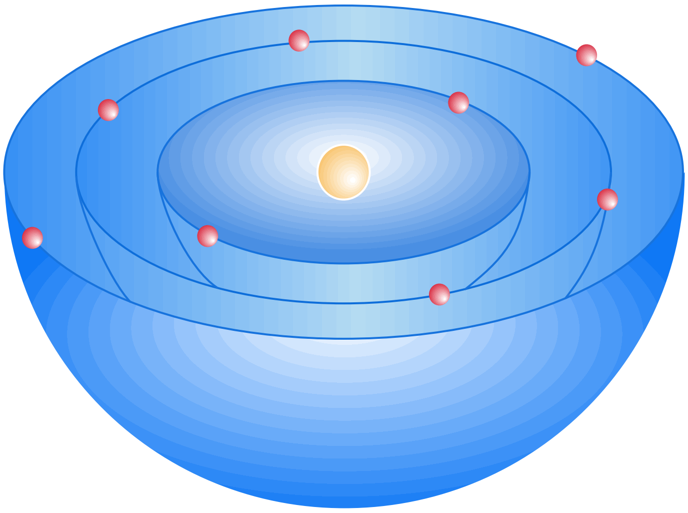


Figure 11.5: **The Rutherford's planetary approach...**

Rutherford applied the results we get in astronomy (see section Astronomy page 5234) during our study of Keplerian orbits in the atom and therefore obtained conical trajectories for the rotation of the electron around the nucleus such as:

$$r = \frac{p}{1+\cos\theta} \tag{11.1.4}$$

where e is the eccentricity ($e = c/a < 1$) and p the focal parameter ($p = b^2/a$) of an ellipse (see section Analytical Geometry page 2779), and where:

$$p = \frac{K^2}{\mu} \qquad \text{and} \qquad e = \sqrt{1 + \frac{2EK^2}{\mu^2}} \tag{11.1.5}$$

Remarks

R1. You will have to remember that when we will discuss later on Bohr's model that in the Rutherford model, r can take theoretically any value!

R2. We will see in our study of the Rutherford scattering (see section Nuclear Physics page 5111) that Rutherford determined that the size of the gold atom as being worth $R \cong 3\cdot 10^{-14}\,[\text{m}]$. So we have a model with a factor 10,000 in comparison of the Dalton's model (that is to say...).

But we have proven that during our study of electromagnetism that Maxwell displacement equations (third Maxwell equation) were given by (see section Electrodynamics page 4101):

$$U(t) = -\frac{\mathrm{d}\Phi_B}{\mathrm{d}t} = \oint_\Gamma \vec{E}\circ \mathrm{d}\vec{l} \Leftrightarrow \vec{\nabla}\times\vec{E} = -\frac{\partial \vec{B}}{\partial t} \tag{11.1.6}$$

and:

$$\oint_\Gamma \vec{B}\circ \mathrm{d}\vec{l} = \mu \iint_\Sigma \vec{j}\circ \mathrm{d}\vec{S} + \mu\varepsilon \iint_\Sigma \vec{E}\circ \mathrm{d}\vec{S} \Leftrightarrow \vec{\nabla}\times\vec{H} = \vec{j} + \varepsilon\frac{\partial \vec{E}}{\partial t} \tag{11.1.7}$$

describe that an electron in motion (accelerated) emits energy in the form of electromagnetic radiation that we name in physics "Bremsstrahlung" explained by the Liénard-Wiechert's potentials (see section Electrodynamics page 4168).

Rutherford and Thomson were therefore faced with the following dilemma:

If the electron emits energy in the form of electromagnetic radiation, it loses kinetic energy (speed) and thus necessarily sooner or later (except external intervention) will fall on the core of the atom (illustration of the phenomenon in the figure below). But we see that the matter surrounding us is however in fact quite stable...

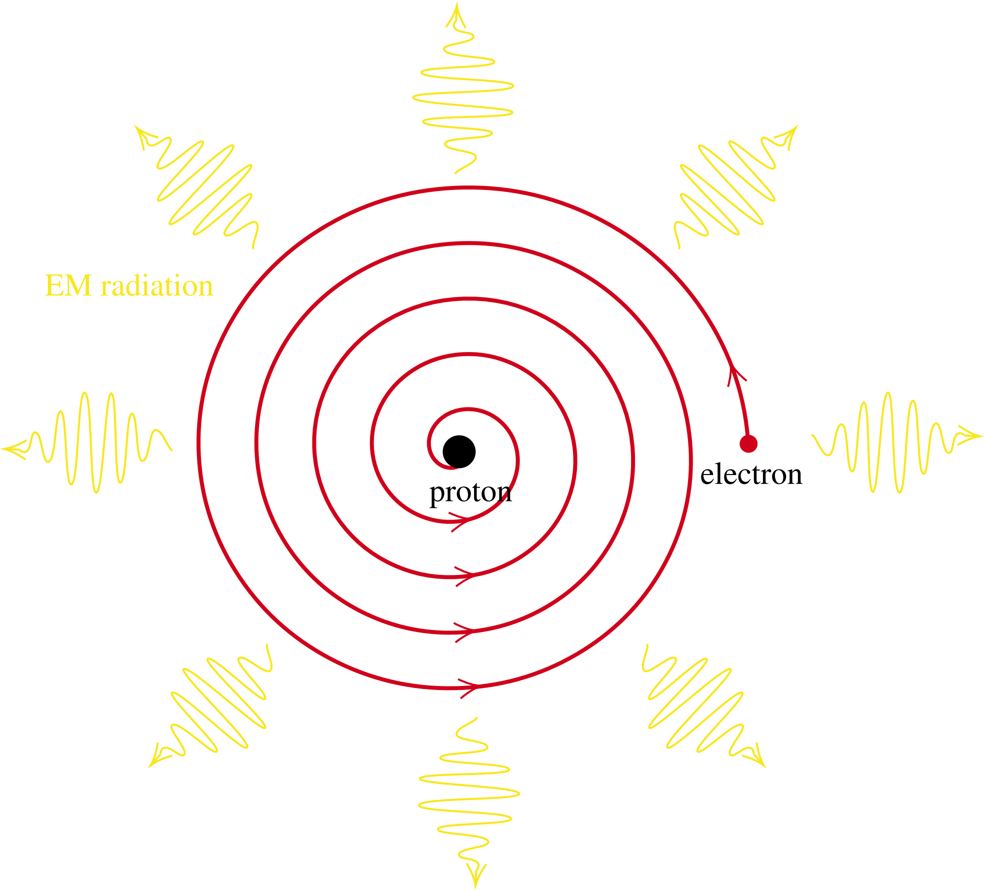

Figure 11.6: **Simplistic illustration of Bremsstrahlung**

So they rejected their model and Bohr intervened then with a revolutionary hypothesis but that had to explain facts and not necessarily true reality... (Bohr was a genius experimentalist physicist and probably the best debate partner of Einstein).

11.1.4 Bohr's Model

In 11913 (holocene calendar), Niels Bohr, who participated to the work of Rutherford on the diffusion α of particles (nuclei of two proton and two neutrons free of electrons), takes the model of Rutherford but includes in it three fundamental assumptions (see [62]):

11.1.4.1 Bohr's Postulates

P1. The electron does not emit radiation when on certain orbits named "stationary orbits". This assertion is contrary to the theories of classical electrodynamics. So this implies that all the orbits are not allowed and this is a revolution in the approach of theoretical physics (the prohibited orbits are named "non-stationary orbits").

P2. On any stable orbit the linear momentum p integrated on the path r of the orbit is an integer multiple of the Planck's constant h (assumption arising from the first one) according to the quantification of energy exchanges established by Planck's relation (see section Thermodynamics page 3719). This assumption is sometimes named "Planck's quantum hypothesis".

P3. The assumed (only experimentally verified and theoretically assumed as unprovable) "Planck-Einstein relation":

$$\boxed{E = h\nu} \tag{11.1.8}$$

applies to the emission[3] or absorption of radiation during the transition of an electron from one energy state E_1 to a state E_2 (which solidifies the first postulate).

In fact, we find here a revolutionary and unprovable concept (today and to our knowledge) consisting in the quantification of certain physical properties.

Remark

The German physicists James Franck and Gustav Hertz performed a collisional excitation experiment in 11914 (holocene calendar) that provided early dramatic evidence for discrete energy levels in atoms. Electrons with varying amounts of initial kinetic energy were sent through a gas of mercury vapor, and the number of electrons per second making it through the gas was measured. When the initial kinetic energy of the electrons was less than $4.9\,[\text{eV}]$, many electrons reached the detector. However, when the initial kinetic energy reached $4.9\,[\text{eV}]$, few electrons reached the detector. The Franck-Hertz experiment was correctly interpreted to mean that the first excited state of a mercury atom is $4.9\,[\text{eV}]$ above the ground state, and an electron with kinetic energy of $4.9\,[\text{eV}]$ can excite the atom, leaving the electron with almost no kinetic energy, so the number of electrons that made it through the gas became very small.

Let us continue our analysis:

---

[3] The time of emission (after absorption) is not fixed and follows also follows a statistical law! This "radiation lifetime" is described by the Wigner-Weisskopf theory of spontaneous decay that we will maybe introduce in this textbook in the future...

11.1.4.2 Quantification

Let M be the mass of the core of an atom with an electric charge $+e$ and m the mass of the electron in "orbit" around the core. We assume that $M \gg m$ and that the central mass is motionless (which is obviously false in reality).

We assimilate the circular motion of the electron around the nucleus to that of a harmonic oscillator (mass connected to a spring exerting a force opposed to a proportional constant k_r to retain the electron linked).

If the oscillations occurs in the plane, its differential equation is (see section Classical Mechanics page 3417):

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+k_rx=0 \Leftrightarrow \frac{\mathrm{d}^2x}{\mathrm{d}t^2}+\omega_0x=0 \tag{11.1.9}$$

A (special) simple solution of this equation is (see section Differential and Integral Calculus page 1610):

$$x=A_0\sin(\omega_0t) \tag{11.1.10}$$

The kinetic energy of the system is therefore given by (see section Classical Mechanics page 3297):

$$E_c=\frac{1}{2}mv^2=\frac{1}{2}m\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2=\frac{1}{2}mA^2\omega_0^2\cos^2(\omega_0t) \tag{11.1.11}$$

and the potential energy of the system (see section Wave Mechanics page 3418):

$$E_p=\frac{1}{2}k_rx^2=\frac{1}{2}m\omega_0^2A^2\sin^2(\omega_0t) \tag{11.1.12}$$

If we denote by ν the frequency of oscillation of the oscillatory motion, we then have of course (see section Wave Mechanics page 3480):

$$\omega_0=2\pi\nu \tag{11.1.13}$$

The total energy of the system is finally written after summation and simplification (elementary trigonometry):

$$E_t=E_c+E_p=2\pi^2mA^2\nu^2 \tag{11.1.14}$$

We now assume that the bounded electron can only occupy certain energy levels (first hypothesis) according to the "Planck-Einstein relation":

$$\boxed{E=n\varepsilon=nh\nu=\frac{h}{2\pi}=\hbar\omega=h\frac{c}{\lambda}} \tag{11.1.15}$$

Figure 11.7: Energy-Wavelength-Frequency electromagnetic values (author: Izaak Neutelings)

Remark

A nice application of this relation is that since we know the radiation power of a light bulb, a star or an antenna for a given surface and a given wavelength, we can calculate the number of photons (having the corresponding wavelength) per unit surface! Typically at a distance of one meter of a 100 [W] light bulb we get 10^{15} visible photons per square centimetre and per second! For an isotropic FM antenna with a power of 100 [W] at a distance of 100 [km] we have a flux of 10^{12} photons per square centimetre and per second.

This gives us when we include the Planck-Einstein relation in the penultimate equation:

$$A^2=n\frac{h}{2\pi^2 m\nu} \tag{11.1.16}$$

We note here that since the energy of the electron is quantified the amplitude of its movement is also quantified.

Consider now the following integral path also named "action integral" (this is in fact angular momentum):

$$\oint p\mathrm{d}r=\oint mv\mathrm{d}r=\oint mv\frac{\mathrm{d}r}{\mathrm{d}t}\mathrm{d}t=\oint mv^2\mathrm{d}t \tag{11.1.17}$$

and considering the expression for velocity previously obtained:

$$\oint p\mathrm{d}r=\oint mA^2\omega_0^2\cos^2(\omega_0 t)\mathrm{d}t=mA^2\omega_0^2\oint\cos^2(\omega_0 t)\mathrm{d}t \tag{11.1.18}$$

Over a period of revolution, we have:

$$\oint\cos^2(\omega_0 t)\mathrm{d}t=\int_0^T\cos^2(\omega_0 t)\mathrm{d}t \tag{11.1.19}$$

Since (see section Trigonometry page 2519):

$$\cos^2(\omega_0 t)=\frac{1+\cos\left(2\omega_0 t\right)}{2} \tag{11.1.20}$$

The integration becomes:

$$\int_0^T\cos^2(\omega_0 t)\mathrm{d}t=\frac{1}{2}\int_0^T\left[1+\cos(2\omega_0 t)\right]\mathrm{d}t=\frac{1}{2}\left(T+\frac{1}{2\omega_0}\sin(2\omega_0 t)\Big|_0^T\right) \tag{11.1.21}$$

Because $\omega=\dfrac{2\pi}{T}$ (see section Wave Mechanics page 3480) we have:

$$\int_0^T\cos^2(\omega_0 t)\mathrm{d}t=\frac{1}{2}\left(T+\frac{1}{2\omega_0}\left[\sin(2\frac{2\pi}{T}T)-\sin(0)\right]\right)=\frac{1}{2}T \tag{11.1.22}$$

So finally we get:

$$\oint \text{pdr} = \frac{1}{2} m A^2 \omega_0^2 T \tag{11.1.23}$$

Given that $A^2 = n\dfrac{h}{2\pi^2 m\nu}$ and $\omega_0 = 2\pi\nu$ and also $\nu = \dfrac{1}{T}$ we get:

$$\oint \text{pdr} = \frac{1}{2} m A^2 \omega_0^2 T = \frac{1}{2} m \left(\frac{nh}{2\pi^2 m\nu}\right) 4\pi^2\nu^2 \frac{1}{\nu} = nh \tag{11.1.24}$$

Finally:

$$\oint \text{pdr} = nh \tag{11.1.25}$$

This condition imposed by Bohr (second postulate) results from the quantization of energy exchanges (Planck-Einstein relation). This has the effect of imposing stationary energy levels that the electron around the nucleus can occupy.

For a circular orbit (remember though for now that we consider a circular orbit!) or radius r the angular momentum (yes in fact the integral action is just the angular momentum) along the length of the orbital is:

$$\oint \text{pd}l = mv(2\pi r) = nh \Rightarrow mvr = n\frac{h}{2\pi} = n\hbar \tag{11.1.26}$$

or by using one of the traditional notation of angular momentum in quantum physics:

$$\boxed{b = mvr = n\hbar} \tag{11.1.27}$$

The angular momentum is quantized and non-zero in the Bohr's model (since n is not zero). We will see that this is no longer the case in the wave model where the angular momentum can be zero.

According to this result, and further results we will get, it is commonly accepted in science that action values or changes smaller than $\hbar \cong 1.06 \cdot 10^{-32}$ [J · s] are not observed.

11.1.4.3 Hydrogen Type Atoms Model without dragging

We define the study of "hydrogen type atom without dragging" as the fact of considering the atoms with a single electron of mass m rotating around a central core with a charge of $Z \cdot e$ and mass M such that $M \gg m$ (so the kernel is supposed fixed).

Let us now calculate the stationary orbits radius!

On its stationary orbit, the electron is in equilibrium because there is a true antagonism between the Coulomb force and centrifugal (fictional) force. This should result in the following equality of strengths:

$$\frac{Ze^2}{4\pi\varepsilon_0 r^2} = m\frac{v^2}{r} = m\frac{(\omega r)^2}{r} = m\omega^2 r \tag{11.1.28}$$

We will write starting from now (to reduce the notations):

$$k=\frac{1}{4\pi\varepsilon_0} \tag{11.1.29}$$

This allows us to write the relation:

$$\omega^2 r^3=k\frac{Ze^2}{m} \tag{11.1.30}$$

By using the quantization condition of Bohr and by squaring:

$$m\omega r^2=n\hbar=n\frac{h}{2\pi}\Leftrightarrow\omega^2 r^4=n^2\frac{h^2}{4\pi^2 m^2} \tag{11.1.31}$$

By dividing the last two relations to one another by:

$$\frac{\omega^2 r^2}{\omega^2 r^3}=\frac{\dfrac{n^2h^2}{4\pi^2m^2}}{k\dfrac{Ze^2}{m}} \tag{11.1.32}$$

we get:

$$r=\frac{1}{k}\frac{n^2h^2}{4\pi^2 mZe^2}=n^2\frac{\varepsilon_0 h^2}{\pi mZe^2} \tag{11.1.33}$$

given the expression of k.

The radius of the electron orbits allowed is then:

$$\boxed{r_n=n^2\frac{\varepsilon_0 h^2}{\pi mZe^2}} \tag{11.1.34}$$

with $n\in\mathbb{N}^*$. This relation is commonly named the "Bohr radius" for $n=Z=1$ and denoted r_0 (or a_0 in some textbooks).

The orbits of an atom in this model therefore looks like:

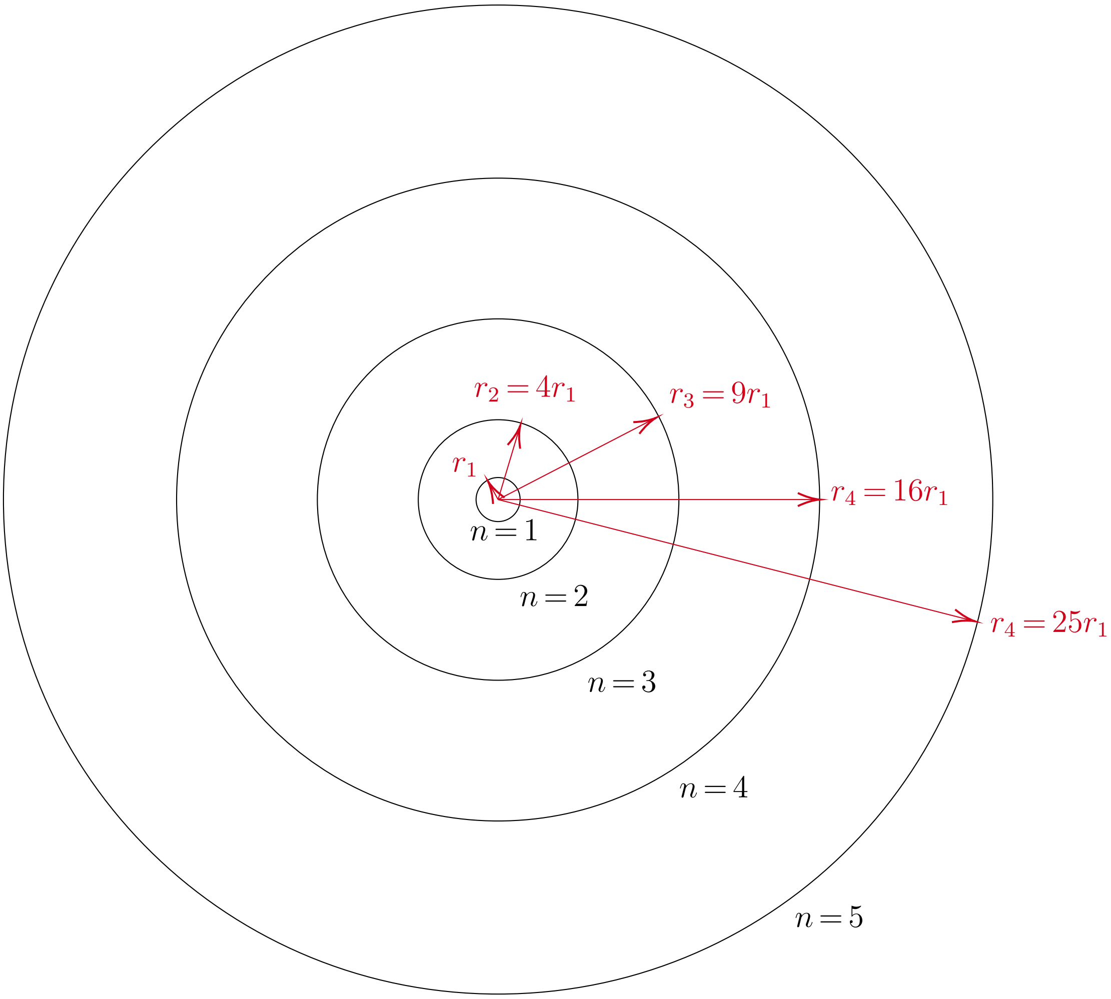

Figure 11.8: Bohr planar planetary model

The energy of the hydrogenoid-like atom without dragging is given by classical mechanics (case of a central force), the sum of kinetic and potential electrostatic energy:

$$E_{\text{tot}} = E_c + E_p = \frac{1}{2}m\omega^2 r^2 - k\frac{Ze^2}{r} \tag{11.1.35}$$

with:

$$\frac{Ze^2}{4\pi\varepsilon_0 r^2} = m\omega^2 r \tag{11.1.36}$$

we get:

$$E_{\text{tot}} = E_c + E_p = \frac{1}{2}m\omega^2 r^2 - k\frac{Ze^2}{r} = \frac{1}{2}k\frac{Ze^2}{r} - k\frac{Ze^2}{r} = -\frac{1}{2}k\frac{Ze^2}{r} \tag{11.1.37}$$

By introducing the expression of quantified radius obtained previously:

$$E_{\text{tot}} = -\frac{1}{2}k\frac{Ze^2}{r_n} = -\frac{1}{2}k\frac{Ze^2}{n^2\dfrac{\varepsilon_0 h^2}{\pi m Z e^2}} = -\frac{mZ^2e^4}{8\varepsilon_0^2 n^2 h^2} \tag{11.1.38}$$

We therefore find that the total energy of the atom is quantified and considered as negative (corresponding to stable states because it takes a supply of energy to undo the link) such that:

$$\boxed{E_{\text{tot}}=-\frac{1}{n^2}\frac{mZ^2e^4}{8\varepsilon_0^2h^2}} \tag{11.1.39}$$

Remark

This relation is often expressed in many textbooks for $Z=1$ and in eV (electron-volts) units as following:

$$E_{\text{tot}}\cong-\frac{13.606}{n^2}\,[\text{eV}] \tag{11.1.40}$$

Between two levels, the transition of an electron of the level n_2 to the level n_1 (we will specify how during the study of the photoelectric effect later) results in the emission of a frequency line given by the expression of Planck's quantization hypothesis:

$$E_{\text{tot}}^{n_2}-E_{\text{tot}}^{n_1}=h\nu_{n_2,n_1} \tag{11.1.41}$$

Thus, quantum physics explains the photon energy emission at a transition between two levels!

In fact, if we assume with Bohr that the energies of an electron on its orbit are given by the inverse of the square of the integer, the energy difference between two orbits characterized by high values of these integers approaches zero when the integers tend to infinity. We find then a semblance of continuous change for the energies exchanged by an atom with the electromagnetic field and the concept of trajectory of an electron takes then again sense!

By using the full expression of the total energy, we then find the appropriate frequency to the line emitted:

$$\nu_{n_2,n_1}=Z^2\frac{me^4}{8\varepsilon_0^2h^3}\left(\frac{1}{n_1^2}-\frac{1}{n_2^2}\right) \tag{11.1.42}$$

The wavelength emitted is thus easily deduced:

$$\boxed{\frac{1}{\lambda}=Z^2\frac{me^4}{8\varepsilon_0^2h^3}\left(\frac{1}{n_1^2}-\frac{1}{n_2^2}\right)=Z^2R_H\left(\frac{1}{n_1^2}-\frac{1}{n_2^2}\right)} \tag{11.1.43}$$

The constant R_H (denoted as R_y depending on the context) is named the "Rydberg constant".

An electron occupying an orbit n is in a "steady state" if its energy does not change. If it's orbit change, we speak then of "quantum jump" or "quantum leap".

Remark

Since the very beginning of quantum mechanics, a debate has raged about how to interpret its bizarre predictions, and at the heart and origin of that debate is the quantum jump or quantum leap. It comes from the idea that electrons in atoms jump instantaneously from one orbit or energy level to another without ever occupying the intervening space. Erwin Schrödinger himself never accepted the idea of the quantum jump, but could also never prove it wrong. That proof required precision measurements that didn't exist in Schrödinger's time. However, in the beginning of the 121st century (holocene calendar) the reality of the quantum jump has finally been tested. Schroedinger claimed that both epicycles and quantum jumps were ingenious constructs of the human mind that nevertheless were not true descriptions of nature. By the 11980s (holocene calendar), we had learn how to trap and cool a single atom with LASERs, and in 11986 (holocene calendar) almost simultaneously, three different teams observed quantum jumps in such an atom. In this way physicists were able to gain fairly direct evidence of a single quantum jump and the downward jumps when the electron decade appeared to occur at completely random times, just as Bohr had predicted. Although the jump appeared random, there was no way to tell whether it was instantaneous or whether the electron passed through some intermediate states during the jump. Fast forward another 30 plus years technology has advanced to the point that we can not only see individual quantum jumps, we can monitor their progress and even interrupt them mid jump. Now this isn't with an actual atom, but rather a sort of artificial atom made of two superconducting circuits. The scientists could actually zoom in on a quantum jump and finally figure out whether it was truly an instantaneous transition, and they found that no, it was not instantaneous after all, but rather was a continuous transition over intermediate states that took a few microseconds, and that transition appeared to be perfectly described by theory. In this case, "quantum trajectory theory" (QTT). QTT addresses the measurement problem in quantum mechanics by providing a detailed description of what happens during the so-called "collapse of the wave function". The theory suggests that "quantum jumps" are not instantaneous but happen in a coherently driven system as a smooth transition through a series of superposition states. This prediction was tested experimentally in 12019 (holocene calendar) by a team at Yale University led by Michel Devoret and Zlatko Minev, in collaboration with Carmichael and others at Yale University and the University of Auckland. But what about the randomness of the event? Well, the theorists showed how quantum states can transition very predictably through a series of superposition states, much as Schrodinger proposed. So nearly a century after Bohr and Schrodinger's started the argument, we may be on the verge of the next quantum leap to learning whether quantum jumps are, instantaneous or continuous, and perhaps whether the quantum world is built upon fundamentally random processes or is driven by a rigidly deterministic mechanic of space-time (for a naive and technical definition of "space-time" see the section of Special Relativity at page 5708).

However, a direct transition $n_2 \rightarrow n_1 (n_1 < n_2)$ is accompanied by the emission of a photon whose energy is given by the frequency as we proved it before. When an electron in an excited energy level of an atom drops down to a lower level, it emits a photon that provides the common source of light or, more generally, electromagnetic radiation, over a spectral range from X-rays to ultraviolet light. This is a quantum phenomenon that, in most interpretations of quantum mechanics, occurs spontaneously, that is, without cause.

The "ionization energy" is the energy it takes to give away an electron to infinity of its orbit. Thus for the ground state of hydrogen, it would be necessary to write $n_1 = 1$ and $n_2 = +\infty$.

The result obtained by Bohr for expressing the frequency depending on the electron energy levels is a great result (which surprised Bohr himself) because by involving only major fundamental constants he theoretically founded the spectrum law that hydrogen lines followed.

Law that Johann Jakob Balmer had discovered experimentally in 11885 according to holocene calendar (28 years before).

Balmer had noticed that the spectral lines were extremely thin. This implied that the energy is not emitted by the atoms continuously but only at certain specific frequencies. Moreover, this fine stripes explains the precision with which he could determine the Rydberg constant.

Chemists had also seen that each element had its own atomic spectrum. It was therefore clear that any atomic theory should reflect these two characteristics and this is what made brilliantly the Bohr's model using the assumptions of energy levels.

We define, moreover, the following spectrum series of the hydrogen atom:

- For the series starting from $n_1=1$ and going to $n_2=2,3,4,\ldots$ we get the result of measurements (spectrum) by Lyman in 11906 (holocene calendar) in the UV.
- For the series starting from $n_1=2$ and going to $n_2=3,4,5,6,\ldots$ we get the result of measurements (spectrum) by Balmer in 11885 (holocene calendar) in the visible spectrum (respectively red, bluegreen, violet, violet).
- For the series starting from $n_1=3$ and going to $n_2=4,5,6\ldots$ we get the result of measurements (spectrum) by Paschen in 11908 (holocene calendar) in the infra-red.
- For the series starting from $n_1=4$ and going to $n_2=5,6,7\ldots$ we get the result of measurements (spectrum) by Brackett in 11928 (holocene calendar) in the infra-red.
- For the series starting from $n_1=5$ and going to $n_2=6,7,8\ldots$ we get the result of measurements (spectrum) by Pfund in 11924 (holocene calendar) in the infra-red.

Remark

If a photon hits let's say a hydrogen atom i.e. with a single electron) with a given energy, four cases can be considered: a) it can scatter elastically, which means it retains its frequency but changes angle b) it can scatter inelastically, which means it changes frequency givin some of its energy to the entire atom c) it can be absorbed raising the energy level of an electron (in a lattice, in a molecule, in an atom) and a different photon is emitted and phases are lost.

Figure 11.10: **Three main series of the hydrogen atom (author: M. El Founani)**

It follows, from what we just seen, something very important in chemistry (to recognize easily with what element we are dealing with) and astrophysics (to analyse the elements in a cloud of gas surrounding a star or another planet turning around a star): the fact that materials (elements) all have a specific Line Spectra (emission spectrum) as shown in the figure below!

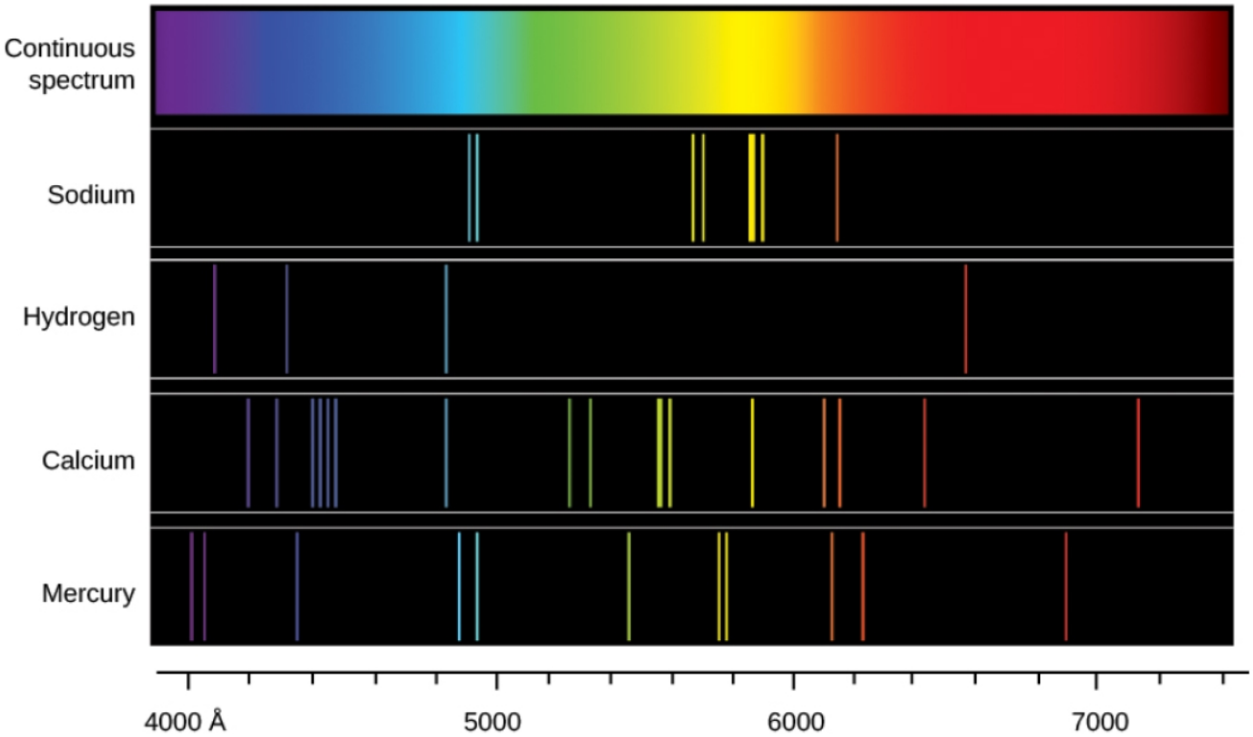

Figure 11.11: Visible line spectra of various elements (source: OpenStax)

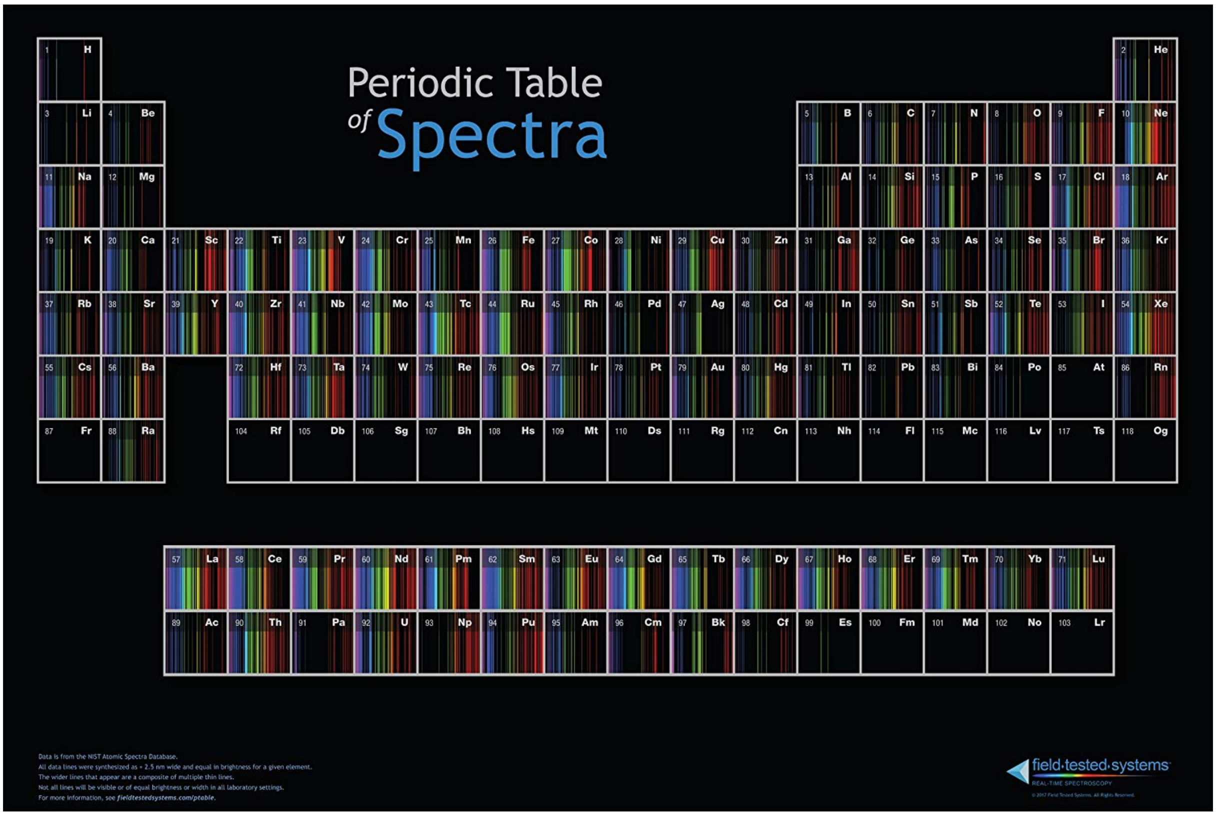
Or a more complete table of elements line spectra (still only in the visible):



Data is from the NIST Atomic Spectra Database.
All data lines were synthesized as ~ 2.5 nm wide and equal in brightness for a given element.
The wider lines that appear are a composite of multiple thin lines.
Not all lines will be visible or of equal brightness or width in all laboratory settings.
For more information, see *fieldtestedsystems.com/ptable*.

Figure 11.12: Visible line spectra of elements (source: NIST atomic spectra database)

Keep in mind that the opposite of an emission spectrum is an absorption spectrum!

Whatever the model of atom we take (Bohr, Sommerfeld, Schrödinger) we will prove that the energy level are so that the structure of the atoms are independent of any fundamental parameters (mass of electron, proton or of fine-structure constant!). All universes with a wide range of values of these parameters will have the same chemistry. This will change only when we can no longer assume the electrons reside outside the nucleus or when the motion of protons can no longer be neglected. So it is very likely that all these constants are not fine-tuned to give chemistry and life based on it.

11.1.4.4 Hydrogen Type Atoms Model with dragging

The atomic nucleus has a mass M that we have assumed stationary for simplification. In reality, the assembly core (M) and electron (m) is rotating about a common center of mass (obviously!).

Hypothesis (assumptions):

H1. The hydrogen-like atom is considered an isolated system.

H2. The nucleus and the electron orbit each in a circular orbit around a common center: the "center of mass CM" (see section Classical Mechanics page 3213).

H3. They have the same angular velocity.

The hydrogenoid atom being an isolated system, the movement of the center of mass is either in uniform rectilinear motion or at rest. It is therefore acceptable to place there an inertial reference system.

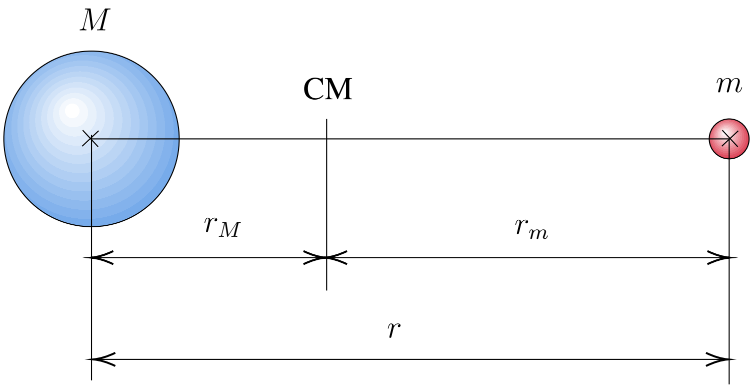


Figure 11.13: **Defining hydrogenoid atom configuration**

The definition of the center of mass in a laboratory system is given by the theorem of the center of mass (see section Classical Mechanics page 3213):

$$\vec{r}=\frac{m_1\vec{r}_1+m_2\vec{r}_2}{m_1+m_2} \tag{11.1.44}$$

The present study will be made relatively to the center of mass! Then, the above relation becomes (see section Classical Mechanics page 3213):

$$M\vec{r}_M + m\vec{r_m} = \vec{0} \tag{11.1.45}$$

From the above relation, taking the norm and absolute value, it follows that:

$$r_M = \frac{m}{M} r_m \tag{11.1.46}$$

The distance between the nucleus and the electron being constant (hypothesis) such that $r = r_M + r_m$ we write:

$$r = r_M + r_m = \frac{m}{M} r_m + r_m = \left(1 + \frac{m}{M}\right) r_m = \left(\frac{M+m}{M}\right) r_m \tag{11.1.47}$$

We conclude that trivially:

$$r_m = \frac{M}{m+M} r \quad \text{and} \quad r_M = \frac{m}{M+m} r \tag{11.1.48}$$

Applying the law of dynamics, we write that the sum of forces (electrostatic and centrifugal) on the electron (only!) is balanced such that:

$$k\frac{Ze^2}{r^2} = m\omega^2 r_m \tag{11.1.49}$$

that we can rewrite by isolating ω^2:

$$\omega^2 = \frac{kZe^2}{mr^2\left(\dfrac{M}{m+M}\right) r} = \frac{kZe^2}{r^3}\frac{1}{\dfrac{mM}{m+M}} = \frac{kZe^3}{\mu r^3} \tag{11.1.50}$$

We find again the well-knows expression of the reduced mass for a two-body system:

$$\mu = \frac{mM}{m+M} = \frac{m}{1 + \dfrac{m}{M}} \tag{11.1.51}$$

The both relations:

$$r = \frac{M+m}{M} r_m \qquad \text{and} \qquad \mu = \frac{mM}{m+M} \tag{11.1.52}$$

will also be useful to us in the sections of Quantum Chemistry and Molecular Chemistry!

Let us now determine the total energy of the atom!

The kinetic energy of the atom is the sum of the kinetic energies of the core (N) and the electron (e) such that:

$$E_c = \frac{1}{2} m v_e^2 + \frac{1}{2} M v_N^2 \tag{11.1.53}$$

As equation with the assumption that the angular velocity is identical for the nucleus and the electron:

$$E_c = \frac{\omega^2}{2}\left(m r_m^2 + M r_N^2\right) \tag{11.1.54}$$

Using the different radii determined previously:

$$\begin{aligned}E_c=&\frac{\omega^2r^2}{2}\left[m\frac{M^2}{(m+M)^2}+M\frac{m^2}{(m+M)^2}\right]=\frac{\omega^2r^2}{2}\left[\frac{mM^2+Mm^2}{(m+M)^2}\right]\\=&\frac{\omega^2r^2}{2}\left[\frac{mM}{(m+M)^2}(m+M)\right]=\mu\frac{\omega^2r^2}{2}\end{aligned}\tag{11.1.55}$$

The potential energy of the electron relatively to the center of mass is given by (see section Electrostatics page 4005):

$$E_p=-\frac{kZe^2}{r}\tag{11.1.56}$$

The total energy of the hydrogen-like atom is then:

$$E_{\text{tot}}=\frac{kZe^2}{2r}-\frac{kZe^2}{r}=-\frac{k}{2}\frac{Ze^2}{r}\tag{11.1.57}$$

Relatively to the center of mass, the total angular momentum is the sum of the angular momentum of the electron b_m and the kernel b_M (remember that the angular momentum is also often denoted by the letter L):

$$b_{\text{tot}}=b_m+b_M=mv_mr_m+Mv_mr_M=\omega(mr_m^2+Mr_m^2)\tag{11.1.58}$$

The parenthesis of the last equality has already been the subject of a calculation previously so we have:

$$b_{\text{tot}}=\mu\omega r^2\tag{11.1.59}$$

It is here that Bohr introduced its quantization condition:

$$b_{\text{tot}}=\mu\omega r^2=n\hbar\tag{11.1.60}$$

But we know the detailed expression of the square of the pulsation:

$$b_{\text{tot}}^2=\mu^2\omega^2r^4=\mu^2\left(\frac{kZe^2}{\mu r^3}\right)r^4=n^2\hbar^2\tag{11.1.61}$$

The quantified radius has therefore for expression:

$$\boxed{r_n=n^2\frac{\varepsilon_0h^2}{\pi\mu Ze^2}}\tag{11.1.62}$$

The total energy of the atom finally becomes:

$$E_{\text{tot}}^n=-\frac{k}{2}\frac{Ze^2}{\dfrac{n^2\varepsilon_0h^2}{\pi\mu Ze^2}}=-\frac{1}{n^2}\frac{\mu Z^2e^4}{8\varepsilon_0^2h^2}=-\frac{1}{n^2}\frac{mZ^2e^4}{8\varepsilon_0^2h^2}\left(\frac{1}{1+\dfrac{m}{M}}\right)\tag{11.1.63}$$

Either with a condensed notation:

$$\boxed{E_{\text{tot}}^n=-\frac{1}{n^2}hcZ^2R_H\left(\frac{1}{1+\dfrac{m}{M}}\right)}\tag{11.1.64}$$

From this last relation, we can easily determine the expression (as we have already done) for wavelengths emitted by a de-excitation of the electron from one orbit n_2 to n_1. Let us calculate with the same way as we did for the free training model, the expression of the wavelength emitted during the transition from one level to another. We then identical developments:

$$E_{\text{tot}}^{n_2}-E_{\text{tot}}^{n_1}=h\nu_{n_2,n_1} \tag{11.1.65}$$

It comes then:

$$\nu_{n_2,n_1}=\left(\frac{1}{n_1^2}-\frac{1}{n_2^2}\right)cZ^2R_H\left(\frac{1}{1+\dfrac{m}{M}}\right) \tag{11.1.66}$$

The wavelength emitted is then easily deduced:

$$\frac{1}{\lambda}=Z^2R_H\left(\frac{1}{1+\dfrac{m}{M}}\right)\left(\frac{1}{n_1^2}-\frac{1}{n_2^2}\right) \tag{11.1.67}$$

Remark

It obviously to realize that this model is more accurate than the previous one.

11.1.4.5 Neutron Assumption

Spectroscopy results are known with high precision, therefore the Rydberg's constants also (because dependent on the mass of the atomic element studied).

The two blue stripes of the Balmer series for the hydrogen atom denoted by the letter H (composed of one proton and one electron) and of deuterium which atom denoted by the letter D (isotope of hydrogen consisting in one neutron more) have a difference of wavelength of $\Delta\lambda\cong 1.32\mathring{A}$.

The wavelength belonging to the Balmer series ($n_1=2, n_2=3,4,5,\ldots$ is therefore expressed by (with the correction of the mass center as seen above):

$$\nu_n=Z^2R_H\left(\frac{1}{2^2}-\frac{1}{n^2}\right)\Rightarrow\lambda=\frac{1}{Z^2R_H\left(\dfrac{1}{2^2}-\dfrac{1}{n^2}\right)}\left(1+\frac{m}{M}\right) \tag{11.1.68}$$

This last expression written successively for hydrogen and deuterium leads to:

$$\lambda_{\text{H}}=\frac{1}{Z^2R_H\left(\dfrac{1}{2^2}-\dfrac{1}{n^2}\right)}\left(1+\frac{m}{M_{\text{H}}}\right)\quad\text{and}\quad\lambda_{\text{D}}=\frac{1}{Z^2R_H\left(\dfrac{1}{2^2}-\dfrac{1}{n^2}\right)}\left(1+\frac{m}{M_{\text{D}}}\right) \tag{11.1.69}$$

where we recall that the mass of the electron m is known to us!

What is interesting here is that these two elements have identical chemical properties (hydrogen and deuterium) but different spectrum lines. Scientists of this time wondered why and after that the Bohr hydrogen atom with dragging get available to them they were able to conclude that this difference came from the difference in the mass of the atomic nucleus.

It is still necessary to determine the difference in mass and explain its origin!

We therefore have:

$$\begin{aligned}\frac{\Delta\lambda}{\lambda_{\mathrm{H}}}=\frac{\lambda_{\mathrm{H}}-\lambda_{\mathrm{D}}}{\lambda_{\mathrm{H}}}&=\frac{\dfrac{1}{Z^2R_H\left(\dfrac{1}{2^2}-\dfrac{1}{n^2}\right)}\left[\left(1+\dfrac{m}{M_{\mathrm{H}}}\right)-\left(1+\dfrac{m}{M_{\mathrm{D}}}\right)\right]}{\dfrac{1}{Z^2R_H\left(\dfrac{1}{2^2}-\dfrac{1}{n^2}\right)}\left(1+\dfrac{m}{M_{\mathrm{H}}}\right)}\\&=\frac{\left(1+\dfrac{m}{M_{\mathrm{H}}}\right)-\left(1+\dfrac{m}{M_{\mathrm{D}}}\right)}{1+\dfrac{m}{M_{\mathrm{H}}}}=\frac{\dfrac{m}{M_{\mathrm{H}}}-\dfrac{m}{M_{\mathrm{D}}}}{1+\dfrac{m}{M_{\mathrm{H}}}}=\frac{\dfrac{M_{\mathrm{H}}}{m}}{\dfrac{M_{\mathrm{H}}}{m}}\frac{\dfrac{m}{M_{\mathrm{H}}}-\dfrac{m}{M_{\mathrm{D}}}}{1+\dfrac{m}{M_{\mathrm{H}}}}\end{aligned}\tag{11.1.70}$$

This simplifies to:

$$\frac{\Delta\lambda}{\lambda_{\mathrm{H}}}=\frac{1-\dfrac{M_{\mathrm{H}}}{M_{\mathrm{D}}}}{\dfrac{M_{\mathrm{H}}}{m}+1}\cong\frac{1-\dfrac{M_{\mathrm{H}}}{M_{\mathrm{D}}}}{1836.5+1}=\frac{1-\dfrac{M_{\mathrm{H}}}{M_{\mathrm{D}}}}{1837.5}\tag{11.1.71}$$

Therefore:

$$\frac{M_{\mathrm{H}}}{M_{\mathrm{D}}}=1-1837.5\frac{\Delta\lambda}{\lambda_{\mathrm{H}}}=1-1837.5\frac{1.32}{4861.3}\cong 0.501\tag{11.1.72}$$

Which showed the scientists of that time that the deuterium nucleus consists of two particle mass equivalent to that of the proton. Thus by logical deduction, this core must be made of a proton (which is obviously knows!) and a neutral particle!!!

This hypothesis is this of the "neutron", which was later discovered experimentally in 11932 (holcoene calendar) by Chadwick.

Today we know that:

$$m_p\cong 1.67262\cdot 10^{-27}\,[\mathrm{kg}]\quad\text{and}\quad m_n\cong 1.675\cdot 10^{-27}\,[\mathrm{kg}]\tag{11.1.73}$$

The reader must know that the experimental and theoretical discovery of the neutron is very important! Indeed, many famous scientists (including Einstein and Rutherford) before that discovery were sure that supply humanity with atom power was an utopia (impossible!) since make an external proton collide with the nucleus of an atom to break that latter require huge amount of energy because both were positively charged (especially the nucleus obviously!). But the discovery of the neutron made this plausible as it is... neutral! Hence the only point remaining was to discover an element that when the nucleus collide with a neutron break itself, emits energy, and afterwards emits a neutron again (stable nuclear reaction useful for power-plants) or emits more than one neutron in order to great a divergent reaction that would lead to an explosion (massive weapon).

Remark

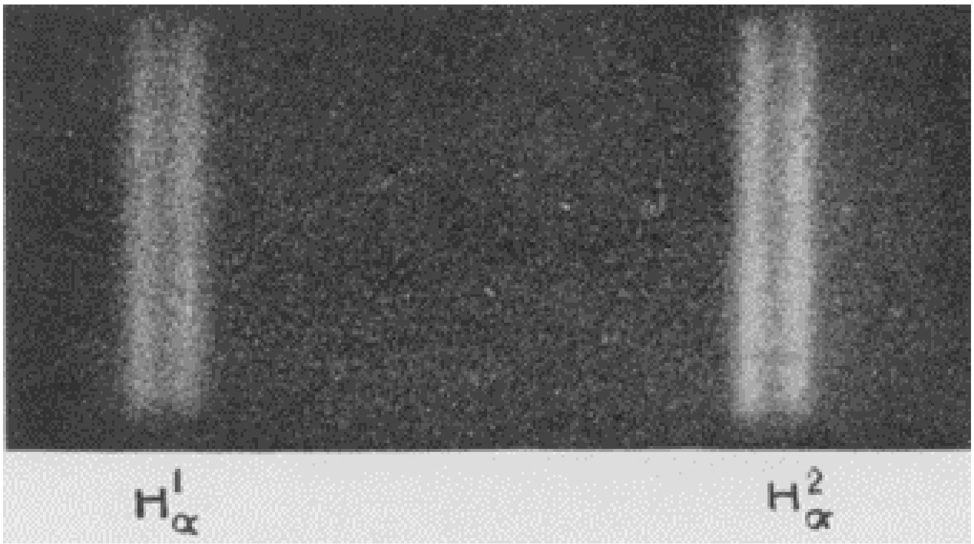
The neutron out of the nucleus will decay! With an average lifetime of about 10 minutes. More precisely, 885 seconds plus or minus 10 (even with measurement made in 12015 according to holocene calendar!). The curious part is such a huge incertitude with technologies of 12015! This is a puzzling situation and might be a harbinger of new physics for the time we write these lines.

For more information about Nuclear Physics the reader should report to the corresponding section on page 5019.

11.1.5 Wilson and Sommerfeld's Model

In developing their model, Sommerfeld and Wilson used classical dynamics to generalize Bohr's model to Keplerian orbits type (thus not only circular but elliptical in the general case!) because the Bohr's model did not explain the splitting of certain spectrum lines (without presence of any electric or magnetic field) that at the time was named "fine structure" (or "multiplet").

Around 11930 (holocene calendar), several spectroscopists using high resolution instruments found that lines in the hydrogen atom spectrum actually are not single lines but they are multiplets as shown for an isotopic mixture of hydrogen, (H_α^1) and deuterium, $(\mathrm{H}_\alpha^2\ )$, in the figure below (such fine structure also was found in spectra of one-electron ions such as He^+):



Above we have a photo of the first line in the Balmer series for atomic hydrogen and deuterium. These lines are identified as H_α^1 (hydrogen) and H_α^2 (deuterium), respectively. From H.E. White, *Introduction to Atomic Spectra* (McGraw-Hill, New York, 1934) p. 132 and G.N. Lewis and F.H. Spedding, A *Spectroscopic Search for* H^3 *in Concentrated* H^2 Phys. Rev. 43, 964 (11933).

We should recall that the H_α^1 line in the Balmer series at 656.279 [nm] was understood as resulting from a single transition of an electron from the $n=3$ energy level to the $n=2$ level. The observation of fine structure revealed that an orbital energy level diagram does not completely describe the energy levels of atoms. This fine structure also provided key evidence at the time for the existence of electron spin, which was used not only to give a qualitative explanation for the multiplets but also to furnish highly accurate calculations of the multiplet splittings.

As we have seen above, in the case of a system with two bodies solicited by a central force, the total energy of the system (we neglect gravitational potential energy...):

$$E_{\text{tot}}=\frac{1}{2}mv^2-k\frac{Ze^2}{r}=m\left(\frac{1}{2}v^2-k\frac{Ze^2}{mr}\right):=mE \tag{11.1.74}$$

To find the expression of the trajectory of the mass m, we will proceed in exactly the same manner as the one used in astronomy (see section Astronomy page 5340) to determine the Keplerian orbits.

Thus, we have proved in the section Astronomy (see page 5234) that:

$$\boxed{r(\theta)=\frac{p}{1+e\cos(\theta)}} \tag{11.1.75}$$

With:

$$p=\frac{K^2}{\mu}=\frac{\left(r^2\dfrac{\mathrm{d}\theta}{\mathrm{d}t}\right)^2}{Gm} \quad \text{and} \quad e=\sqrt{1+\frac{2EK^2}{\mu^2}}=\sqrt{1+\frac{2E_{\text{tot}}\left(r^2\dfrac{\theta}{\mathrm{d}t}\right)}{m(Gm)^2}} \tag{11.1.76}$$

We don't need to insist that in our case, it's not anymore a gravitational potential but an electric potential. Which brings us to write to our problem as following:

$$\mu=\frac{kZe^2}{m} \tag{11.1.77}$$

We still yet have to find the expression of K in a quantified form (according to the Bohr's postulate).

We fill focus first to determine the expression of the focal parameter p of the trajectory:

In our current problem, kinetic and potential energy expressed in polar coordinates give (see section Vector Calculus page 1863):

$$E_c=\frac{1}{2}m(\dot{r}+r^2\dot{\theta}^2) \quad \text{and} \quad E_p=-k\frac{Ze^2}{r} \tag{11.1.78}$$

The total energy of the atom is therefore given by:

$$E_{\text{tot}}=E_c+E_p=\frac{1}{2}m(\dot{r}+r^2\dot{\theta}^2)-k\frac{Ze^2}{r} \tag{11.1.79}$$

In an identical way of that of Bohr, Sommerfeld and Wilson applied the same form of quantification for the vector-radius and extended it to the quantification for the azimuthal angle.

Given the angular momentum:

$$b_r=\oint p_r\mathrm{d}r=n_rh \text{ and } b_\theta=\oint p_\theta\mathrm{d}\theta=n_\theta h \tag{11.1.80}$$

Momentums are obtained by derivation of the Lagrangian relatively to the generalized coordinates (see section Analytical Mechanics page 3181):

$$\begin{aligned}p_r&=\frac{\partial L}{\partial\dot{r}}=\frac{\partial}{\partial\dot{r}}\left[\frac{1}{2}m(\dot{r}+r^2\dot{\theta}^2)+k\frac{Ze^2}{r}\right]=m\dot{r}\\p_\theta&=\frac{\partial L}{\partial\dot{\theta}}=\frac{\partial}{\partial\dot{\theta}}\left[\frac{1}{2}m(\dot{r}+r^2\dot{\theta}^2)+k\frac{Ze^2}{r}\right]=mr^2\dot{\theta}\end{aligned} \tag{11.1.81}$$

The quantification on the angle is immediate, since p_θ is a constant of the motion. Indeed, the Lagrangian L being independent of θ (but no of $\dot{\theta}$), the invariance of the angular momentum results in the following Lagrange equation:

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial\dot{\theta}}-0=0\Leftrightarrow\dot{p}_\theta=0\Leftrightarrow p_\theta=c^{te} \tag{11.1.82}$$

This gives us:

$$\oint p_\theta \mathrm{d}\theta = p_\theta \oint \mathrm{d}\theta = p_\theta 2\pi = n_\theta h \Rightarrow p_\theta = n_\theta \hbar \tag{11.1.83}$$

with $n_\theta \in \mathbb{N}^*$ being the "azimuthal quantum number" (i.e. the second quantum number), to remember that it is related to the quantization of the polar angle.

From this last relation we also get:

$$p_\theta = n_\theta \hbar = mr^2\dot{\theta} \Leftrightarrow \frac{\mathrm{d}\theta}{\mathrm{d}t} = \frac{n_\theta \hbar}{mr^2} \tag{11.1.84}$$

Let us come back to:

$$p = \frac{K^2}{\mu} = \frac{\left(r^2\dfrac{\mathrm{d}\theta}{\mathrm{d}t}\right)^2}{\dfrac{kZe^2}{m}} \tag{11.1.85}$$

That give us:

$$\boxed{p = \frac{\left(\dfrac{n_\theta \hbar}{m}\right)^2}{\dfrac{kZe^2}{m}} = n_\theta^2 \frac{\hbar^2}{mkZe^2}} \tag{11.1.86}$$

Let us focus now to determine the eccentricity e of the path (notation not to be confused with the electrical charge if possible!).

This give us:

$$e = \sqrt{1 + \frac{2}{\mu^2}EK^2} = \sqrt{1 + \frac{2}{\left(\dfrac{k^2Z^2e^4}{m^2}\right)} \frac{E_{\text{tot}}}{m} \frac{n_\theta^2 \hbar^2}{m^2}} = \sqrt{1 + \frac{2E_{\text{tot}} n_\theta^2 \hbar^2}{mk^2Z^2e^4}} \tag{11.1.87}$$

To determine the quantization of the angular momentum with respect to the radial variable, we will use a substitution:

$$\oint p_r \mathrm{d}r = \oint m\dot{r}\mathrm{d}r = n_r h \tag{11.1.88}$$

By simply denoting r' the derivative $\mathrm{d}r/\mathrm{d}\theta$, the integral will be written:

$$\oint m\dot{r}\mathrm{d}r = \int\limits_0^{2\pi} m{r'}_2\dot{\theta}\mathrm{d}\theta = p_\theta \int\limits_0^{2\pi} \frac{r'^2}{r^2}\mathrm{d}\theta \tag{11.1.89}$$

where we used $\dot{\theta} = p_\theta/(mr^2)$ as we have already prove it.

Reporting it:

$$r(\theta) = \frac{p}{1 + e\cos(\theta)} \tag{11.1.90}$$

in the integral of the radial momentum, we get (easy to obtain but you can ask for the details if needed as always):

$$b_r = n_r h = 2\pi\left(\frac{1}{\sqrt{1-e^2}} - 1\right)p_\theta \tag{11.1.91}$$

from which we deduce given $p_\theta = n_\theta \hbar$ that:

$$b_r = n_r h = 2\pi\left(\frac{1}{\sqrt{1-e^2}} - 1\right)n_\theta \hbar \tag{11.1.92}$$

which brings us to:

$$e = \sqrt{1 - \frac{1}{\left(\dfrac{n_\theta + n_r}{n_\theta}\right)^2}} \tag{11.1.93}$$

and therefore:

$$1 - \frac{1}{\left(\dfrac{n_\theta + n_r}{n_\theta}\right)^2} = e^2 = 1 + \frac{2E_{\text{tot}} n_\theta^2 \hbar^2}{mk^2 Z^2 e^4} \tag{11.1.94}$$

After some elementary algebraic simplifications we finally get:

$$\boxed{E_{\text{tot}}^n = \frac{-mZ^2 e^4}{8\varepsilon_0 h^2 (n_\theta + n_r)^2}} \tag{11.1.95}$$

where r, also named "radial quantum number" can be null! Because this is the case when $\dot{r} = 0$, that is to say, if the trajectory is a circle (special case of Bohr model!!!).

We introduce then an integer n so named "principal quantum number" as:

$$\boxed{n = n_r + n_\theta} \tag{11.1.96}$$

with $n \in \mathbb{N}^*$.

Sommerfeld and Wilson the proved that the orbital Bohr model must be determined by these two new quantum numbers:

✍**Example:**

For $n = 2$ we have two possible sub-orbital:

$$n = 2 = n_r + n_\theta \begin{cases} 2 = 1 + 1 \\ 2 = 2 + 0 \end{cases} \tag{11.1.97}$$

The value $n_\theta = 0$ is impossible by definition because it would mean that the minor axis is zero (ellipse degenerated into a line) and the electron can not pass through the nucleus (in the classical model at least...). So the smallest possible integer value for n_θ is 1.

There is therefore n orbits giving the same spectral term. In other words, there are n times the same quantization energy. We also say that the energy level (total) E_n is "n times degenerated".

The idea of Sommerfeld was to account the richness of the observed spectra. From this point of view, the results are disappointing: the quantification of all degrees of freedom clearly shows more states (now we need two quantum numbers to completely specify the state, while the Bohr model only considers one) but the additional degree only introduces an energy degeneration (sad!).

To summarize this model, so there is exactly the same number of energy levels and therefore the same number of transitions of possible energy states than the Bohr model. At the spectral point of view, the Sommerfeld-Wilson theory does nothing more than that of Bohr except that the orbits are elliptical and therefore does not explain the extent of the observed spectra.

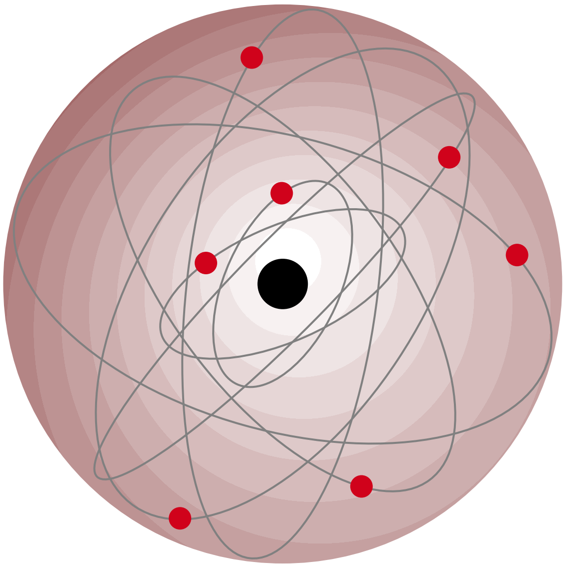


Figure 11.14: The eccentric... Sommerfeld approach...

In fact, the idea is going to be from now to take again the same model but by adding relativistic corrections. The work will necessarily be longer but oh so successful!

11.1.6 Relativistic Sommerfeld Model

However, the Sommerfeld-Wilson's model can be considered incomplete if we do not take into account changes in parameters engendered by the results of the theory of Special Relativity (see section Special Relativity page 5627) as did Sommerfeld a few years after (see [506]).

By assuming that the relativity of time would cause the mass of an electron moving in an elliptical orbit to increase as it approaches perihelion (or perinucleon) where the tangential velocity is maximum and decrease as it recedes from perihelion, Sommerfeld introduced a perturbation into the equation of motion that produced a precession of the perihelion that accounted for the fine structure in the spectral lines. The fine structure in the spectral lines was first identified in 11887 (holocene calendar) by Michelson and Morley yet it went unexplained by the Bohr model. Sommerfeld's correction to the hydrogen atom was based on an analogy with Einstein's relativistic correction to Newton's model of the solar system. The anomalous precession of the perihelion of Mercury amounted to a fine structure of the planetary orbits that could not be explained by Newton's law of gravitation. Einstein's relativistic correction accounted for the fine structure of the solar system; Sommerfeld's relativistic correction accounted for the fine structure of the spectral lines of hydrogen!

Remark

The section of Quantum Relativistic Quantum Physics is reserved solely to the study of probabilistic quantum physics based on the relativistic version of the Schrödinger equation (so strictly speaking the Relativistic Quantum Physics section should be named "Relativistic Wave Quantum Physics"). This is why it seemed to us more appropriate to put a corpuscular model, deterministic and relativistic (opposite of a wave model, probabilistic and relativistic) such as we will now study in the section of Corpuscular Quantum Physics.

Indeed, as we have proved in the development of the Bohr model, the kinetic energy of the electron is given by:

$$E_c^n=\frac{1}{2}mv^2=\frac{Z^2e^4m}{8\varepsilon_0^2n^2h^2} \tag{11.1.98}$$

That give us:

$$v=\frac{Ze^2}{2\varepsilon_0 nh} \tag{11.1.99}$$

For hydrogen and the level $n=1$, we find $v=2.19\cdot 10^{19}\;[\text{ms}^{-1}]$ and as Michelson-Morley factor (see section Special Relativity page 5636):

$$\frac{1}{\sqrt{1-\beta^2}}=\frac{1}{\sqrt{1-\left(\dfrac{v}{c}\right)^2}}\cong 1.00002667 \tag{11.1.100}$$

What the reader can quickly check with the then English version of Microsoft® Excel®:

```
=1/ROOT(1-(1*(1.60217656E-19)^2/(2*8.854187E-12*1*6.62068E-34))^2/(299792458)^2)
```

For sure the change is small but spectrometry values were so accurate that it was necessary to introduce Special Relativity to accommodate these tiny variations and thus validate the theory by experiment.

Remark

As we can easily see it, the relation shows that the particle is more away from the nucleus (n large) more its speed is low. This result has been confirmed experimentally by replacing the electron artificially by a muon and scientists have found that the lifetime of the latter slightly increased with the value of n.

Let us determine in the order of things, the expression of quantification conditions with the relativistic factors. Before we begin, it is important to understand that we consider the nucleus as fixed and as a repository of our system. Thus, compared to the referential, the mass of the electron undergoes a relativistic variation but not the electric potential (we should take into account the variation of the latter - as it is energy - if and only if the repository was the electron itself).

In relativistic dynamics (see section Special Relativity page 5679), we proved that the kinetic energy (in the form of Lagrangian notation Lagrangian with "T" instead of E_c) is expressed in the form:

$$T=mc^2-m_0c^2=mc^2\left(1-\sqrt{1-\beta^2}\right) \tag{11.1.101}$$

The potential energy (in Lagrangian notation with "V" instead of E_p) not undergoing relativistic variation, we always have:

$$V=-k\frac{Ze^2}{r} \tag{11.1.102}$$

The Lagrangian is therefore:

$$L=T-V=mc^2\left(1-\sqrt{1-\beta^2}\right)+k\frac{Ze^2}{r} \tag{11.1.103}$$

By working in polar coordinates, where the velocity has for expression (see section Vector Calculus page 1863):

$$v^2=\dot{r}^2+r^2\dot{\theta}^2 \tag{11.1.104}$$

Therefore:

$$\beta=\left(\frac{v}{c}\right)^2=\frac{\dot{r}^2+r^2\dot{\theta}^2}{c^2} \tag{11.1.105}$$

The Sommerfeld quantization conditions being:

$$\begin{aligned}b_r&=\oint p_r\mathrm{d}r=n_rh\\ b_\theta&=\oint p_\theta\mathrm{d}\theta=n_\theta h\end{aligned} \tag{11.1.106}$$

Now we must seek relativistic expressions for b_r and b_θ.

Let us begin p_r:

$$p_r=\frac{\partial L}{\partial\dot{r}}=\frac{\partial}{\partial\dot{r}}\left[mc^2(1-\sqrt{1-\beta^2})+k\frac{Ze^2}{r}\right] \tag{11.1.107}$$

with:

$$\beta^2=\frac{1}{c^2}\left(\dot{r}^2+r^2\dot{\theta}^2\right) \tag{11.1.108}$$

Therefore:

$$\begin{aligned}m_ec^2\frac{\partial}{\partial\dot{r}}\left(mc^2(1-\sqrt{1-\beta^2})\right)^{1/2}&=-m_ec^2\left[\frac{1}{2}(1-\beta^2)^{-1/2}\right]\frac{\partial}{\partial\dot{r}}(1-\beta^2)\\ \frac{\partial}{\partial\dot{r}}(1-\beta^2)=-\frac{\partial}{\partial\dot{r}}\beta^2=-\frac{1}{c^2}\frac{\partial}{\partial\dot{r}}v^2&=-\frac{1}{c^2}\frac{\partial}{\partial\dot{r}}\left(\dot{r}^2+r^2\dot{\theta}^2\right)=-\frac{2\dot{r}}{c^2}\end{aligned} \tag{11.1.109}$$

This gives:

$$mc^2\left[\frac{1}{2}(1-\beta^2)^{-1/2}\right]\left(-\frac{2\dot{r}}{c^2}\right)=\frac{mc^22\dot{r}}{2(1-\beta^2)^{1/2}c^2}=\frac{m\dot{r}}{(1-\beta^2)^{1/2}} \tag{11.1.110}$$

As:

$$\frac{\partial}{\partial\dot{r}}k\frac{Ze^2}{r}=0 \tag{11.1.111}$$

We finally have:

$$p_r=\frac{m\dot{r}}{(1-\beta^2)^{1/2}} \tag{11.1.112}$$

The first quantification condition gives therefore:

$$\boxed{b_r=\oint p_r\mathrm{d}r=\oint\frac{m\dot{r}}{(1-\beta^2)^{1/2}}\mathrm{d}r=n_rh} \tag{11.1.113}$$

For p_θ:

$$p_\theta=\frac{\partial L}{\partial\dot{\theta}}=\frac{\partial}{\partial\dot{\theta}}\left[mc^2(1-\sqrt{1-\beta^2})+k\frac{Ze^2}{r}\right] \tag{11.1.114}$$

always with:

$$\beta^2=\frac{1}{c^2}(\dot{r}^2+r^2\dot{\theta}^2) \tag{11.1.115}$$

Therefore:

$$\begin{gathered}mc^2\frac{\partial}{\partial\dot{\theta}}(1-\sqrt{1-\beta^2})=-mc^2\left[\frac{1}{2}(1-\beta^2)^{-1/2}\right]\frac{\partial}{\partial\dot{\theta}}(1-\beta^2)\\ \frac{\partial}{\partial\dot{\theta}}(1-\beta^2)=-\frac{\partial}{\partial\dot{\theta}}\beta^2=-\frac{1}{c^2}\frac{\partial}{\partial\dot{\theta}}(\dot{r}^2+r^2\dot{\theta}^2)=-\frac{2r^2\dot{\theta}}{c^2}\end{gathered} \tag{11.1.116}$$

Which gives:

$$-mc^2\left[\frac{1}{2}(1-\beta^2)^{-1/2}\left(-\frac{2r^2\dot{\theta}}{c^2}\right)\right]=\frac{mr^2\dot{\theta}}{(1-\beta)^{1/2}} \tag{11.1.117}$$

As:

$$\frac{\partial}{\partial\dot{\theta}}k\frac{Ze^2}{r}=0 \tag{11.1.118}$$

we finally have:

$$p_\theta=\frac{mr^2\dot{\theta}}{(1-\beta^2)^{1/2}} \tag{11.1.119}$$

The second quantification condition is therefore written:

$$\boxed{b_\theta=\oint p_\theta\mathrm{d}\theta=\oint\frac{mr^2\dot{\theta}}{(1-\beta^2)^{1/2}}\mathrm{d}\theta=n_\theta h} \tag{11.1.120}$$

In summary, the conditions of quantification for the relativistic atom of Sommerfeld are:

$$b_r=\oint\frac{m\dot{r}}{(1-\beta^2)^{1/2}}\mathrm{d}r=n_rh \quad \text{and} \quad b_\theta=\oint\frac{mr^2\dot{\theta}}{(1-\beta^2)^{1/2}}\mathrm{d}\theta=n_\theta h \tag{11.1.121}$$

We could, seeing the bot above results, conclude a little bit too quickly by thinking it would suffice to multiply the two conditions of quantification by the Michelson-Morley factor relative to the relativistic mass transformation. But, such a shortcut is completely wrong and all but rigorous! Indeed, if you apply this reasoning, it would be sufficient to take the expression of the total energy of the non-relativistic Sommerfeld-Wilson model and introduce everywhere where the mass appears the Michelson-Morley factor. However the result we get following this way has absolutely nothing in common with the result that we will get further below. So we must always be careful and work as a mathematician: without leapfrogging!

The total relativistic energy of the atom (sum of kinetic energy, mass energy and the potential energy of the electric field for the whole atom) is given by:

$$E_{\text{tot}}=\frac{mc^2}{(1-\beta^2)^{1/2}}-k\frac{Ze^2}{r} \tag{11.1.122}$$

Indeed, using the notation of the section of Special Relativity:

$$E_{\text{tot}}=E_c+E_{\text{m}}+E_p=\underbrace{E_c+m_0c^2}_{=mc^2}+\left(-k\frac{Ze^2}{r}\right)=mc^2+\left(-k\frac{Ze^2}{r}\right)=\frac{m_0c^2}{\sqrt{1-\beta^2}}+\left(-k\frac{Ze^2}{r}\right) \tag{11.1.123}$$

Now, as part of the study of particle quantum physics, it is (unfortunately) usage to write the rest mass with the symbol of the relativistic mass as:

$$m_0=m \tag{11.1.124}$$

Therefore:

$$E_{\text{tot}}=\frac{mc^2}{\sqrt{1-\beta^2}}+\left(-k\frac{Ze^2}{r}\right) \tag{11.1.125}$$

We must express this total energy in function of the quantization conditions. There's a long mathematical work to do but necessary to achieve the result of our study.

Given the calculation of the expression:

$$\frac{p_\theta^2}{r^2}+p_r^2 \tag{11.1.126}$$

with:

$$p_\theta=\frac{mr^2\dot{\theta}}{\sqrt{1-\beta^2}} \quad \text{and} \quad p_r=\frac{m\dot{r}}{\sqrt{1-\beta^2}} \tag{11.1.127}$$

Squaring:

$$p_\theta=\frac{mr^2\dot{\theta}}{\sqrt{1-\beta^2}}\rightarrow\frac{p_\theta^2}{r^2}=\frac{m^2r^2\dot{\theta}^2}{1-\beta^2} \quad \text{and} \quad p_r^2=\frac{m^2\dot{r}^2}{1-\beta^2} \tag{11.1.128}$$

Therefore:

$$\frac{p_\theta^2}{r^2}+p_r^2=\frac{m^2r^2\dot{\theta}^2}{1-\beta^2}+\frac{m^2\dot{r}^2}{1-\beta^2}=\frac{m^2(\dot{r}^2+r^2\dot{\theta}^2)}{1-\beta^2}=\frac{m^2v^2}{1-\beta^2} \tag{11.1.129}$$

We add of both sides of the equality m^2c^2 (in the idea to include the mass energy as you'll see some lines below), which gives:

$$\begin{aligned}m^2c^2+\frac{p_\theta^2}{r^2}+p_r^2=m^2c^2+\frac{m^2v^2}{1-\beta^2}&=m^2c^2+\frac{m^2\dfrac{v^2}{c^2}c^2}{1-\beta^2}\\&=\frac{m^2c^2(1-\beta^2)+m^2\beta^2c^2}{1-\beta^2}=\frac{m^2c^2}{1-\beta^2}\end{aligned} \tag{11.1.130}$$

By multiplying both sides by c^2 we get:

$$c^2\left(m^2c^2+\frac{p_\theta^2}{r^2}+p_r^2\right)=\frac{m^2c^4}{1-\beta^2} \tag{11.1.131}$$

Extracting the square root:

$$\sqrt{c^2\left(m^2c^2+\frac{p_\theta^2}{r^2}+p_r^2\right)}=\frac{mc^2}{\sqrt{1-\beta^2}} \tag{11.1.132}$$

If we introduce this last relation in the expression of the total energy we get:

$$\boxed{E_{\text{tot}}=c\sqrt{m^2c^2+\frac{p_\theta^2}{r^2}+p_r^2}-k\frac{Ze^2}{r}} \tag{11.1.133}$$

Now it remains to us to determine the expressions of $N-r$ and n_θ according to p_r and p_θ.

The integral of quantification of the azimuthal angle is immediate:

$$b_\theta=\oint\frac{mr^2\dot{\theta}}{(1-\beta^2)^{1/2}}\mathrm{d}\theta=\int\limits_0^{2\pi}\frac{mr^2\dot{\theta}}{(1-\beta^2)^{1/2}}\mathrm{d}\theta=\frac{mr^2\dot{\theta}}{(1-\beta^2)^{1/2}}\theta\bigg|_0^{2\pi}=\frac{2\pi mr^2\dot{\theta}}{(1-\beta^2)^{1/2}}=n_\theta h \tag{11.1.134}$$

Therefore:

$$\boxed{\frac{mr^2\dot{\theta}}{(1-\beta^2)^{1/2}}=p_\theta=n_\theta\hbar} \tag{11.1.135}$$

The integral of quantification of the radius-vector requires a more significant development:

$$b_r=\oint\frac{m\dot{r}}{(1-\beta^2)^{1/2}}\mathrm{d}r=n_rh \tag{11.1.136}$$

Then come long and joyful mathematical developments...

Reusing the expression of the total energy:

$$E_{\text{tot}}=c\sqrt{m^2c^2+\frac{p_\theta^2}{r^2}+p_r^2}-k\frac{Ze^2}{r} \tag{11.1.137}$$

We get:

$$\left(E_{\text{tot}}+k\frac{Ze^2}{r}\right)=c\sqrt{m^2c^2+\frac{p_\theta^2}{r^2}+p_r^2} \tag{11.1.138}$$

By squaring and by making a few changes:

$$\left(E_{\text{tot}}+k\frac{Ze^2}{r}\right)^2=c^2\left(m^2c^2+\frac{p_\theta^2}{r^2}+p_r^2\right) \tag{11.1.139}$$

$$\frac{1}{c^2}\left(E_{\text{tot}}+k\frac{Ze^2}{r}\right)^2=m^2c^2+p_r^2+\frac{p_\theta^2}{r^2} \tag{11.1.140}$$

$$p_r^2=\frac{1}{c^2}\left(E_{\text{tot}}+k\frac{Ze^2}{r}\right)^2-m^2c^2-\frac{p_\theta^2}{r^2} \tag{11.1.141}$$

Therefore:

$$\begin{aligned}p_r^2&=\frac{1}{c^2}\left(E_{\text{tot}}^2+\frac{k^2Z^2e^4}{r^2}+2E_{\text{tot}}\frac{kZe^2}{r}\right)-m^2c^2-\frac{p_\theta^2}{r^2}\\&=\frac{E_{\text{tot}}^2}{c^2}+\frac{k^2Z^2e^4}{c^2r^2}+2\frac{E_{\text{tot}}}{c^2}\frac{kZe^2}{r}-m^2c^2-\frac{p_\theta^2}{r^2}\\&=\left(\frac{E_{\text{tot}}^2}{c^2}-m^2c^2\right)+\frac{k^2Z^2e^4}{c^2r^2}+2\frac{E_{\text{tot}}}{c^2}\frac{kZe^2}{r}-\frac{p_\theta^2}{r^2}\end{aligned} \tag{11.1.142}$$

Working on the bracketed term, we will put it as being equal to A as:

$$A=\frac{E_{\text{tot}}^2}{c^2}-m^2c^2 \tag{11.1.143}$$

By adding and subtracting $2E_{\text{tot}}m$ and decomposing the term $-m^2c^2$ in $m^2c^2-2m^2c^2$ and then by regrouping:

$$\begin{aligned}A&=\left[\frac{E_{\text{tot}}^2}{c^2}+2E_{\text{tot}}m-2E_{\text{tot}}m\right]+[m^2c^2-2m^2c^2]\\&=\left[\frac{E_{\text{tot}}^2}{c^2}-2E_{\text{tot}}m+m^2c^2\right]+[2E_{\text{tot}}m-2m^2c^2]\\&=\frac{2E_{\text{tot}}^2-2E_{\text{tot}}mc^2+m^2c^4}{c^2}+[2E_{\text{tot}}m-2m^2c^2]=\frac{(2E_{\text{tot}}-mc^2)^2}{c^2}+2m(2E_{\text{tot}}-mc^2)\end{aligned} \tag{11.1.144}$$

We will put for the simplification of the calculations (to reduce the number of terms to handle):

$$E'=E_{\text{tot}}-mc^2 \tag{11.1.145}$$

Therefore we get:

$$A=\frac{E'^2}{c^2}=E_{\text{tot}}+2mE' \tag{11.1.146}$$

By taking m^2c^2 in evidence, we have:

$$A=m^2c^2\left(\frac{E'^2}{m^2c^4}+2\frac{E'}{mc^2}\right) \tag{11.1.147}$$

By adding and subtracting 1 in the parenthesis:

$$A=m^2c^2\left[\left(\frac{E'^2}{m^2c^4}+2\frac{E'}{mc^2}+1\right)-1\right]=m^2c^2\left[\left(1+\frac{E'}{mc^2}\right)^2-1\right] \tag{11.1.148}$$

$$\frac{k^2Z^2e^4}{c^2r^2}+2\frac{E_{\text{tot}}}{c^2}\frac{kZe^2}{r}-\frac{p_\theta^2}{r^2} \tag{11.1.149}$$

As $E_{\text{tot}}=E'+mc^2$ we have:

$$2\frac{kZe^2(E'+mc^2)}{rc^2}+\frac{k^2Z^2e^4}{c^2r^2}-\frac{p_\theta^2}{r^2}=\frac{2}{r}\frac{kZe^2(E'+mc^2)}{c^2}+\frac{k^2Z^2e^4}{c^2r^2}-\frac{p_\theta^2}{r^2} \tag{11.1.150}$$

By putting:

$$B=k\frac{Ze^2E'}{c^2}+kmZe^2 \tag{11.1.151}$$

By putting also:

$$C=\frac{k^2Z^2e^4}{c^2}-n_\theta^2\hbar^2 \tag{11.1.152}$$

as $p_\theta=n_\theta\hbar$

Sommerfeld then introduced what he named the "fine-structure constant α" defined by the relation:

$$\boxed{\alpha=\frac{e^2}{\hbar c}\cong\frac{1}{137.0359911}=7.29735\cdot 10^{-3}} \tag{11.1.153}$$

We will meet this constant again in the section of Particle Physics.

Remark

The fine-structure constant is one of the most important physical constants. First, because it is dimensionless, and secondly because it is so far the best known (in terms of accuracy) of all constants and thirdly, because it depends only on terms that seem to be fundamental constants of the atomic world. So physicists and astrophysicists are looking to see if the value of this constant varies over time, which would imply immediately that at least one of the implicit constant is not timeless.

Caution!!!! In quantum electrodynamics the renormalization group dictates how the strength of the electromagnetic interaction grows logarithmically as the relevant energy scale increases. The value of the fine-structure constant α is linked to the observed value of this coupling associated with the energy scale of the electron mass: the electron's mass gives a lower bound for this energy scale, because it (and the positron) is the lightest charged object whose quantum loops can contribute to the running. Therefore, $1/137.03600$ is the "asymptotic value of the fine-structure constant at zero energy". At higher energies, such as the scale of the Z boson, about 90 $[\text{GeV}]$, one instead measures an effective $\alpha\approx 1/127$ (see [194] for more information).

Given the fine-structure constant, we write:

$$C=k^2Z^2\left(\frac{e^4}{c^2\hbar^2}\right)-n_\theta^2\hbar^2=k^2Z^2\alpha^2\hbar^2-n_\theta^2\hbar^2=-n_\theta^2\hbar^2\left(1-\frac{k^2Z^2\alpha^2}{n_\theta^2}\right) \quad (11.1.154)$$

To summarize:

$$p_r=\pm\sqrt{A+\frac{2B}{r}+\frac{C}{r^2}} \quad (11.1.155)$$

With:

$$\begin{aligned}A&=\frac{E'^2}{c^2}+2mE'=m^2c^2\left[\left(1+\frac{E'}{mc^2}\right)^2-1\right]\\ B&=\frac{kZe^2E'}{c^2}+kmZe^2\\ C&=-n_\theta^2\hbar^2\left(1-\frac{k^2Z^2\alpha^2}{n_\theta^2}\right)\end{aligned} \quad (11.1.156)$$

So we arrive at the following integral:

$$\oint p_r\mathrm{d}r=\oint\frac{m\dot{r}}{\sqrt{1-\beta^2}}\dot{r}\mathrm{d}r=\oint\sqrt{A+\frac{2B}{r}+\frac{C}{r^2}}\mathrm{d}r=n_rh \quad (11.1.157)$$

The residue theorem (see section Complex Analysis page 2440) applied to the preceding integral gives for expression:

$$\oint\sqrt{A+\frac{2B}{r}+\frac{C}{r^2}}\mathrm{d}r=2\pi\mathrm{i}\sum r_i \quad (11.1.158)$$

We see that there is a trivially a pole at origin $r=0$.

We will calculate the residue at this point going to the limit $r=0$. We put for this:

$$f(r)=\sqrt{A+\frac{2B}{r}+\frac{C}{r^2}} \quad (11.1.159)$$

Passing to the limit built on the basis of the residue theorem:

$$\lim_{r\to0}rf(r)=\lim_{r\to0}\sqrt{Ar^2+2Br+C}=\sqrt{C} \quad (11.1.160)$$

The residue corresponding to the pole $r=0$ is then:

$$r_1=\sqrt{C} \quad (11.1.161)$$

We also see that there is a second residue at infinity $r=+\infty$ and to calculate it, we make again a change of variable. We put (according to the method that we saw in the section of Complex Analysis):

$$z=\frac{1}{r}\Rightarrow\mathrm{d}z=-\frac{\mathrm{d}r}{r^2}=-z^2\mathrm{d}r\Rightarrow\mathrm{d}r=-\frac{\mathrm{d}r}{z^2} \quad (11.1.162)$$

The integral is then written:

$$\oint\sqrt{A+\frac{2B}{r}+\frac{C}{r^2}}\mathrm{d}r=\oint\sqrt{A+2Bz+Cz^2}\left(-\frac{\mathrm{d}z}{z^2}\right)=\oint-\frac{\sqrt{A}}{z^2}\sqrt{1+\frac{2B}{A}z+\frac{C}{A}z^2}\mathrm{d}z \tag{11.1.163}$$

To find the residue, we will make a Laurent series expansion of:

$$-\frac{\sqrt{A}}{z^2}\sqrt{1+\frac{2B}{A}z+\frac{C}{A}z^2} \tag{11.1.164}$$

around this pole of zero value. To do this, we put:

$$u=\frac{2B}{A}z+\frac{C}{A}z^2 \tag{11.1.165}$$

We know the Taylor expansion (see section Sequences and Series page 1703) of the resulting expression of this variable change:

$$\sqrt{1+u}=1+\frac{1}{2}u-\frac{1}{8}u^2+\ldots \tag{11.1.166}$$

Applied to the radical, we get:

$$\sqrt{1+\frac{2B}{A}z+\frac{C}{A}z^2}=1+\frac{1}{2}\left(\frac{2B}{A}z+\frac{C}{A}z^2\right)-\frac{1}{8}\left(\frac{2B}{A}z+\frac{C}{A}z^2\right)^2+\ldots \tag{11.1.167}$$

It comes then automatically the Laurent series (nice!):

$$\begin{aligned}-\frac{\sqrt{A}}{z^2}\sqrt{1+\frac{2B}{A}z+\frac{C}{A}z^2}&=\frac{\sqrt{A}}{z^2}-\frac{\sqrt{A}}{2z^2}\left(\frac{2B}{A}z+\frac{C}{A}z^2\right)+\frac{\sqrt{A}}{8z^2}\left(\frac{2B}{A}z+\frac{C}{A}z^2\right)^2-\ldots\\&=-\frac{\sqrt{A}}{z^2}-\underbrace{\frac{\sqrt{A}B}{A}}_{\text{residue}}\frac{1}{z}-\frac{\sqrt{A}C}{2A}+\frac{\sqrt{A}}{8z^2}\left(\frac{4B^2z^2}{A^2}+\frac{C^2}{A}z^4+\frac{2BC}{A^2}z^3\right)-\ldots\end{aligned} \tag{11.1.168}$$

where we see quite quickly that the pole is of order 2.

The second residue is the coefficient on $1/z$:

$$r_2=-\frac{B}{\sqrt{A}} \tag{11.1.169}$$

Indeed, we have simply applied the relation proved in the section of Complex Analysis:

$$\text{Res}[g(z);0]=-\lim_{t\to 0}\frac{1}{(k-1)!}\frac{\mathrm{d}^{k-1}}{\mathrm{d}z^{k-1}}\left[z^k\frac{1}{z^2}f\left(\frac{1}{z}\right)\right] \tag{11.1.170}$$

$$\oint\sqrt{A+\frac{2B}{r}+\frac{C}{r^2}}\mathrm{d}r=2\pi\mathrm{i}\sum r_i=2\pi\mathrm{i}\left(\sqrt{C}-\frac{B}{\sqrt{A}}\right)=n_rh \tag{11.1.171}$$

With:

$$\sqrt{C}=\sqrt{-n_\theta^2\hbar^2\left(1-\frac{k^2Z^2\alpha^2}{n_\theta^2}\right)}=\mathrm{i}n_\theta\hbar\sqrt{1-\frac{k^2Z^2\alpha^2}{n_\theta^2}} \tag{11.1.172}$$

For the calculation of $\dfrac{B}{\sqrt{A}}$ we have:

$$\begin{aligned}\frac{B}{\sqrt{A}}&=\frac{\dfrac{kZe^2E'}{c^2}+kmZe^2}{\sqrt{m^2c^2\left[\left(1+\dfrac{E'}{mc^2}\right)^2-1\right]}}=\frac{\dfrac{kZe^2E'}{mc^3}+\dfrac{kZe^2}{c}}{\sqrt{\left(1+\dfrac{E'}{mc^2}\right)^2-1}}=\frac{\dfrac{kZe^2E'}{mc^3}+\dfrac{kZe^2}{c}}{\mathrm{i}\sqrt{1-\left(1+\dfrac{E'}{mc^2}\right)^2}}\\&=-\mathrm{i}\frac{\dfrac{kZe^2E'}{mc^3}+\dfrac{kZe^2}{c}}{\sqrt{1-\left(1+\dfrac{E'}{mc^2}\right)^2}}\end{aligned} \tag{11.1.173}$$

Therefore the curvilinear integral has for expression:

$$\boxed{2\pi\mathrm{i}\left(\mathrm{i}n_\theta\hbar\sqrt{1-\frac{k^2Z^2\alpha^2}{n_\theta^2}}\right)-2\pi\mathrm{i}\left[-\mathrm{i}\frac{\dfrac{kZe^2E'}{mc^3}+\dfrac{kZe^2}{c}}{\sqrt{1-\left(1+\dfrac{E'}{mc^2}\right)^2}}\right]=n_rh} \tag{11.1.174}$$

After simplification:

$$-n_\theta h\sqrt{1-\frac{k^2Z^2\alpha^2}{n_\theta^2}}-\frac{2\pi\left(\frac{kZe^2E'}{mc^3}+\frac{kZe^2}{c}\right)}{\sqrt{1-\left(1+\frac{E'}{mc^2}\right)^2}}=n_rh$$

$$-\frac{\frac{2\pi kZe^2E'}{mc^3}+\frac{2\pi kZe^2}{c}}{\sqrt{1-\left(1+\frac{E'}{mc^2}\right)^2}}=n_\theta h\sqrt{1-\frac{k^2Z^2\alpha^2}{n_\theta^2}}+n_rh$$

$$-\frac{\frac{2\pi kZe^2E'}{mc^3h}+\frac{2\pi kZe^2}{ch}}{\sqrt{1-\left(1+\frac{E'}{mc^2}\right)^2}}=n_\theta\sqrt{1-\frac{k^2Z^2\alpha^2}{n_\theta^2}}+n_r=n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\tag{11.1.175}$$

$$-\frac{\sqrt{1-\left(1+\frac{E'}{mc^2}\right)^2}}{\frac{2\pi kZe^2E'}{mc^3h}+\frac{2\pi kZe^2}{ch}}=\frac{1}{n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}}$$

$$-\frac{\sqrt{1-\left(1+\frac{E'}{mc^2}\right)^2}}{kZ\underbrace{\frac{2\pi e^2}{ch}}_{=\alpha}\left(\frac{E'}{mc^2}+1\right)}=\frac{1}{n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}}$$

Finally:

$$-\frac{\sqrt{1-\left(1+\frac{E'}{mc^2}\right)^2}}{kZ\left(\frac{E'}{mc^2}+1\right)}=\frac{\alpha}{n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}}\tag{11.1.176}$$

We raise squared and at each line below we simplify and rearrange:

$$\begin{aligned}
-\frac{1-\left(1+\dfrac{E'}{mc^2}\right)^2}{k^2Z^2\left(\dfrac{E'}{mc^2}+1\right)}&=\frac{\alpha^2}{\left(n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\right)^2}\\
-\frac{1-\left(1+\dfrac{E'}{mc^2}\right)^2}{\left(\dfrac{E'}{mc^2}+1\right)}&=\frac{k^2Z^2\alpha^2}{\left(n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\right)^2}\\
\frac{1}{\left(1+\dfrac{E'}{mc^2}\right)^2}-1&=\frac{k^2Z^2\alpha^2}{\left(n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\right)^2}\\
\frac{1}{\left(1+\dfrac{E'}{mc^2}\right)^2}&=1+\frac{k^2Z^2\alpha^2}{\left(n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\right)^2}\\
1+\frac{E'}{mc^2}&=\left[1+\frac{k^2Z^2\alpha^2}{\left(n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\right)^2}\right]^{-1/2}
\end{aligned}\tag{11.1.177}$$

Therefore:

$$\frac{E'}{mc^2}=-1+\left[1+\frac{k^2Z^2\alpha^2}{\left(n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\right)^2}\right]^{-1/2}\tag{11.1.178}$$

hence:

$$\begin{aligned}
E'&=mc^2\left\{-1+\left[1+\frac{k^2Z^2\alpha^2}{\left(n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\right)^2}\right]^{-1/2}\right\}\\
&=-mc^2\left\{1-\left[1+\frac{k^2Z^2\alpha^2}{\left(n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\right)^2}\right]^{-1/2}\right\}
\end{aligned}\tag{11.1.179}$$

We put $n=n_r+n_\theta$. By working on the denominator:

$$n_r+\sqrt{n_\theta^2-k^2Z^2\alpha^2}\tag{11.1.180}$$

we can transform:

$$n_r+n_\theta\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}\tag{11.1.181}$$

By adding and subtracting n_θ:

$$(n_r+n_\theta)+n_\theta\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right)=n+n_\theta\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right) \tag{11.1.182}$$

Therefore:

$$E'=-mc^2\left\{1-\left[1+\frac{k^2Z^2\alpha^2}{\left[n+n_\theta\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right)\right]^2}\right]^{-1/2}\right\} \tag{11.1.183}$$

or also:

$$E'=-mc^2\left\{1-\left[1+\frac{k^2Z^2\left(\frac{\alpha}{n}\right)^2}{\left[1+\frac{n_\theta}{n}\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right)\right]^2}\right]^{-1/2}\right\} \tag{11.1.184}$$

or also:

$$E'=-mc^2\left(1-\left\{1+k^2Z^2\left(\frac{\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right)\right]^{-2}\right\}^{-1/2}\right) \tag{11.1.185}$$

We consider in the term:

$$\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right) \tag{11.1.186}$$

the radical that can be written:

$$\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}\left\{1+\left[-\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}^{1/2} \tag{11.1.187}$$

Given the series development (see section Sequences and Series page 1703) in analogy with the previous relation:

$$(1+x)^{1/2}=1+\frac{1}{2}x-\frac{1}{8}x^2+\frac{3}{48}x^3-\ldots \tag{11.1.188}$$

then:

$$\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}=\left\{1+\left[-\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}^{1/2}=1+\frac{1}{2}\left[-\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]-\frac{1}{8}\left[-\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]+\ldots \tag{11.1.189}$$

Therefore:

$$\left\{1+\left[-\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}^{1/2}=1-\frac{1}{2}\left(\frac{kZ\alpha}{n_\theta}\right)^2-\frac{1}{8}\left(\frac{kZ\alpha}{n_\theta}\right)^4+\ldots \tag{11.1.190}$$

As $\dfrac{\alpha}{n_\theta}\ll 1$, we can neglect the terms above the order 2 such that:

$$\left\{1+\left[-\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}^{1/2}\cong 1-\frac{1}{2}\left(\frac{kZ\alpha}{n_\theta}\right)^2 \tag{11.1.191}$$

Finally we can the write:

$$\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right)\cong 1-\frac{1}{2}\left(\frac{kZ\alpha}{n_\theta}\right)^2-1=-\frac{1}{2}\left(\frac{kZ\alpha}{n_\theta}\right)^2 \tag{11.1.192}$$

Working on the term in the brackets we get taking into account our previous result:

$$\begin{aligned}E'&=\left[1+\frac{n_\theta}{n}\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-\right)-1\right]^{-2}\cong\left[1+\frac{n_\theta}{n}\left(-\frac{1}{2}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right)\right]^{-2}\\&=\left[1-\frac{1}{2}\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]^{-2}\end{aligned} \tag{11.1.193}$$

Given the following Taylor series development (see section Sequences and Series page 1703):

$$(1+x)^{-2}=1-2x+3x^2-\ldots \tag{11.1.194}$$

then:

$$\left[1+\left(-\frac{1}{2}\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right)\right]^{-2}=1-2\left[-\frac{1}{2}\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]+3\left[-\frac{1}{2}\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]^2-\ldots \tag{11.1.195}$$

Neglecting terms over order 2 we have finally:

$$\left[1+\frac{n_\theta}{n}\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right]^{-2}\cong 1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2 \tag{11.1.196}$$

Therefore the term between braces can be written:

$$\left\{1\left(\frac{kZ\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right)\right]^{-2}\right\}^{-1/2}\cong\left\{1+\left(\frac{kZ\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\} \tag{11.1.197}$$

We undertake the Taylor series development of the right term between braces using again:

$$(1+x)^{-1/2}=1-\frac{1}{2}x+\frac{3}{8}x^2-\frac{15}{48}x^3+\ldots \tag{11.1.198}$$

Neglecting terms over order 2 we have finally (an approximation of an approximation that is itself an approximation...):

$$\begin{gathered}\left\{1+\underbrace{\left(\frac{kZ\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]}_{:=x}\right\}^{-1/2}\\ \cong 1-\frac{1}{2}\left\{\left(\frac{kZ\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}+\frac{3}{8}\left\{\left(\frac{kZ\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}^2\end{gathered} \tag{11.1.199}$$

By developing the square of the third term, we get:

$$\left\{\left(\frac{kZ\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}^2=\left\{\left(\frac{kZ\alpha}{n}\right)^4\left[1+\underbrace{\left(\frac{n_\theta}{n}\right)^2\left(\frac{kZ\alpha}{n}\right)^4}_{\ll 1}+2\underbrace{\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n}\right)^2}_{\ll 1}\right]\right\} \tag{11.1.200}$$

Therefore:

$$\left\{1+\underbrace{\left(\frac{kZ\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]}_{:=x}\right\}^{-1/2}\cong 1-\frac{1}{2}\left\{\left(\frac{kZ\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}+\frac{3}{8}\left[\left(\frac{kZ\alpha}{n}\right)^2\right]^2 \tag{11.1.201}$$

The total energy of this atom the becomes:

$$\begin{aligned}
{E'}_{n,n_\theta}&=-mc^2\left(1-\left\{1+k^2Z^2\left(\frac{\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\sqrt{1-\left(\frac{kZ\alpha}{n_\theta}\right)^2}-1\right)\right]^{-2}\right\}^{-1/2}\right)\\
&\cong-mc^2\left(1-\left\{1-\frac{1}{2}\left\{\left(\frac{kZ\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}+\frac{3}{8}\left[\left(\frac{kZ\alpha}{n}\right)^2\right]^2\right\}\right)\\
&\cong-mc^2\left(1-\left\{1-\frac{k^2Z^2}{2}\left\{\left(\frac{\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}+\frac{3}{8}\left[\left(\frac{kZ\alpha}{n}\right)^2\right]^2\right\}\right)\\
&=-mc^2\left(\frac{k^2Z^2}{2}\left\{\left(\frac{\alpha}{n}\right)^2\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2\right]\right\}-\frac{3}{8}\left[\left(\frac{kZ\alpha}{n}\right)^2\right]^2\right)\\
&=-\frac{mc^2k^2Z^2\alpha^2}{2n^2}\left[1+\frac{n_\theta}{n}\left(\frac{kZ\alpha}{n_\theta}\right)^2-\frac{3}{4}\left(\frac{kZ\alpha}{n}\right)^2\right]\\
&=-\frac{mc^2k^2Z^2\alpha^2}{2n^2}\left[1+\frac{n_\theta n}{n^2}\left(\frac{kZ\alpha}{n_\theta}\right)^2-\frac{3}{4}\left(\frac{kZ\alpha}{n}\right)^2\right]\\
&=-\frac{mc^2k^2Z^2\alpha^2}{2n^2}\left[1+\frac{n}{n_\theta}\left(\frac{kZ\alpha}{n}\right)^2-\frac{3}{4}\left(\frac{kZ\alpha}{n}\right)^2\right]
\end{aligned}\tag{11.1.202}$$

Finally we get of the expression of the energy:

$${E'}_{n,n_\theta}\cong-\frac{mc^2k^2Z^2\alpha^2}{2n^2}\left\{1+\left(\frac{kZ\alpha}{n}\right)^2\left[\frac{n}{n_\theta}-\frac{3}{4}\right]\right\}\tag{11.1.203}$$

We can give another expression for the energy of the hydrogenoid atom as:

$$k=\frac{1}{4\pi\varepsilon_0}\quad\text{and}\quad\alpha=\frac{e^2}{\hbar c}=\frac{2\pi e^2}{hc}\tag{11.1.204}$$

The expression of the total energy of the hydrogen-like atom becomes then:

$${E'}_{n,n_\theta}\cong-\frac{mc^2\left(\dfrac{1}{16\pi^2\varepsilon_0^2}Z^2\left(\dfrac{4\pi^2e^4}{h^2c^2}\right)\right)}{2n^2}\left\{1+\left[\frac{\dfrac{1}{4\pi\varepsilon_0}Z\dfrac{2\pi e^2}{hc}}{n}\right]^2\left[\frac{n}{n_\theta}-\frac{3}{4}\right]\right\}\tag{11.1.205}$$

Therefore:

$${E'}_{n,n_\theta}\cong-\frac{mZ^2e^4}{8\varepsilon_0^2h^2n^2}\left\{1+\frac{Z^2e^4}{4\varepsilon_0^2h^2c^2n^2}\left[\frac{n}{n_\theta}-\frac{3}{4}\right]\right\}\tag{11.1.206}$$

In the literature, we find other expressions for the total energy that are more interesting than the previous one (because more traditional). So, considering that $n=n_r+n_\theta$, we get:

$${E'}_{n,n_\theta}\cong-\frac{mc^2k^2Z^2\alpha^2}{2n^2}\left\{1+\left(\frac{kZ\alpha}{n}\right)^2\left[\frac{n_r+n_\theta}{n_\theta}-\frac{3}{4}\right]\right\}=-\frac{mc^2k^2Z^2\alpha^2}{2n^2}\left\{1+\left(\frac{kZ\alpha}{n}\right)^2\left[\frac{1}{4}+\frac{n_r}{n_\theta}\right]\right\}\tag{11.1.207}$$

If we seek for an expression using to the Rydberg constant R_H (see above) we get:

$$E'_{n,n_\theta} \cong \underbrace{\frac{me^4}{8\varepsilon_0^2 h^3 c}}_{R_H} Z^2 \frac{hc}{n^2}\left\{1+\frac{Z^2e^2}{4\varepsilon_0^2h^2c^2n^2}\left[\frac{n}{n_\theta}-\frac{3}{4}\right]\right\}=-\frac{hc}{n^2}Z^2R_H\left\{1+\frac{Z^2e^2}{4\varepsilon_0^2h^2c^2n^2}\left[\frac{n}{n_\theta}-\frac{3}{4}\right]\right\} \tag{11.1.208}$$

So the most condensed expression of the total relativistic energy of the hydrogenoid that we can find in the literature and we adopt in this textbook is:

$$\boxed{E'_{n,n_\theta} \cong -\frac{hc}{n^2}Z^2R_H\left\{1+\frac{Z^2e^2}{4\varepsilon_0^2h^2c^2n^2}\left[\frac{n}{n_\theta}-\frac{3}{4}\right]\right\}} \tag{11.1.209}$$

The above relation shows well the existence of a fine structure as the characteristics n_r and $n_\theta$of the electron orbit appear separately in a ratio and not just as a sum as in the first model of Sommerfeld and Wilson.

But strictly speaking, we should write because of the nucleus movement:

$$E'_{n_r,n_\theta} \cong -\frac{\mu Z^2e^4}{8\varepsilon_0^2h^2n^2}\left\{1+\frac{Z^2e^4}{4\varepsilon_0^2h^2c^2n^2}\left[\frac{n}{n_\theta}-\frac{3}{4}\right]\right\} \tag{11.1.210}$$

or:

$$E'_{n_r,n_\theta} \cong -\frac{hc}{n^2}Z^2R'_H\left\{1+\frac{Z^2e^2}{4\varepsilon_0^2h^2c^2n^2}\left[\frac{1}{4}+\frac{n_r}{n_\theta}\right]\right\} \tag{11.1.211}$$

In which the Rydberg constant R'_H is defined as:

$$R'_H=\frac{\mu e^4}{8\varepsilon_0^2h^3c} \tag{11.1.212}$$

However, as the mass of the core is $1,840$ times heavier than that of the electron, we can admit that as a first approximation in the case of the hydrogenous atom:

$$\mu=\frac{m_em_N}{m_e+m_N}=\frac{m_em_p}{m_e+m_p}\cong m_e \tag{11.1.213}$$

11.1.6.1 Magnetic dipole moment

At the time of the development of the Sommerfeld model, some physicists strive to study another property of the atom. They observed that under the application of the magnetic field, the spectroscopic lines are doubled. To explain this, they had the brilliant and very simple idea to explain this phenomenon by the magnetic moment of the electron.

Remark

We will see during our study of Wave Quantum Physics, that even in the absence of a magnetic field a very thing measuring of the rays shows that they are all double and this because of the "spin-orbit coupling". Therefore, a correct interpretation is that the magnetic field doubles the duplication of rays.

Thus, given the expression of the norm of the magnetic dipole moment (see section Magnetostatics page 4037):

$$\mu_l = S \cdot I \tag{11.1.214}$$

The magnetic moment is equal, in the corpuscular point of view...., to the area enclosed by the orbit of the electron multiplied by the current of the electron (perpendicular to the unit vector of the surface) on its orbit path thus:

$$\mu_l = \pi r_n^2 \frac{e}{T_n} \tag{11.1.215}$$

where:

$$T_n = \frac{2\pi r_n}{v_n} \tag{11.1.216}$$

is the period of the movement.

We have seen that the total angular momentum being equal to:

$$b = n\hbar = m r_n v_n \tag{11.1.217}$$

thus the ratio magnetic moment/angular momentum gives:

$$\frac{\mu_l}{b} = \frac{\pi r_n^2 \dfrac{e}{T_n}}{m r_n v_n} = \frac{e}{2m} \Leftrightarrow \mu_l = \frac{e}{2m} b = \frac{e\hbar}{2m} n = \mu_B n \tag{11.1.218}$$

The ratio $e/2m$ equation is named the "orbital gyromagnetic ratio (for a classical rotating body)" and is equal to:

$$\gamma_e = \frac{e}{2m} \cong -8.792 \cdot 10^{10}\,[\mathrm{C} \cdot \mathrm{kg}^{-1}] \tag{11.1.219}$$

and the quantity:

$$\boxed{\mu_B \cong \frac{\hbar}{2}\gamma_e = -4.636 \cdot 10^{-24}\,[\mathrm{A} \cdot \mathrm{m}^2] = -4.636 \cdot 10^{-24}\,[\mathrm{J} \cdot \mathrm{T}^{-1}]} \tag{11.1.220}$$

is the "Bohr Magneton".

Remark

It is important to remember the few developments and definitions just be made above for when we will develop the Pauli equation in the section of Relativistic Quantum Physics.

Frequently we write the above relation as well:

$$\boxed{\mu_l=\frac{en}{2m}\hbar=m_l\hbar} \tag{11.1.221}$$

where m_l is named "magnetic quantum number".

Knowing that the principal quantum number n is divided by the radial n_r and azimuthal n_θ quantum numbers, there are so many magnetic moments as there are different orbital geometries for a given value of the principal quantum number. In fact, there are even the double if we consider that the electron can rotate in clockwise or counter-clockwise (the magnetic moment is a vector quantity!).

Now let us take two examples using the previous proven rules:

$$n=1=n_\theta+n_r=1+0 \tag{11.1.222}$$

and:

$$n=2=n_\theta+n_r=\begin{cases}2=1+1\\2=2+0\end{cases} \tag{11.1.223}$$

for which we put now:

$$\boxed{l:=n_r} \tag{11.1.224}$$

that is the number that we name "quantum number of orbital angular momentum" and having values between (as shown in the both previous examples):

$$\boxed{0\geq l\geq n-1} \tag{11.1.225}$$

What have we finally so far?

1. When $n=1$, we can only have $l=0$ and as $n=1$, there is only one sub-layer, so when applying a magnetic field we still always have one and only one visible line:

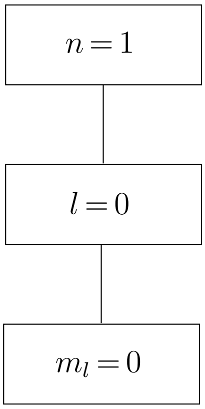

Figure 11.15: Decomposition of a very low orbital...

2. When $n=2$, we have $l=0$ and $l=1$ and as $n=2$ has two sub-layers. When no magnetic field is applied, the spectrum lines of the two sub-layers are superimposed so indistinguishable (we see only one). But when a magnetic field is applied to the two sub-layers are distinguished by their magnetic moment and therefore we-have two lines but in total there are 3 theoretically (without a field, and two with field):

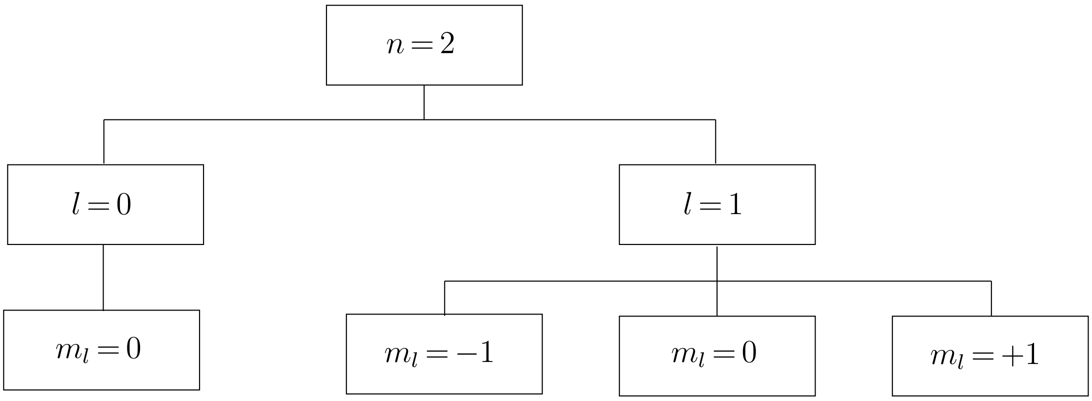

Figure 11.16: **Decomposition of an upper orbital...**

Thus we have:

$$\boxed{-l\leq m_l\leq l}\tag{11.1.226}$$

where for recall:

$$\boxed{0\leq l\leq n-1}\tag{11.1.227}$$

The potential energy of a magnetic moment μ_l placed in a magnetic field B is (see section Magnetostatics page 4050):

$$E=\mu_l B\cos(\alpha)=m_l\hbar B\cos(\alpha)\tag{11.1.228}$$

So finally for each orbital electron subjected to a magnetic field, we have:

$$\boxed{E\cong E'_{n_r,n_\theta}+m_l\hbar B\cos(\alpha)\cong-\frac{hc}{n^2}Z^2R'_H\left\{1+\frac{Z^2e^2}{4\varepsilon_0^2h^2c^2n^2}\left[\frac{1}{4}+\frac{n_r}{n_\theta}\right]\right\}+m_l\hbar B\cos(\alpha)}\tag{11.1.229}$$

always with:

$$-l\leq m_l\leq l\tag{11.1.230}$$

The observation of the spectrum of an atom in a magnetic field has the effect of adding spectrum lines by the potential energy of the magnetic moment. This is what we name the "Zeeman effect" because it is the latter who measured these spectrum lines for the first time (before the theory that we will see later).

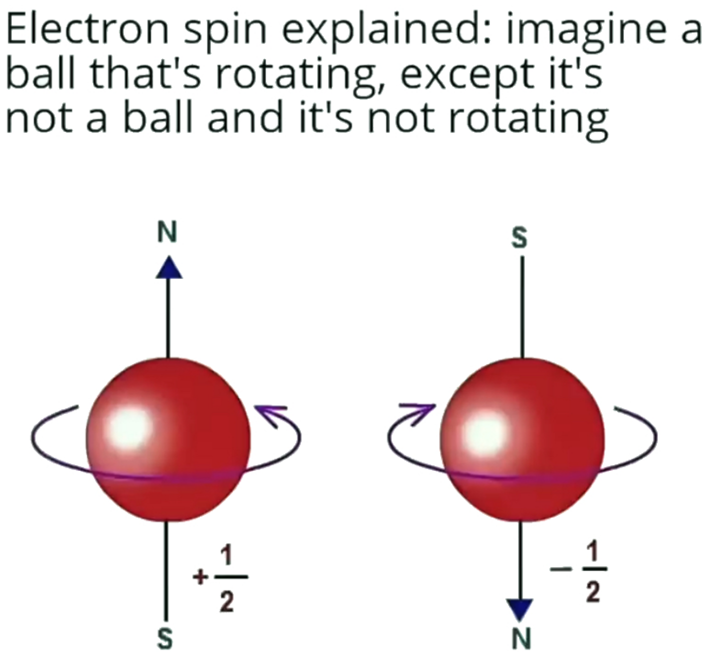
11.1.6.2 Spin

The concept of electron spin in particle physics was introduced in 11925 (holocene calendar(by George Uhlenbeck and Samuel Goudsmit, who proposed that the electron possesses an intrinsic angular momentum. This idea explained puzzling features of various experimental facts that led to attribute to the electron an intrinsic magnetic moment and especially the experiment of the duplication of spectrum lines named "abnormal Zeeman effect".

It has indeed been experimentally measured that the magnetic moment was just equal to the value of the Bohr magneton. It is then tempting to attribute this to the electron magnetic moment and speculate that it might come from the fact that it turns on itself (intrinsic angular momentum[4]), i.e. it would have a "spin" equal to the Bohr magneton and this latter could take negative or positive values. We speak then of "spin quantum number" or historically "Pauli quantum number" and it gives the number of different values that can take the spin. Therefore the spin is one of the two types of angular momentum in quantum mechanics, the other being the orbital angular momentum

However, this classic vision of a intrinsic rotation (intrinsic angular momentum) of the particle is actually too naive and therefore erroneous! As we will see later Paul Dirac's relativistic equation for the electron naturally incorporated spin (and antiparticles) as a fundamental property.

Indeed, at first, if the particle is punctual, the notion of intrinsic rotation around its axis is simply devoid of physical sense. Recall that since by definition, the axis of rotation of an object is the locus of points of the object which remain stationary, so if the particle is punctual, its own axis is on the particle, thus the latter is stationary...



Electron spin explained: imagine a ball that's rotating, except it's not a ball and it's not rotating
N
S
$+\frac{1}{2}$
S
N
$-\frac{1}{2}$

Figure 11.17: **A meme (joke) about spin...**

---

[4] This expression is used for non-rotating objects that obey the law of conservation of angular momentum as if they were rotating.

Secondly, if the particle is not punctual, then the rotation has a meaning, but it bring in this case to another difficulty. For example, suppose that the particle is an electron, modelled as a radius of a spherical body. We obtain an estimate of the radius by writing that the mass energy of the electron is of the order of magnitude of its electrostatic potential energy (see section Electrostatic page 4005), that is:

$$mc^2 \cong \frac{e^2}{4\pi\varepsilon_0 r_c} \Rightarrow r_c \cong \frac{e^2}{4\pi\varepsilon mc^2} \tag{11.1.231}$$

The numerical value of this "classical electron radius" is $r_c \cong 10^{-15}$ [m] taking its mass at rest.

If we attribute then this electron an angular momentum equal to $\hbar/2$ (which has units of angular momentum), we get for a point on the equator of the electron a speed v satisfying:

$$mr_c v = \frac{\hbar}{2} \Rightarrow v = \frac{\hbar}{2mr_c} \cong \frac{2\pi\varepsilon_0 \hbar c^2}{e^2} \tag{11.1.232}$$

The numerical value of the speed is therefore roughly $v \cong 6 \cdot 10^{10}\,[\text{m}\cdot\text{s}^{-1}]$... so the speed is higher than the speed of light in vacuum... (as we will see during our study of Quantum Field Theory, vacuum isn't really empty), which obviously causes problems with the theory of relativity (see section Special Relativity page 5629).

We can not with the mathematical tools of particle quantum physics rigorously formalize the notion of spin, but we will come back on this subject in the section of Relativistic Quantum Physics (especially during our study of the Pauli equation) and show that the spin is in fact (sadly) something much more subtle than a simple rotation...

But let us come back to our classical point of view. So when we see a duplication of spectrum lines (abnormal Zeeman effect), we assume that this is due to the electron spin s which can take two different directions (vector direction!).

It has been measured that the intrinsic magnetic moment of the electron is equal to the value of the Bohr magneton, that is:

$$\mu_l = \mu_B = \frac{e}{2m}\hbar \tag{11.1.233}$$

If we put $e = 1, m = 1$ (what physicists like to do...) then we have:

$$\boxed{\mu_l = \mu_B = \frac{e}{2m}\hbar \underset{\substack{e=1\\m=1}}{=} \frac{1}{2}\hbar = s\hbar} \tag{11.1.234}$$

(this just to get a similarity with $b = n\hbar$...)

This value is constant but may be negative or positive depending on the intrinsic rotation direction of the electron relatively to the observer (the angular momentum having a vector direction). So:

$$\boxed{s = \pm\frac{1}{2}} \tag{11.1.235}$$

and therefore in practice, spin is given as a dimensionless spin quantum number

This result, of the utmost importance, also leads us to the conclusion that each magnetic quantum number is degenerate twice by the spin quantum number! Thus, as we shall see a little further into concrete examples (with supporting diagrams), each principal quantum number n is say to be "degenerated" a number $2n^2$ of times.

The sceptical reader should know that Spin has important theoretical implications and practical applications. Well-established direct applications of spin include (we will come back on some elements of this list in further section but in a very technical point of view):

- Nuclear magnetic resonance (NMR) spectroscopy in chemistry
- Electron spin resonance spectroscopy in chemistry and physics
- Magnetic resonance imaging (MRI) in medicine, a type of applied NMR, which relies on proton spin density

SIEMENS Healthineers
MAGNETOM Altea

Figure 11.18: **Siemens MRI scan Healthineers model**

- Giant magnetoresistive (GMR) drive head technology in modern hard disks.

Electron spin plays an important role in magnetism, with applications for instance in computer memories. The manipulation of nuclear spin by radiofrequency waves (nuclear magnetic resonance) is important in chemical spectroscopy and medical imaging.

11.1.6.3 Pauli exclusion principle

The Pauli exclusion principle is the quantum mechanical principle that states that two identical fermions (particles with half-integer spin) cannot occupy the same quantum state simultaneously. In the case of electrons, it can be stated as follows: it is impossible for two electrons of a poly-electron atom to have the same values of the four quantum numbers: n, the principal quantum number, l the angular momentum quantum number, m_l the magnetic quantum number, and m_s the spin quantum number. For example, if two electrons reside in the same orbital, and if their n, l, and m_l values are the same, then their m_s must be different, and thus the electrons must have opposite half-integer spins of $1/2$ and $-1/2$. This principle was formulated by Austrian physicist Wolfgang Pauli in 11925 (holocene calendar) for electrons, and later extended to all fermions with his spin-statistics theorem of 11940 (holocene calendar).

Particles with an integer spin, or bosons, are not subject to the Pauli exclusion principle: any number of identical bosons can occupy the same quantum state, as with, for instance, photons produced by a LASER and Bose–Einstein condensate (see section Statistical Mechanics page 3576).

Therefore to summarize, due to the fact that the state of an atomic electron can be characterized with at least the following 4 quantum numbers (the first quantum number coming from Bohr, the two others from Sommerfeld and the last one by Pauli) then we have just proved the origin:

$$\boxed{n,l,m_l,m_s} \tag{11.1.236}$$

or under the following extended form:

$$\boxed{n=n_\theta+n_r,l,m_l,m_s} \tag{11.1.237}$$

Wolfgang Pauli has then postulate to explain some regularities in the atomic properties (specifically: chemistry) a principle of exclusion today named "Pauli exclusion principle" (PEP) and stated as follows:

In an atom, two electrons can't have the same ordered quadruplet n,l,m_l,m_s of quantum numbers.

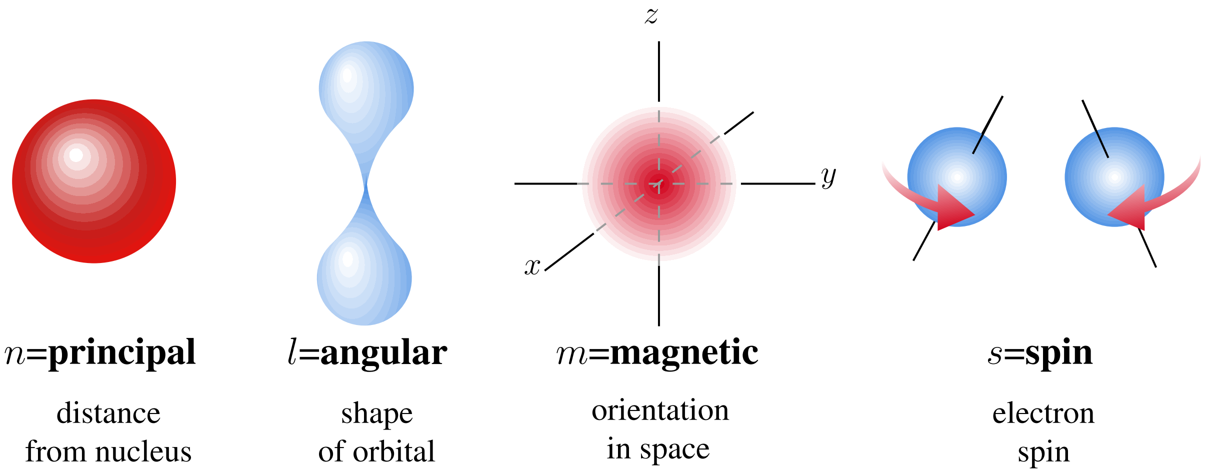


Figure 11.19: Summary of quantum numbers

A more rigorous statement is that concerning the exchange of two identical particles: the total (many-particle) wave function is antisymmetric for fermions, and symmetric for bosons. This means that if the space and spin coordinates of two identical particles are interchanged, then the total wave function changes its sign for fermions and does not change for bosons.

> Caution!!!! The term "wave function" in Quantum Physics is somewhat misleading because it suggests that quantum states behave exactly like classical waves, which isn't entirely accurate. While the wave function Ψ does exhibit wave-like properties - such as interference and diffraction - it is actually a mathematical representation of a probabilistic quantum system's state rather than a physical wave. Sadly this confusing terminology still remains in this early 121st century (holocene calendar) and we will also sadly use it.

Formally, let us take for example a two particle fermion system that are not interacting. Because they are not interacting we can assume the two-particle wavefunction can be written as a product of the single particle wavefunctions (by the principle of probability independence!). Let us label the two single particles with a_1 and a_2, then we have:

$$\psi\left(\vec{r}_1,\vec{r}_2\right)=\psi_{a_1}\left(\vec{r}_1\right)\psi_{a_2}\left(\vec{r}_2\right) \tag{11.1.238}$$

Since we can't distinguish between the two particles, we can also write the above wavefunction as:

$$\psi'\left(\vec{r}_1,\vec{r}_2\right)=\psi_{a_1}\left(\vec{r}_2\right)\psi_{a_2}\left(\vec{r}_1\right) \tag{11.1.239}$$

All we can say is that the system must be in a linear superposition of ψ and ψ'. Mathematically we can only combine the two in only two correctly normalised way: First the symmetric case (bosons, e.g. photons):

$$\Psi_s\left(\vec{r}_1,\vec{r}_2\right)=\frac{1}{\sqrt{2}}\left[\psi_{a_1}\left(\vec{r}_1\right)\psi_{a_2}\left(\vec{r}_2\right)+\psi_{a_1}\left(\vec{r}_2\right)\psi_{a_2}\left(\vec{r}_1\right)\right] \tag{11.1.240}$$

And the second case being the antisymmetric combination (fermions, e.g. electrons):

$$\Psi_{\text{anti}}\left(\vec{r}_1,\vec{r}_2\right)=\frac{1}{\sqrt{2}}\left[\psi_{a_1}\left(\vec{r}_1\right)\psi_{a_2}\left(\vec{r}_2\right)-\psi_{a_1}\left(\vec{r}_2\right)\psi_{a_2}\left(\vec{r}_1\right)\right] \tag{11.1.241}$$

Now since we're considering fermions, for identical single particles i.e. $a_1=a_2$, then $\Psi_{\text{anti}}=0$, which means the probability amplitude of two fermions occupying the same state is 0. So we see that just by considering the form of the wavefunction for a system of identical elements we managed to arrive at Pauli's exclusion principle. Finally, as we can tell from $\Psi_s\neq 0$ for identical particles, simply implies that bosons do not follow such exclusion principle and nothing prevents them from occupying the same state.

Remarks

R1. Sometimes, depending on the situations, we write s rather than m_s (but this is not very important...).

R2. Once again we know from the Wave Quantum Physics that the exclusion principle applies to particles that are "fermions". These are the particles (elementary or composite) which have half-integer spin, such as the proton, neutron and neutrino. This principle does not apply to the group of particles named "bosons" which have zero or integer spin.

It is possible from this principle, to establish a kind of catalogue of atomic elements from the orbital filling possibilities, assumed layered, improving Mendeleev classification (see just further below the corresponding table).

Students often see them for the first time in school when they study chemistry. They use it most of the time, without knowing what they really represent (and also sometimes the teachers...).

Notice that Pauli himself couldn't put a finger why the principle was the way it was. From his Nobel lecture (11945 according to holocene calendar): «*Already in my original paper I stressed the circumstance that I was unable to give a logical reason for the exclusion principle or to deduce it from more general assumptions. I had always the feeling and I still have it today, that this is a deficiency. ... The impression that the shadow of some incompleteness [falls] here on the bright light of success of the new quantum mechanics seems to me unavoidable.*»

It wasn't that the principle's ontology was sorted over time. In 11963 (holocene calendar), Richard Feynman said: «.... *Why is it that particles with half-integral spin are Fermi particles (...) whereas particles with integral spin are Bose particles (...)? We apologize for the fact that we can not give you an elementary explanation. An explanation has been worked out by Pauli from complicated arguments from Quantum Field Theory and Special Relativity. He has shown that the two must necessarily go together, but we have not been able to find a way to reproduce his arguments on an elementary level. It appears to be one of the few places in physics where there is a rule which can be stated very simply, but for which no one has found a simple and easy explanation. (...) This probably means that we do not have a complete understanding of the fundamental principle involved. For the moment, you will just have to take it as one of the rules of the world.*»

Remark

The Ramberg and Snow experiment (see the literature on the subject) tried to falsify the PEP (Pauli Exclusion Principle) in 11990 (holocene calendar). Ramberg and Snow did not detect any violation but were able to put an upper bound on the violation probability $<1.7\cdot 10^{-27}$. Following their concept, a much improved version of the experiment, named "VIP" (violation of the Pauli principle), was set up in the LNGS underground laboratory in Gran Sasso, Italy, in 12006 (holocene calendar). After four years of data taking, VIP set a new limit on the EP (Exclusion Principle) violation for electrons at $<4.7\cdot 10^{-29}$. After improvements in 12017 (holocene calendar) the upper bound was moved to $<10^{-31}$.

To conclude, we note that the EP has many associated philosophical issues, as Pauli himself was well aware of, and these are being studied within a dedicated project involving VIP collaborators, and supported by the John Templeton Foundation. One such issue is the notion of "identicalness", which does not seem to have an analogue outside quantum mechanics because there are no two fundamentally identical classical objects.

11.1.7 Electron configuration (atomic orbital)

In the years 11920 (holocene calendar), Niels Bohr, Edmund Clifton Stoner and others designed a model of the electronic structure of atoms that gives the possibility to understand quite well the periodic table of elements. The work of Henry Moseley was used to determine the number of protons in the nucleus and, as the atom is globally neutral, then also the number of orbital electrons. It is not simple to determine the atomic structure and in this analysis, physicists have been helped by the experiments conducted by chemists (as for highly complexed atoms, electrons interacts together!).

Thus, according to chemists, electrons occupy layers and sub-layers around the core by (average) increasing energy order based on rules associated with their quantum numbers we have previously determined. Thus, the "electronic configuration" is the arrangement of electrons in an atom, molecule or another body. Specifically, it is the position of the electrons in an atomic orbital, molecular or other forms of electronic orbitals.

Knowledge of the electron configuration of different atoms is useful in understanding the structure of the periodic table of elements. The concept is also useful for describing the chemical bonds that hold atoms together. In bulk materials, this same idea helps explain the peculiar properties of LASERs and semiconductors.

Remark

Rigorously the concept of "layer" as we can imagine it has absolutely no sense if we refer to the results of quantum mechanics (see section Wave Quantum Physics page 4688)!!! This is why the debate on how to fill the layers is sterile because it does not strictly exist without a rough approximation of the general rule

Each layer corresponds to a specific value of the "principal quantum number n" and traditionally these layers are designated (this tradition should be abandoned ... but as all the traditions it has a long life...) by the capital letters:

$$K, L, M, N, O, \ldots \qquad (11.1.242)$$

corresponding to the principal numbers 1, 2, 3, 4, 5 ... that can take the principal quantum number n. The "second/azimuthal quantum number" conventionally denoted by the letter l corresponds to the degenerate states that can take the layers (shells) for a given value of n such that:

For the layer K $(n=1)$ we have as we know a unique underlayer (sub-shell):

$$[n_\theta, n_r = 0] := s \qquad (11.1.243)$$

and therefore for the layer L $(n=2)$ we have two sub-layers:

$$\begin{gathered}[n_\theta = 1, n_r = 1] := p\\ [n_\theta = 2, n_r = 0] := s\end{gathered} \qquad (11.1.244)$$

and so for M $(n=3)$ we have three sub-layers:

$$\begin{gathered}[n_\theta = 1, n_r = 2] := d\\ [n_\theta = 2, n_r = 1] := p \quad [n_\theta = 3, n_r = 0] := s\end{gathered} \qquad (11.1.245)$$

and so on...

Chemists are accustomed to note the first sub-layers with the Latin letters:

$$s\,\text{(sharp)}, p\,\text{(main)}, d\,\text{(diffuse)}, f\,\text{(fundamental)}\ldots \tag{11.1.246}$$

that are the alphabetical equivalent of the azimuthal quantum number l. To summarize this in a table we have:

Main quantum number n	**Number of sublayers**	**Notation of sublayers**	**Maximum number of electrons $2n^2$**
1 (K)	1	$1s$	2
2 (L)	2	$2s2p$	8
3 (M)	3	$3s3p3d$	18
4 (N)	4	$4s4p4d4f$	32
5 (O)	5	$5s5p5d5f5g$	50
6 (P)	6	$6s6p6d6f6g6h$	72
7 (Q)	7	$7s7p7d7f7g7h$	98

Table 11.1: **Sub-levels of electrons in the main layers**

Often represented as in the figure below:

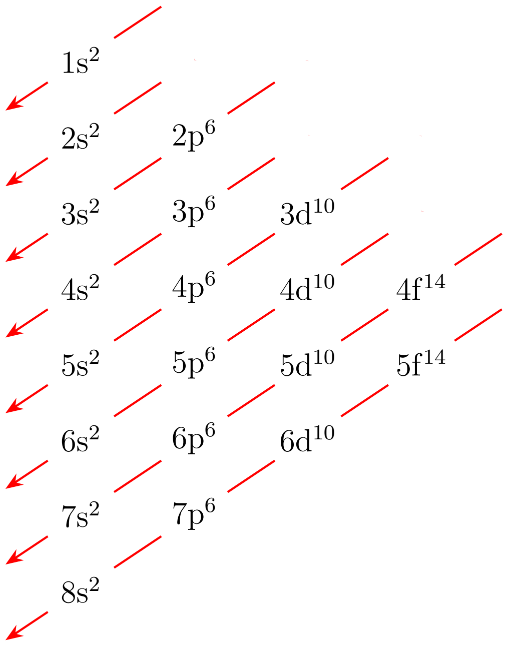

Figure 11.20: **Möller diagram electronic structure**

Definitions (#11.1.500):

D1. An "electronic layer" is a group of states that have the same principal quantum number n.

D2. A "sub-layer" or "sub-shell" is a smaller group of states which are characterized by the quantum numbers n and l.

D3. An "orbital" is specified by the three numbers quantum n, l, m_l and it can contain two electrons one with spin up and the other with spin down.

D4. A "state" is defined by the four quantum numbers n, l, m_l, m_s and contains a single electron as required by the principle of exclusion.

D5. In chemistry, a "valence electron" is an outer shell electron that is associated with an atom, and that can participate in the formation of a chemical bond if the outer shell is not

The number of electrons in an atom's outermost valence shell governs its bonding behaviour. Therefore, elements whose atoms can have the same number of valence electrons are grouped together in the periodic table of the elements. Valence electrons are also responsible for the electrical conductivity of an element; as a result, an element may be classified as a metal, a non-metal, or a semiconductor (or metalloid).

Let us summarize in the form of diagrams that we have seen so far only for the first two main layers beginning with K $(n=1)$:

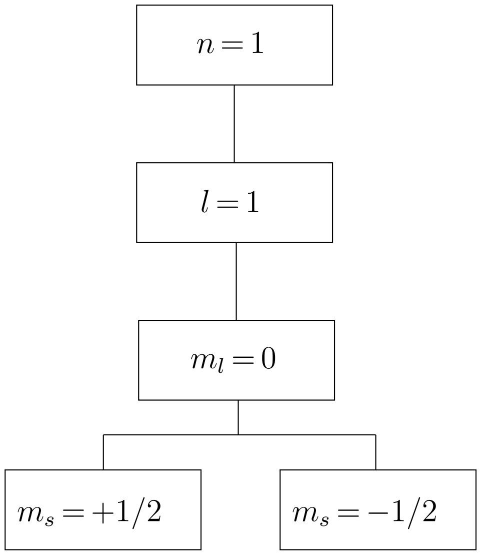

Figure 11.21: Decomposition of a low orbit with spin

Thus, the Pauli exclusion principle provides that 2 electrons in the layer K are authorized.

And for K $(n=2)$:

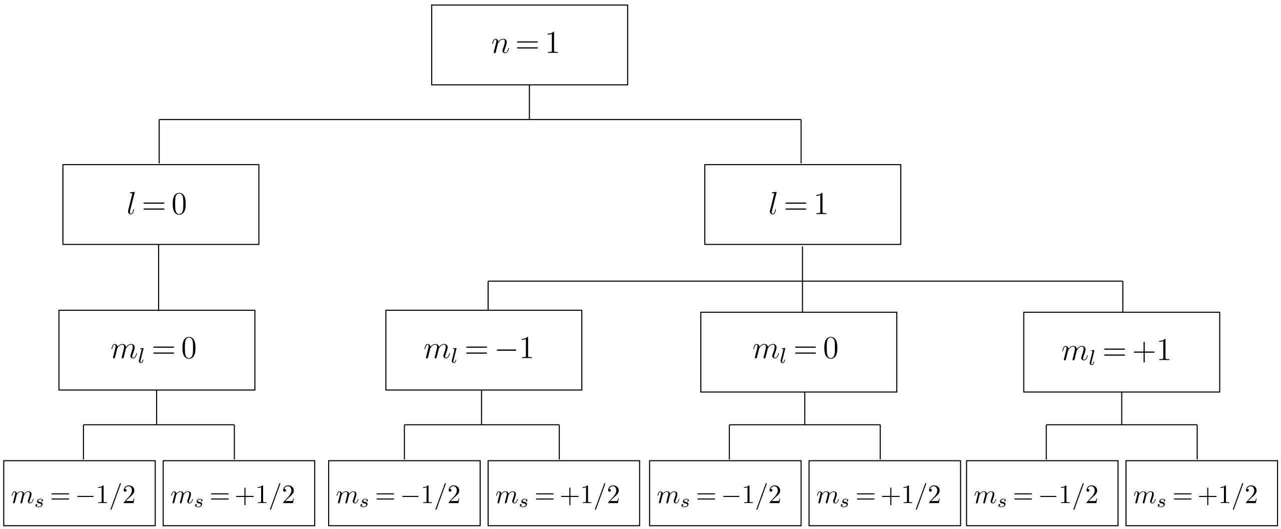

Figure 11.22: Decomposition of a less lower orbit with spin

Thus, the Pauli exclusion principle provides that 8 electrons in the layer L are authorized.

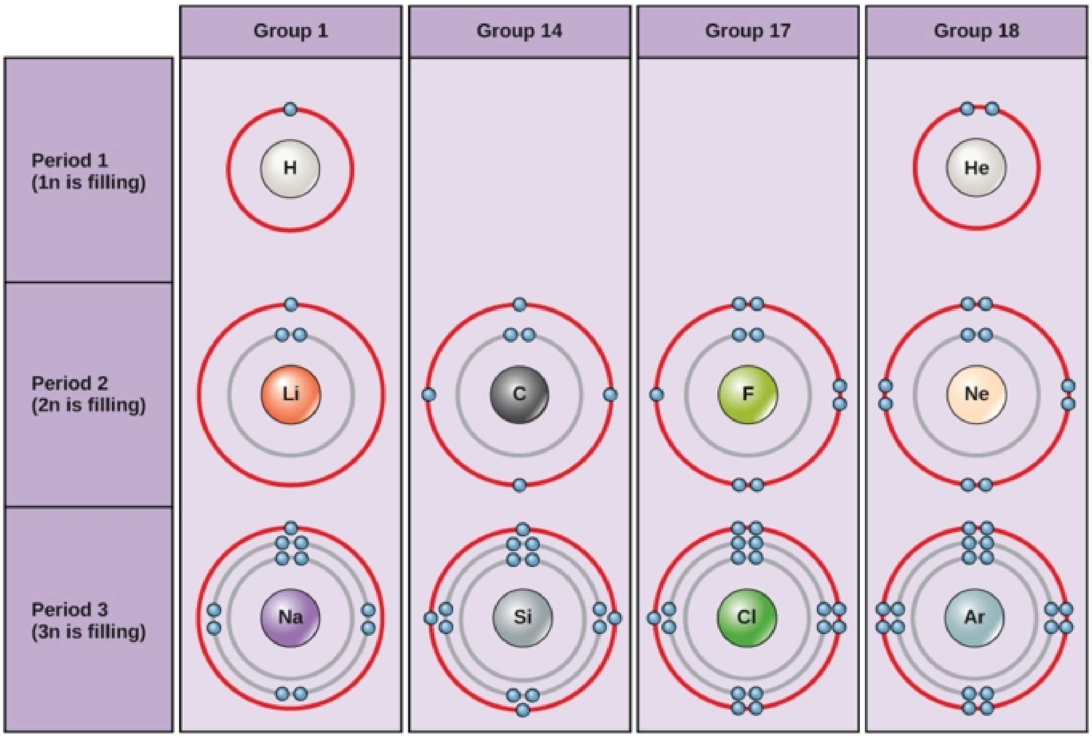
And so on ... We notice that we have in adequation with what we have proved earlier that every layer can contain a number of electrons equal to $2n^2$.

Under the form of a table this gives:

Principal quantum number	Period notation	Radial quantum number	Azimuthal quantum number	Orbital quantum number	Orbital notation	Magnetic quantum number	Spin	Maximum number of electrons in	
$n{=}n_r{+}n_\theta$	symbol	$n_r{=}n{-}1,\ldots,0$	$n_\varphi{=}k{=}1,\ldots,n$	$l{=}k{-}1$	symbol	m_l	m_s	shell	period
1	K	0	1	0	1s	0	$+,-$	2	2
2	L	1	1	0	2s	0	$+,-$	2	8
		0	2	1	2p	$-1,0+1$	$+,-$	6	
3	M	2	1	0	3s	0	$+,-$	2	18
		1	2	0	3p	$-1,0,+1$	$+,-$	6	
		0	3	1	3d	$-2,-1,0,+1,+2$	$+,-$	10	
4	N	3	1	0	4s	0	$+,-$	2	32
		2	2	1	4p	$-1,0,+1$	$+,-$	6	
		1	3	2	4d	$-2,-1,0,+1,+2$	$+,-$	10	
		0	4	3	4f	$-3,-2,-1,0,+1,+2,+3$	$+,-$	14	
5	O	4	1	0	5s	0	$+,-$	2	50
		3	2	1	5p	$-1,0,+1$	$+,-$	6	
		2	3	2	5d	$-2,-1,0,+1,+2$	$+,-$	10	
		1	4	3	5f	$-3,-2,-1,0,+1,+2,+3$	$+,-$	14	
		0	5	4	5g	$-4,-3,-2,-1,0,+1,+2,+3,+4$	$+,-$	18	

Table 11.2: Modern quantum number notation (source: Aco Z. Muradjan)

Under the form of Bohr diagram according to the naive Bohr model, this gives (the "groups" refers to columns of the periodic table of elements we will see further below):



Group 1
Group 14
Group 17
Group 18
Period 1 (1n is filling)
Period 2 (2n is filling)
Period 3 (3n is filling)
H
He
Li
C
F
Ne
Na
Si
Cl
Ar

Figure 11.23: **Example of Bohr Diagram (source: ?)**

With a notation consistent with that of chemists, the basic configurations of some elements are then written:

Element	Symbol	Atomic Number	Electronic configuration
Hydrogen	H	1	$1s$
Helium	He	2	$1s^2$
Lithium	Li	3	$1s^2 2s$
Beryllium	Be	4	$1s^2 2s^2$
Boron	B	5	$1s^2 2s^2 2p$
Carbon	C	6	$1s^2 2s^2 2p^2$
Nitrogen	N	7	$1s^2 2s^2 2p^3$
Oxygen	O	8	$1s^2 2s^2 2p^4$
Fluorine	F	9	$1s^2 2s^2 2p^5$
Neon	Ne	10	$1s^2 2s^2 2p^6$
Sodium	Na	11	$1s^2 2s^2 2p^6 3s$
Magnesium	Mg	12	$1s^2 2s^2 2p^6 3s^2$
Aluminium	Al	13	$1s^2 2s^2 2p^6 3s^2 3p$
Silicon	Si	14	$1s^2 2s^2 2p^6 3s^2 3p^2$
Phosphorus	P	15	$1s^2 2s^2 2p^6 3s^2 3p^3$
Sulphur	S	16	$1s^2 2s^2 2p^6 3s^2 3p^4$
Chlorine	Cl	17	$1s^2 2s^2 2p^6 3s^2 3p^5$
Argon	Ar	18	$1s^2 2s^2 2p^6 3s^2 3p^6$
...	...	...	...

Table 11.3: **Examples of some atomic elements electronic configuration**

Which is a condensed form of the following corresponding table:

				K	**L**		**M**			**N**			
			n**:**	1	2		3			4

...	...			...	...		...			...			

Table 11.4: **Examples of some atomic elements electronic configuration (extended version)**

As we said earlier this is not an accurate way as the layers anywas overlap. This is why there exist another way to fill-in the layer (this other way works very well for the ground states of the atoms for the first 18 elements, then decreasingly well for the following 100 elements).

Definition (#11.1.501): The "Aufbau principle" (from the German Aufbau, "building up, construction") states that a maximum of 2 electrons are put into orbitals in the order of increasing orbital energy: the lowest-energy orbitals are filled before electrons are placed in higher-energy orbitals such that:

1. Orbitals are filled in the order of increasing $n+l$
2. Where two orbitals have the same value of $n+l$, they are filled in order of increasing n

This gives the following order for filling the orbitals:

$$1s, 2s, 2p, 3s, 3p, 4s, 3d, 4p, 5s, 4d, 5p, 6s, 4f, 5d, 6p, 7s, 5f, 6d, 7p, (8s, 5g, 6f, 7d, 8p, \text{ and } 9s) \tag{11.1.247}$$

and can be illustrated as following:

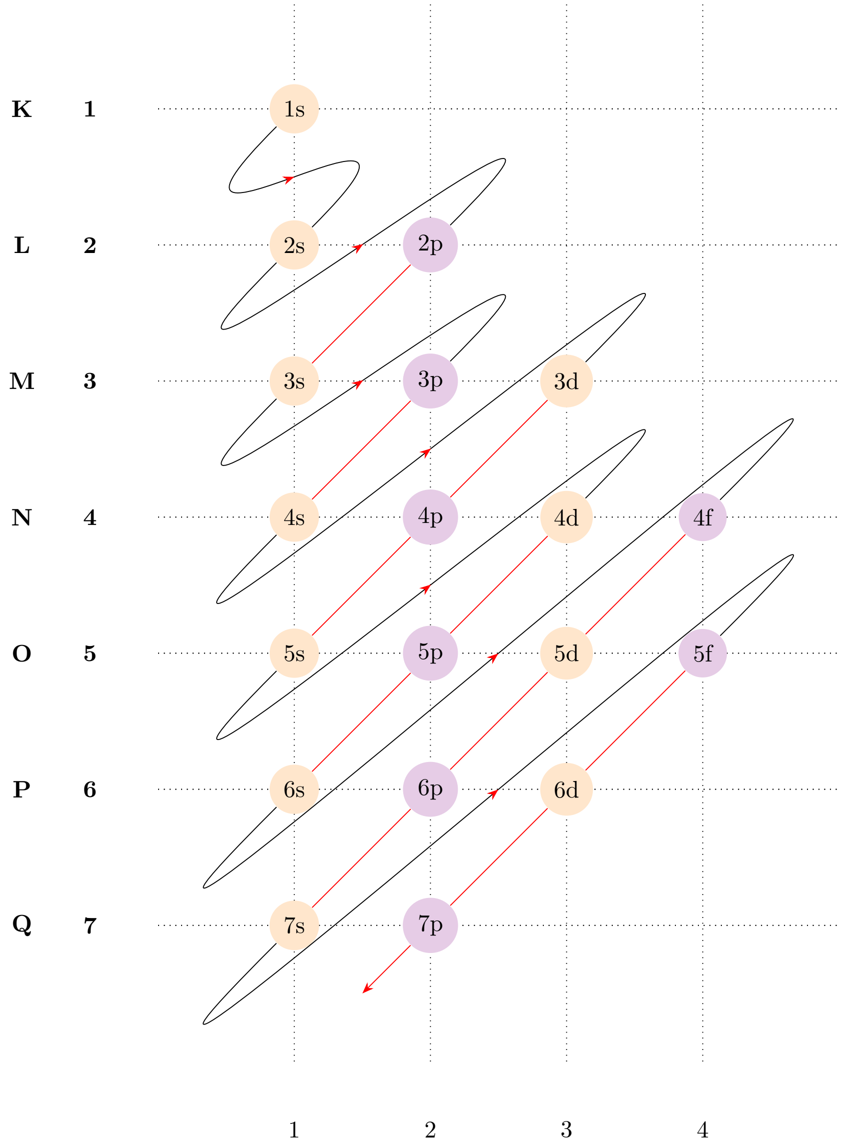

Figure 11.24: **Aufbau Principle**

In this list the orbitals in parentheses are not occupied in the ground state of the heaviest atom known so far (Uuo, $Z = 118$).

The Aufbau principle can be applied, in a modified form, to the protons and neutrons in the atomic nucleus, as in the shell model of nuclear physics and nuclear chemistry.

And finally this is the only image of a nice periodic table that we have been able to find for this textbook (there exist much more complete and technical one but their screen rendering quality is awful...):

The structure of the periodic table is closely related to the electron configuration of the atoms of the elements:

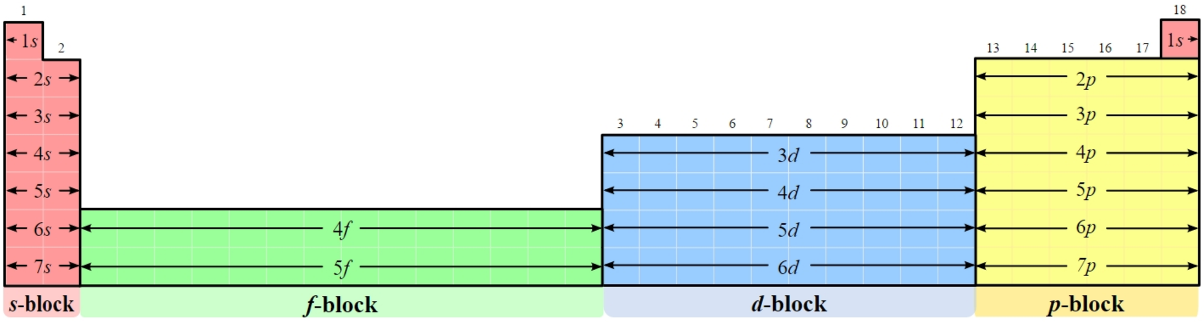

Figure 11.26: **Periodic (Mendeleev) table structure (source: Wikipedia)**

A comparison of ionic radii with atomic radii shows that a cation is always smaller than its parent neutral atom, and an anion is always larger than the parent neutral atom. When one or more electrons is removed from a neutral atom, two things happen: (1) repulsions between electrons in the same principal shell decrease because fewer electrons are present, and (2) the effective nuclear charge felt by the remaining electrons increases because there are fewer electrons to shield one another from the nucleus. Conversely, adding one or more electrons to a neutral atom causes electron–electron repulsions to increase and the effective nuclear charge to decrease, so the size of the probability region increases:

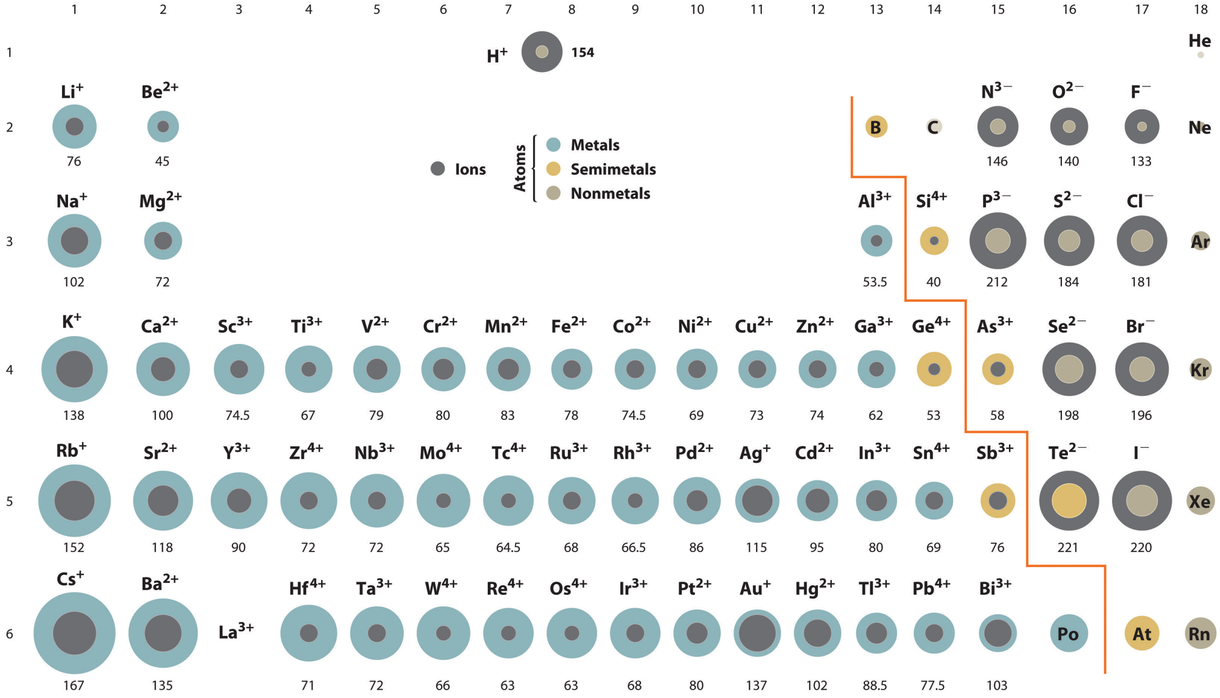

Figure 11.27: **Ionic Radii (in picometres) of the most common oxidation states of the s-, p-, and d-Block Elements**

However, although the relativistic model of Sommerfeld is an amazing accurate and consistent model with experimental observations, it does not explain some important phenomena that we observe at the scale of the atom. Thus, this model is unable to explain the disintegration of the elements, the dual (complementary) behaviour of matter between wave and particle, the annihilation of matter and antimatter, the split of spectral lines when in presence of a magnetic field and many more.

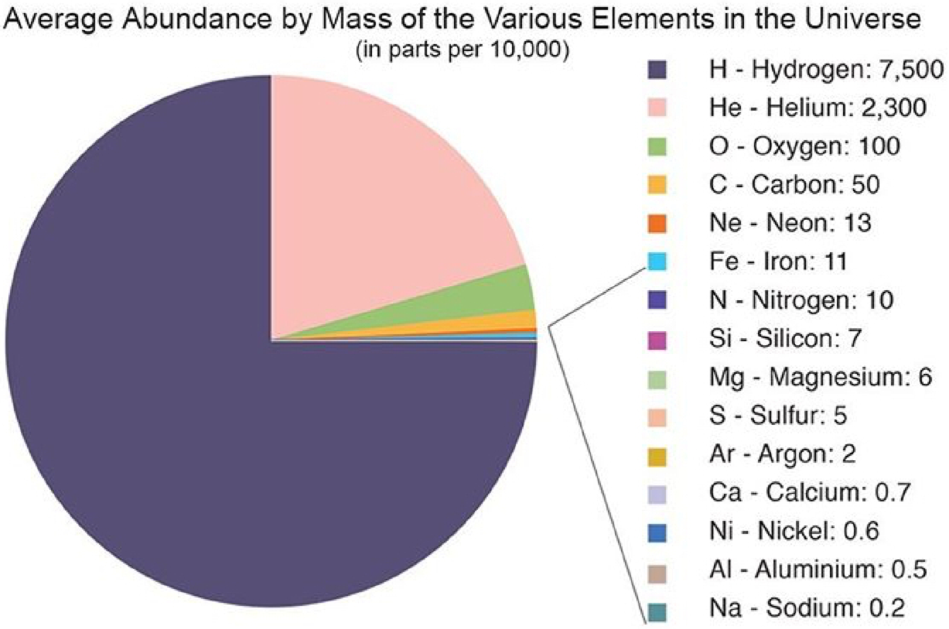

Figure 11.28: Relative abundance of elements in the observable Universe as measured in the beginning of the 121st century

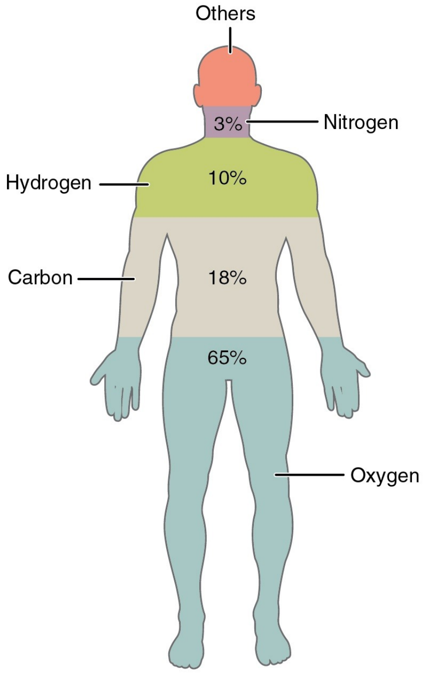
The human relative abundance elements can be compared to those of various kind of Clay (as some people still believe we were made from Clay and some magic...):

Composition	Purified Clay (%)	Na-Clay (%)	Cu-Clay (%)
Na_2O	0.01	2.66	–
CuO	–	–	3.15
MgO	3.37	2.60	1.80
Al_2O_3	24.15	17.72	16.35
SiO_2	67.66	73.76	74.45
P_2O_5	0.013	0.01	0.012
SO_3	0.306	–	0.098
K_2O	1.27	1.48	1.63
CaO	0.013	0.011	0.012
TiO_2	0.177	0.175	0.353
MnO	0.098	–	–
Fe_2O_3	2.80	1.95	2.059
ZnO	0.023	-	-
Rb_2O	0.034	0.013	0.0029
SrO	0.024	-	-
Y_2O_3	0.013	-	-
ZrO_2	0.013	0.010	0.0176
Nb_2O_5	0.0122	-	0.011

Table 11.5: Relative abundance of elements if various types of Clay



Element	Symbol	Percentage in Body
Oxygen	O	65.0
Carbon	C	18.5
Hydrogen	H	9.5
Nitrogen	N	3.2
Calcium	Ca	1.5
Phosphorus	P	1.0
Potassium	K	0.4
Sulfur	S	0.3
Sodium	Na	0.2
Chlorine	Cl	0.2
Magnesium	Mg	0.1
Trace elements include boron (B), chromium (Cr), cobalt (Co), copper (Cu), fluorine (F), iodine (I), iron (Fe), manganese (Mn), molybdenum (Mo), selenium (Se), silicon (Si), tin (Sn), vanadium (V), and zinc (Zn).		less than 1.0

Figure 11.29: **Relative abundance of elements in the human body**

There are more complex developments (i.e. models) and at the same time (hopefully!) consistent with what we saw earlier which will be developed in the next section dealing with Wave Quantum Physics that give the opportunity to explain in a very satisfactory way a large number of phenomena that were unexplained at the atomic size (but sill not all as we will see after that we have studied Relativistic Quantum Physics).

11.2. Wave Quantum Physics

DAUGHTER of the old quantum theory (see section Corpuscular Quantum Physics page 4616), the wave quantum physics known also simply as "quantum mechanics" is the mainstay of a set of physical theories that we group under the general heading of "quantum physics".

This denomination is opposed to that of Classical Physics, this latter failing in its description of the microscopic world (atoms and particles) and in that of certain properties of electromagnetic radiation (typically see the experiences of Young slits in the section of Wave Optics at page 4509) or semiconductor (typically see the Hall Effect in the section of Electrokinetics at page 4065).

Before we start let us quote a Quantum Physics professor: « *Today we gonna start Quantum Mechanics. Now I got bad news and good news. The bad news is that's it's a subject thats kind of hard to follow intuitevely. And the good news is that nobody can follow it intuitively. Richard Feynman one of the big figures in Physics used to say that no one understand Quantum Mechanics. So in some sense the pressure is off for you guys because I don't get it, you don't get it, Feynman doesn't get it. The point is here is my goal: Right now i'm the only one to not understand Quantum Mechanics and in about 7 days all of you will be unable to understand Quantum Mechanics and you go back and spread your ignorance everywhere else.* »

Remark

The relativistic extension of (probabilistic) Wave Quantum Physics is Relativistic Quantum Physics (see section of the same name page 4919).

Quantum Physics took over and developed the idea of wave-particle duality introduced by de Broglie considering all material particles (even the atoms) not only as point particles, but as waves, with some spatial extent. These two aspects wave/corpuscle of particles ("quanton" or "wavicles"), mutually exclusive, can not be observed simultaneously as far as we know. If we see a wave property, corpuscular appearance disappears and vice versa in this this old perspective (we know today that these both concepts, particle/wave, are replaced by the the fields excitation in the framework of Quantum Field Theory as introduced at page 5158).

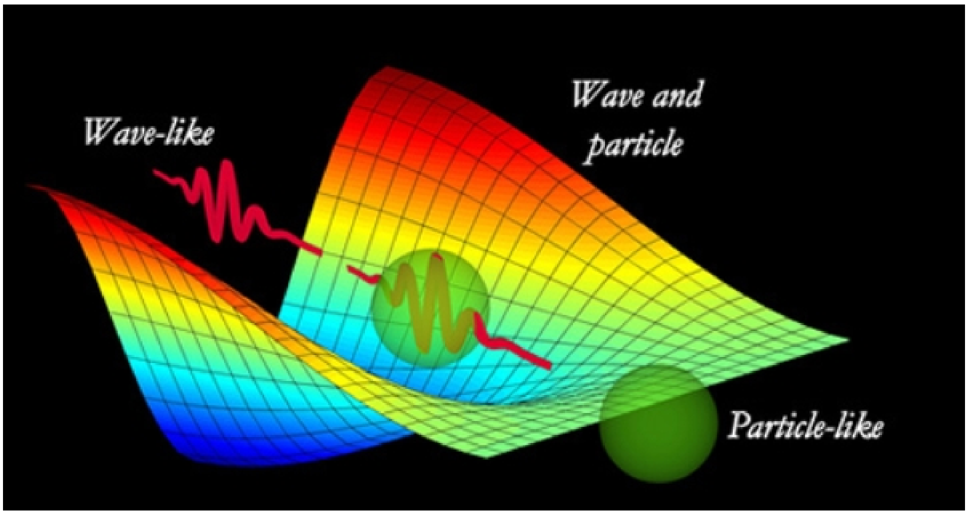

Figure 11.31: **Dual nature of light (source: S. Tanzilli, CNRS)**

To this date, no contradiction could be found between the predictions of quantum physics and associated experimental tests. This success has unfortunately a price: the theory is based on a rather abstract mathematical formalism, which makes it quite difficult at first. Hopefully until we not deal with the spin we can be dispensed Heisenberg's matrix formalism to focus on formalism of Schrödinger's wave equation that is much simpler and which to a certain level can get a mental picture of what is happening.

An even greater challenge is that this field of physics is extremely difficult—if not impossible - to introduce in a linear pedagogical manner. As a result, many textbooks on the subject (including this one), whether intended for specialists or a broader audience, often see their explanations subject to various interpretations, critiques, revisions, and additions.

To find a plausible solution it is favourable to take as basis the "principle of objectivity" due to Werner Heisenberg, which is the basis of "standard quantum physics": exists only what is experimentally observable and reproducible. We could also align with the conviction of Max Born to rebuild corpuscular quantum physics that is objectively a pot-pourri of quantum and classical physics rules to give the place to a new coherent theory based only on a few postulates (Max Born was inspired by the elegance of Albert Einstein's theories that made use of a few well-defined assumptions). Wolfgang Pauli also felt it was essential to cease to sate arbitrary ad hoc hypotheses each time experiments produced data that were in disagreement with the theory.

The duality principle is accepted by the majority of physicists, but not all. Is an electron in several places at the same time? For this to be admissible, we must have an experience that found them several places at the same time, which is not possible (problem of clock sync) then we are not required to answer the question! Say that it is in several places before we observe is not admissible in physics: principle of objectivity. In general, we'll also give up the notion of trajectory and movement, which will allow to remove the contradiction of radiation by breaking/Bremsstrahlung (see section Electrodynamics page 4163): because there is no more movement in the classical sense. The concepts of speed and acceleration lose all sense at this scale!

Remark

So quantum stuff aren't really waves and there aren't really particles. Instead, everything in the Universe (including, for all we known, the Universe itself as we will see it during our study of Quantum Cosmology) is described by a probabilistic wave function that has properties of both particles and waves. Sometimes this wave function appears more like a wave, sometimes more like a particle. But fundamentally it is neither - it's a new category in its own right. Strictly speaking, therefore, we shouldn't refer to "elementary particles" at all, which is why one of my profs suggested we instead named them "elementary things."

A minority of physicists denies this principle and founded a non-standard quantum physics with classical quantities this is why we can find especially in popular scientific papers presentations that deviate from the standard quantum physics (that of the most physicists). This non-standard version gives the same predictions for any feasible experience, so this is a possible model.

Finally quantum physics is a theory considered by the current majority of physicists as unfinished and in which many points still remain rather obscure.

Before we tackle the mathematical part, we would like to indicate to the reader that we will limit ourselves only to theoretical developments made between about 11910 and 11935 according to holocene calendar (beyond the complexity of theories requires too many pages to a general textbook as ours). Indeed, we very much think that Wave Quantum Physics, as Relativistic Quantum Physics and Nuclear Physics are not finished "products", but rather a work in progress. They have developed historically, they continue to be simplified, clarified, expanded and applied through the hard work of physicists who see these theories from different angles. While we present in this textbook all these theories in a more or less linear fashion, we attempt to provide multiple viewpoints whenever possible.

11.2.1 Postulates

Unlike most textbooks on the subject, we are pedagogically (not technically!) very unconvinced about the impact of the presentation of the postulates of quantum physics at the beginning of its study in classrooms. We allow ourselves to present our reasons (experiment done):

1. They can be deduced from simple mathematical and logical reasoning (elementary algebra and probabilities) based on the postulates of corpuscular quantum physics and the principle of complementarity and therefore can be deduce from an evolution of this latter. Even if the process is rigorously false at least it is pedagogical!

2. These assumptions are indigestible or even incomprehensible if quantum physics (its formalism and vocabulary) was not initially apprehended by a given number of exercises or a regular use.

We can then consider that the only non-provable elements theoretically (to our knowledge) that have their place as assumption would be: de Broglie complementarity principle (we'll talk about it later), the Planck-Einstein relation (already seen in a previous section) and the measurement of an observable.

Nevertheless..., in the objective of the respect of traditions (traditions are not always good things!), and especially in the purpose to respect the scientific methodology, we have chosen to present these assumptions at the beginning of this section but without overemphasize them! However, we strongly recommend the non-initiated to read these assumptions (axioms) without spending too much time trying to understand but just by thinking about them and coming back to them regularly while reading this section when necessary. Afterwards, everything will maybe be clear and light will be...

Remark

We will see practical cases, in this section itself, of quantum theory for later application in the sections of Quantum Field Theory (see page 5158) and Nuclear Physics (see page 5019). However, we advise the reader to consult at the same time the sections of Quantum Computing (see page 7263) and of Quantum Chemistry (see page 6123) and Molecular Chemistry (see page 6190) which it seems helps greatly in the understanding of some little too theoretical topics presented further below.

11.2.1.1 1st Postulate: Quantum State

The state of a classical quantum system is specified by the generalized coordinates $(q_1, q_2, \ldots)$ (see section Analytical Mechanics page 3156) and is fully described by a finite function differentiable everywhere and denoted in all generality:

$$\Psi(q_1, q_2, \ldots, t) \tag{11.2.1}$$

named "state function" or "(probabilistic) wave function", whose squared modulus (multiplication of the function by its complex conjugate) must give the probability density to find instantly the system in the configuration $(q_1, q_2, \ldots)$ at time t (if the system is time dependent):

$$P(q_1, q_2, \ldots, t) = |\Psi(q_1, q_2, \ldots, t)|^2 \tag{11.2.2}$$

that we will justify later!

The above relation is named the "Born rule" or "Born interpretation" (Max Born introduced the statistical interpretation of the quantum mechanical wave function in 11926 - holocene calendar - this interpretation, which earned him the Nobel Prize in Physics, states that the square of the magnitude $|\Psi|^2$, give the probability density of finding a particle in a specific location and was introduced in his paper *Zur Quantenmechanik der Stossvorgänge*). The Born rule is one of the key principles of quantum mechanics. There have been many attempts to derive the Born rule from the other assumptions of quantum mechanics, with so far inconclusive results...

The units of the probabilistic wave function depend on the dimensionality of the system. For a single particle in one dimension (1D), the units are typically $[\Psi] = [\mathrm{L}^{-1/2}]$ (length to the power of negative one half). In 3D, the units would be $[\Psi] = [\mathrm{L}^{-3/2}]$ and the integral over all space of the square function has therefore units of probability is therefore unit less $[-]$.

This is because the integral of $|\Psi|^2$ over all space must equal 1 (normalization condition), and $|\Psi|^2$ has units of probability per unit length $[\mathrm{L}^{-1/2}]$

Remarks

R1. The fact that we speak of "wave" instead of "particle" comes from the brilliant postulate and in fact quite logical of de Broglie that we name "complementarity principle" (which we will detail later too) and which associates with any material particle, a wave and vice versa (for reminder that's because of the results of the Young, Photoelectric and Airy disk experiments as we have already know!).

R2. The fact that we deal with probabilities and that they are proportional to the square of the wave function module comes from the Heisenberg's uncertainty principle (HUP) that we will prove further below (see 4704) later and mainly from the experience of Young slits experiment with electrons (see section Wave Optics page 4509).

Caution!!!! There is at the day we write these lines an experiment (only one... see [584]) providing quite strong evidence that we have to consider the (probabilistic) wave function ontic view, i.e. that a pure quantum state directly corresponds to physical reality (in contrast, the epistemic view treats the state as representing knowledge about some underlying physical state)!

As a corollary, the particle being necessarily located somewhere in the entire space, we have the normalization condition that the integral over all space is:

$$\int |\Psi|^2 \mathrm{d}V = 1 \tag{11.2.3}$$

to a given phase factor. In other words Ψ must be normalized, what we traditionally name the "de Broglie normalization condition" (even if a posteriori the concept seems to come from Max Born).

Indeed the Born rule was formulated by Born in a 11926 (holocene calendar) paper. In this paper, Born solves the Schrödinger equation for a scattering problem and, inspired by Einstein's work on the photoelectric effect, concluded, in a footnote, that the Born rule gives the only possible interpretation of the solution. In 11954 (holocene calendar), together with Walther Bothe, Born was awarded the Nobel Prize in Physics for this and other work.

Remarks

R1. Note that even normalized, Ψ is determined to a given phase factor. In addition, it is preferable for Ψ to be differentiable, because differential operators act on it to get the theoretical predictions on measurable properties, and also finished to be normalizable...

R2. When the integral given above provides a finite amount, we say it is "square integrable". Otherwise, you have to normalize it so that the theoretical model corresponds to reality! We will also discussed it in more details later (with proofs!).

Let us recall that a "phase factor" is a complex constant factor having a unitary module. We can write it (depending on what we have studied in the section on Numbers during our study of complex numbers) $e^{i\delta}$, where δ is any angle, named the "phase" (see section Wave Mechanics page 251). We will also prove further below rigorously why it has no influence!

We can express this postulate in a little more formal way, because as we will see it in several examples, the wave function is often a complex polynomial which can then be expressed in the Hilbert space of polynomials. This gives therefore in the language of Dirac bra-ket formalism (see further below for details) the following definition:

Definition (#11.2.502): The state vector "ket" represented by $|\Psi(t)\rangle$ belonging to the vector space $\mathcal{H}$ (Hilbert space) defines the state of the quantum system at time t. This state vector has all the mathematical properties required by quantum physics and especially the dot product of the vector $|\Psi(t)\rangle$ by its dual vector (complex conjugate) "bra" $\langle\Psi(t)|$ must satisfy the functional scalar product:

$$\boxed{\langle\Psi(t)|\Psi(t)\rangle = 1} \tag{11.2.4}$$

Remark

The bra-ket notation was introduced by Paul Adrien Maurice Dirac to facilitate (at least it's supposed to...) the notation of quantum physics equations, but also to highlight the potential vector aspect of the object representing a quantum state. What is specific to quantum physics is that the vectors are not drawn with arrows but with ket and bra (not the bra you can think about...), but it is only a matter of notations and brings nothing mathematically new. Moreover, you should not imagine that we wrote explicitly in the calculations these vectors as column vectors (think to complex numbers.... it is rare that we write them in vector form in fact)!

To summarize these last paragraphs, the two relations:

$$\langle\Psi(t)|\Psi(t)\rangle = 1 \tag{11.2.5}$$

and:

$$\int |\Psi|^2 \mathrm{d}V = 1 \tag{11.2.6}$$

are therefore equivalent!

A generalization of the Born rule also exist (still as a postulate!). Indeed, if $|\varphi\rangle$ is a function (or vector) representing a state of a system and if $|\chi\rangle$ represents another state of this same system, then there exists and amplitude of probability $A(\varphi \rightarrow \chi)$ to find $|\varphi\rangle$ in the state $|\chi\rangle$, which is given by the dot product on $\mathcal{H}$:

$$A(\varphi \rightarrow \chi) = \langle\chi|\varphi\rangle \tag{11.2.7}$$

The probability $P(\varphi \rightarrow \chi)$ for the state $|\varphi\rangle$ to pass the test $|\chi\rangle$ is then obtained by taking the square module of this amplitude:

$$\boxed{P(\varphi \rightarrow \chi) = \frac{|\langle\chi|\varphi\rangle|^2}{|||\chi\rangle||^2|||\varphi\rangle||^2}} \tag{11.2.8}$$

That is the probability equivalent to the quantum system that is the normalized projection P_χ of the original system ket onto the ket (or kets) corresponding to the result of the measurement, i.e.:

$$|\psi'\rangle = \frac{P_\chi|\psi\rangle}{\sqrt{\langle\psi|P_\chi|\psi\rangle}} = \frac{|\chi\rangle\,\langle\chi\,|\,\psi\rangle}{\sqrt{\langle\psi\,|\,\chi\rangle\,\langle\chi\,|\,\psi\rangle}} \qquad (11.2.9)$$

and this is related to the 4th postulate of the measure of a property that we will introduce just further below.

11.2.1.2 2nd postulate: Time evolution of a quantum state

If the system is not disturbed, the evolution (supposed non-relativistic!) of its state is governed by the Schrödinger's equation of evolution (so time dependent!):

$$\mathrm{i}\hbar\frac{\partial H}{\partial t} = H\Psi \qquad (11.2.10)$$

also denoted in ket-bra notation:

$$\mathrm{i}\hbar\frac{d}{dt}|\psi(t)\rangle = H(t)|\psi(t)\rangle \qquad (11.2.11)$$

This relation simply means that it is the operator "total energy" or "Hamiltonian" H of the system, which is responsible for the system to evolve over time. Indeed, the form of the equation shows that, in applying the Hamiltonian to the wave function Ψ of the system, we obtain the derivative with respect to time, that is to say: how it varies over time!

The term on the left side represents the time evolution of the wave function. The units of the imaginary unit i are dimensionless. The reduced Planck constant $\hbar$ has units of $[\mathrm{J}\cdot\mathrm{s}]$. The time derivative $\partial/\partial t$ has units of $[\mathrm{s}^{-1}]$. The wave function in the the 3D case has unit of $[\mathrm{m}^{-3/2}]$. Therefore, the entire left side and right side have units of $[\mathrm{J}\cdot\mathrm{m}^{-3/2}]$.

Caution!!!! A state vector and a wave function are not the same object, even though in many simple quantum-mechanics courses they appear to be interchangeable. A state vector is the abstract, basis-independent description of a quantum state; a wave function is just its coordinate representation in a chosen basis (often the position basis). This distinction matters because quantum states can be represented in many different ways, and the wave function is only one of them.

Remark

We will prove further below this relation in details (it will not be trivial unfortunately... but it is possible (!) and so it eliminates the need to define it as a postulate).

In the latter relation, H is the Hamiltonian operator (total energy) of the system that we will prove further below as having for value in a particular and simple case:

$$H = E_c + E_p = -\frac{\hbar^2}{2m}\cdot\vec{\nabla} + V(q_1, q_2, \ldots, t) = \sum_{i=1}^{n}\left(-\frac{\hbar^2}{2m}\frac{\partial}{\partial q_k^2}\right) + V(q_1, q_2, \ldots, t) \qquad (11.2.12)$$

In the case where the potential $\vec{V}(q_1, q_2, \ldots, q_n)$ is independent of time (corresponding to a conservative system in classical mechanics), there are (we will see it in various examples later) a set of independent particular solutions time independent and satisfying (relation which we will prove the origin later):

$$H\psi_k(q_1, q_2, \ldots) = E_k\psi_k(q_1, q_2, \ldots) \tag{11.2.13}$$

where the $\psi_k(q_1, q_2, \ldots)$ are the "eigenfunctions" (in analogy with the eigenvectors seen in the section Linear Algebra at page 1997) of the Hamiltonian / operator H with eigenvalue / observable E_k.

These particular solutions then describe special states named "stationary states" (as independent of time...), which we will show later the properties and origin of the name, and which form an orthogonal basis.

The previous eigenvalue equation is often named "time independent Schrödinger equation". It defines the stationary states and has a sense of course only that if the system is conservative.

This is especially the time independent Schrödinger equation that concerns quantum chemistry and molecular chemistry (topics we cover in the Chemistry chapter of the textbook). Indeed, we seek in these fields to get the wave functions describing the stationary states, and especially the state of lowest energy, "fundamental state" of atoms and molecules. The transitions observed in spectroscopy are done between these stationary states (as we will prove it further below), their determination is thus a prerequisite for the study of spectroscopy. However, we must remember that it is the Schrödinger evolution equation, which is (at first ...) the fundamental equation of non-relativistic wave quantum physics: it plays the same role as the Newton equation in Classical Mechanics, or that of an equation of motion (see the proof of the Ehrenfest's theorem further below).

Remark

In fact, we will prove (see section Relativistic Quantum Physics page 4921) that the Schrödinger evolution equation is only a special case of what we name the "free Klein-Gordon equation" which itself is a special case of the "generalized Klein-Gordon equation", which itself is a limited model relatively to the "linearised Dirac equation" ... in short we have not finished to do maths....

11.2.1.3 3rd postulate: Observables and operators

For each measurable physical property (an "observable") of a system denoted for example by:

$$\mathcal{O}(q_k, p_k) \tag{11.2.14}$$

where q_k are the generalized coordinates and p_k the generalized momentum according to notations adopted in the section of Analytical Mechanics, corresponds a linear operator (so it can also be a matrix!) named "Hermitian operator", frequently denoted with a hat such that for the chosen example above it will be denoted by:

$$\hat{\mathcal{O}}(q_k, p_k) \tag{11.2.15}$$

which always intervene in the theoretical calculation of a physically measurable property (see the section Linear Algebra page 1953 for a recall of what is an Hermitian matrix).

In other words (but this is more related to the postulates that will follow): An observable value is represented by a quantum operator which operates on the wave function to predict the measurement value of the latter observable (the operator $\hat{\mathcal{O}}$ fix the mathematical representation of $\mathcal{O}$).

To make ... a Hermitian operator in quantum physics is a mathematical expression as such that if we take its complex conjugate (or its adjoint matrix if the mathematical expression is a matrix!) then the theoretical calculation of the measurable value is always given by the same expression.

Here are the best known examples for which we will prove in details the origin in this section and of this of Relativistic Quantum Physics:

✍**Examples:**

E1. Coordinates:

$$q_k \rightarrow \hat{q}_k \tag{11.2.16}$$

for which we will see a practical example with the Ehrenfest theorems in this section.

E2. Momentum:

$$p_k \rightarrow \hat{p}_k \equiv -\mathrm{i}\hbar\partial_k \tag{11.2.17}$$

for which we will also see several practical examples (including one with the Ehrenfest theorems).

These two examples are sometimes referred to under the name "correspondence principle".

E3. Kinetic momentum:

$$b_z \rightarrow \hat{b}_z \equiv x\hat{p}_y - \hat{p}_x y \tag{11.2.18}$$

E4. Pauli matrices (that as we will see later correspond to the spin operators):

$$\sigma_0 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \sigma_1 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \sigma_2 = \begin{bmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{bmatrix}, \sigma_2 = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \tag{11.2.19}$$

E5. The operator of evolution of energy of a quantum state:

$$E \rightarrow \hat{E} \equiv \mathrm{i}\hbar\partial_t \tag{11.2.20}$$

Remarks

R1. This may seem to fall from the sky ... but we will see that it just comes naturally when we will later do the development of some very concrete examples or when reading the section of Quantum Computing.

R2. As part of this textbook, we write indifferently, the operators and observable without the hat symbol (that's the reader to know what we are working with... without being confused...).

We will see also that some operators are not commutative and obey to what we name "anticommutation relations" (which are the source of the Heisenberg' principles of uncertainty).

✍**Example:**

Here is an example of such a relation that we will prove later:

$$[q_k,p_l]=[q_k,p_l]_-=q_kp_l-p_lq_k=\mathrm{i}\hbar\delta_{kl} \tag{11.2.21}$$

then we say that the two components of the two observable position and momentum are "canonically conjugate".

We will also see using a practical case that two observables A, B whose respective operators commute such as:

$$[\hat{A},\hat{B}]=0 \tag{11.2.22}$$

possess a common eigenvectors base. We then say that they are simultaneously measurable (the precise determination of one does not preclude the other's) with accuracy (otherwise we have an uncertainty... of Heisenberg). The two quantities A, B can then be named "compatible observable C.O." This then means that the two operators should have the same specific eigenfunctions (so they are compatible only if the associated operators admit such common functions).

The set of all attached C.O. to a physical system is a "complete set of compatible observables C.S.C.O.".

11.2.1.4 4th postulate: Measure of a property (collapse postulate)

The consequence of the previous postulate is that the measurement of $\mathcal{O}$ therefore always gives an eigenvalue of the associated Hermitian operator $\hat{\mathcal{O}}$. In other words, the only observable values of the property $\mathcal{O}$ are the eigenvalues (denoted for example: o) of the operator $\hat{\mathcal{O}}$!

$$\underbrace{\hat{\mathcal{O}}}_{\text{operator}}\cdot\underbrace{\phi_k}_{k\text{th eigenfunction}}=\underbrace{o_k}_{k\text{th eigenvalue}}\cdot\underbrace{\phi_k}_{k\text{th eigenfunction}} \tag{11.2.23}$$

The eigenvectors and eigenvalues of an operator values have special meaning: the eigenvalues are the values that can result from an ideal measure of this property, the eigenvectors are the quantum states of the system during the measurement.

It is because of this assumption that it is important to ensure that any physical property is represented by a Hermitian operator.

Theorem 11.1. In other words, the hermiticity of $\hat{\mathcal{O}}$ ensures that its eigenvalues (so denoted by example: o) are real.

Let's us first do the proof with the usual algebraic notation and then with another approach using the Dirac notation.

Proof 11.1.1. Since an operator is associated with a specific eigenfunction and an eigenvalue by (see section Linear Algebra page 1997):

$$\hat{\mathcal{O}}\varphi_k = o_k\varphi_k \tag{11.2.24}$$

Using the property proved during in our study of complex numbers in the section Numbers like that the complex conjugate product of two complex numbers is the product of two conjugate numbers we have:

$$\overline{\hat{\mathcal{O}}}\bar{\varphi}_k = \bar{o}_k\bar{\varphi}_k \tag{11.2.25}$$

If we multiply the first relation by the complex conjugate of φ_k and integrate over all space, we have:

$$\int \bar{\varphi}_k\hat{\mathcal{O}}\varphi_k \mathrm{d}V = o_k\int \bar{\varphi}_k\varphi_k \mathrm{d}V \tag{11.2.26}$$

and same with the prior previous relation:

$$\int \varphi_k\hat{\mathcal{O}}\bar{\varphi}_k \mathrm{d}V = \bar{o}_k\int \varphi_k\bar{\varphi}_k \mathrm{d}V \tag{11.2.27}$$

As by definition $\hat{\mathcal{O}}$ is Hermitian (therefore equal to its own conjugate complex), both left sides of the previous two relations are equal. Then we have:

$$o_k\int \bar{\varphi}_k\varphi_k \mathrm{d}V = \bar{o}_k\int \varphi_k\bar{\varphi}_k \mathrm{d}V \tag{11.2.28}$$

Therefore it comes:

$$(o_k-\bar{o}_k)\int \bar{\varphi}_k\varphi_k \mathrm{d}V = 0 \tag{11.2.29}$$

and as the integral is physically of square integrable and therefore not zero, this requires that:

$$o_k-\bar{o}_k = 0 \tag{11.2.30}$$

and therefore:

$$o_k = \bar{o}_k \tag{11.2.31}$$

and this is only possible if the eigenvalue is real.

Now, with the Dirac notation and with an approach a little bit different:

Since an operator is associated with a specific eigenfunction and eigenvalue by (see section Linear Algebra page 1997):

$$\hat{\mathcal{O}}|\varphi_k\rangle = o_k|\varphi_k\rangle \tag{11.2.32}$$

We then have if the eigenfunction is normalized in Dirac notation:

$$o_k = \langle\varphi_k|\hat{\mathcal{O}}|\varphi_k\rangle \tag{11.2.33}$$

And if the operator $\hat{\mathcal{O}}$ is a Hermitian operator (therefore equal to its complex conjugate in the case of a function and equal to the transposed complex in the case of a matrix), we have:

$$\bar{o}_k = \overline{\langle\varphi_k|\hat{\mathcal{O}}|\varphi_k\rangle} = \langle\varphi_k|\hat{\mathcal{O}}^\dagger|\varphi_k\rangle = \langle\varphi_k|\hat{\mathcal{O}}|\varphi_k\rangle = o_k \tag{11.2.34}$$

So if the operator is indeed Hermitian we have:

$$\bar{o}_k = o_k \tag{11.2.35}$$

and this can only be satisfy if the eigenvalues are real.

■ Q.E.D.

Thus, own hermitic operator values are always real numbers (hopefully ...).

Now we can introduce the final form of the postulate: After a measurement of A that yields the result a_n, the quantum system is in a new state that is the normalized projection P_n of the original system ket onto the ket (or kets) corresponding to the result of the measurement:

$$|\psi'\rangle = \frac{P_n|\psi\rangle}{\sqrt{\langle\psi|P_n|\psi\rangle}} = \frac{|a_n\rangle\langle a_n\,|\,\psi\rangle}{\sqrt{\langle\psi\,|\,a_n\rangle\langle a_n\,|\,\psi\rangle}} = \frac{\langle a_n\,|\,\psi\rangle}{|\langle a_n\,|\,\psi\rangle|}\,|a_n\rangle = e^{i\varphi}\,|a_n\rangle \tag{11.2.36}$$

and hence:

$$\langle\psi'\,|\,\psi'\rangle = \langle a_n|\,e^{-i\varphi}e^{i\varphi}\,|a_n\rangle = \langle a_n\,|\,a_n\rangle = 1 \tag{11.2.37}$$

11.2.1.5 5th postulate: Average of a property

This postulate is the less intuitive and more difficult to prove (we will prove it with an example when studying the Ehrenfest theorems at page 4870). Its statement is as follows:

The mean value (expected) of a physical property $\mathcal{O}$, when the system is in the state described by the normalized function Ψ is given by (do not confuse the notation of the average of an operator with that of the complex conjugate of an eigenvalue !!!):

$$\boxed{\langle\mathcal{O}\rangle = \bar{\mathcal{O}} = \int\bar{\Psi}\hat{\mathcal{O}}\Psi\mathrm{d}V = \langle\Psi|\hat{\mathcal{O}}|\Psi\rangle} \tag{11.2.38}$$

An equivalent expression quite difficult to read is the following: the probability of finding the eigenvalue o_k (of the operator $\hat{\mathcal{O}}$ predominantly Hermitian), when measuring the property $\mathcal{O}$

at time t on a quantum system prepared in state described by the function Ψ is given by the square of module of the projection of the function Ψ on the eigenfunction φ_k associated to the eigenvalue o_k (and its operator):

$$P(o_k,t|\Psi)=|\langle\varphi_k|\Psi\rangle|^2 \tag{11.2.39}$$

where the "projection" (or "representative") is defined by:

$$\langle\varphi_k|\Psi\rangle=\int\bar{\varphi}_k\Psi\mathrm{d}V \tag{11.2.40}$$

the index k being here to indicate that there may be for a given quantum system multiple eigenvalues with their corresponding eigenvectors.

The point of eigenstates and the entire linear algebra of quantum mechanics is that the projections $\langle\phi\,|\,\psi\rangle$ of the state $|\psi\rangle$ onto each eigenstate $|\phi\rangle$ represent the probability amplitudes of each eigenstate. In particular, this means:

$$\sum|\langle\phi\,|\,\psi\rangle|^2=1=|\langle\psi\,|\,\psi\rangle|^2 \tag{11.2.41}$$

Where the summation is taken over all the eigenstates of an operator. As this must be true for all states $|\psi\rangle$, the thing on the left must be a Pythagoran sum, so the $|\phi\rangle$ s must form an orthogonal basis. Alternatively, one may just note that we must have $\langle\phi_1\,|\,\phi_2\rangle=0$ if the eigenvalues corresponding are distinct, as two distinct observations must be mutually exclusive.

Remark

We will come back on this formalism and relations further below. They are also several practical examples provided in the section of Quantum Computing and a single and very nice example at the end of the section of Quantum Chemistry (for the mean radius and the mean angular momentum).

For example, in one dimension and for a system that is time dependent, we use the operators presented in the previous postulate (but on which we will also return in detail):

$$\begin{aligned}\langle x\rangle&=\int\bar{\Psi}\hat{x}\Psi\mathrm{d}x=\int\bar{\Psi}x\Psi\mathrm{d}x=\int x\bar{\Psi}\Psi\mathrm{d}x\\ \langle p\rangle&=\int\bar{\Psi}\hat{p}\Psi\mathrm{d}x=\int\bar{\Psi}(-\mathrm{i}\hbar\partial_x)\Psi\mathrm{d}x=-\mathrm{i}\hbar\int x\bar{\Psi}\frac{\partial\Psi}{\partial x}\mathrm{d}x\\ \langle E\rangle&=\int\bar{\Psi}\hat{E}\Psi\mathrm{d}x=\int\bar{\Psi}(\mathrm{i}\hbar\partial_t)\Psi\mathrm{d}x=\mathrm{i}\hbar\int x\bar{\Psi}\frac{\partial\Psi}{\partial t}\mathrm{d}x\end{aligned} \tag{11.2.42}$$

For which we will see practical examples in the sections already mentioned!

Notice that therefore quantum mechanics is also an interesting example of an experimentally verifiable theory that doesn't require all mathematical structures to be directly observables. Indeed, wave functions are not themselves measurable (at least today!); what is measurable is merely the probability distribution that is derived from the wave function! Now, not everybody is happy with this state of affairs. But however quantum mechanics is highly successful regardless. So there isn't a priori anything unscientific about a theory that contains unobservable elements at the moment that the predictions can be reproduced and are consistent (i.e. lead to the same conclusions) around the World.

Remark

Some physicists have tried to rule out the imaginary number i that appears in various equations of Quantum Physics. Even if its possible in the majority of situations it can't be done for some special cases as proven theoretically in [97] and this may be experimentally refutable as some further developments show that complex quantum theory should outperforms statistically real quantum theory (see [572]).

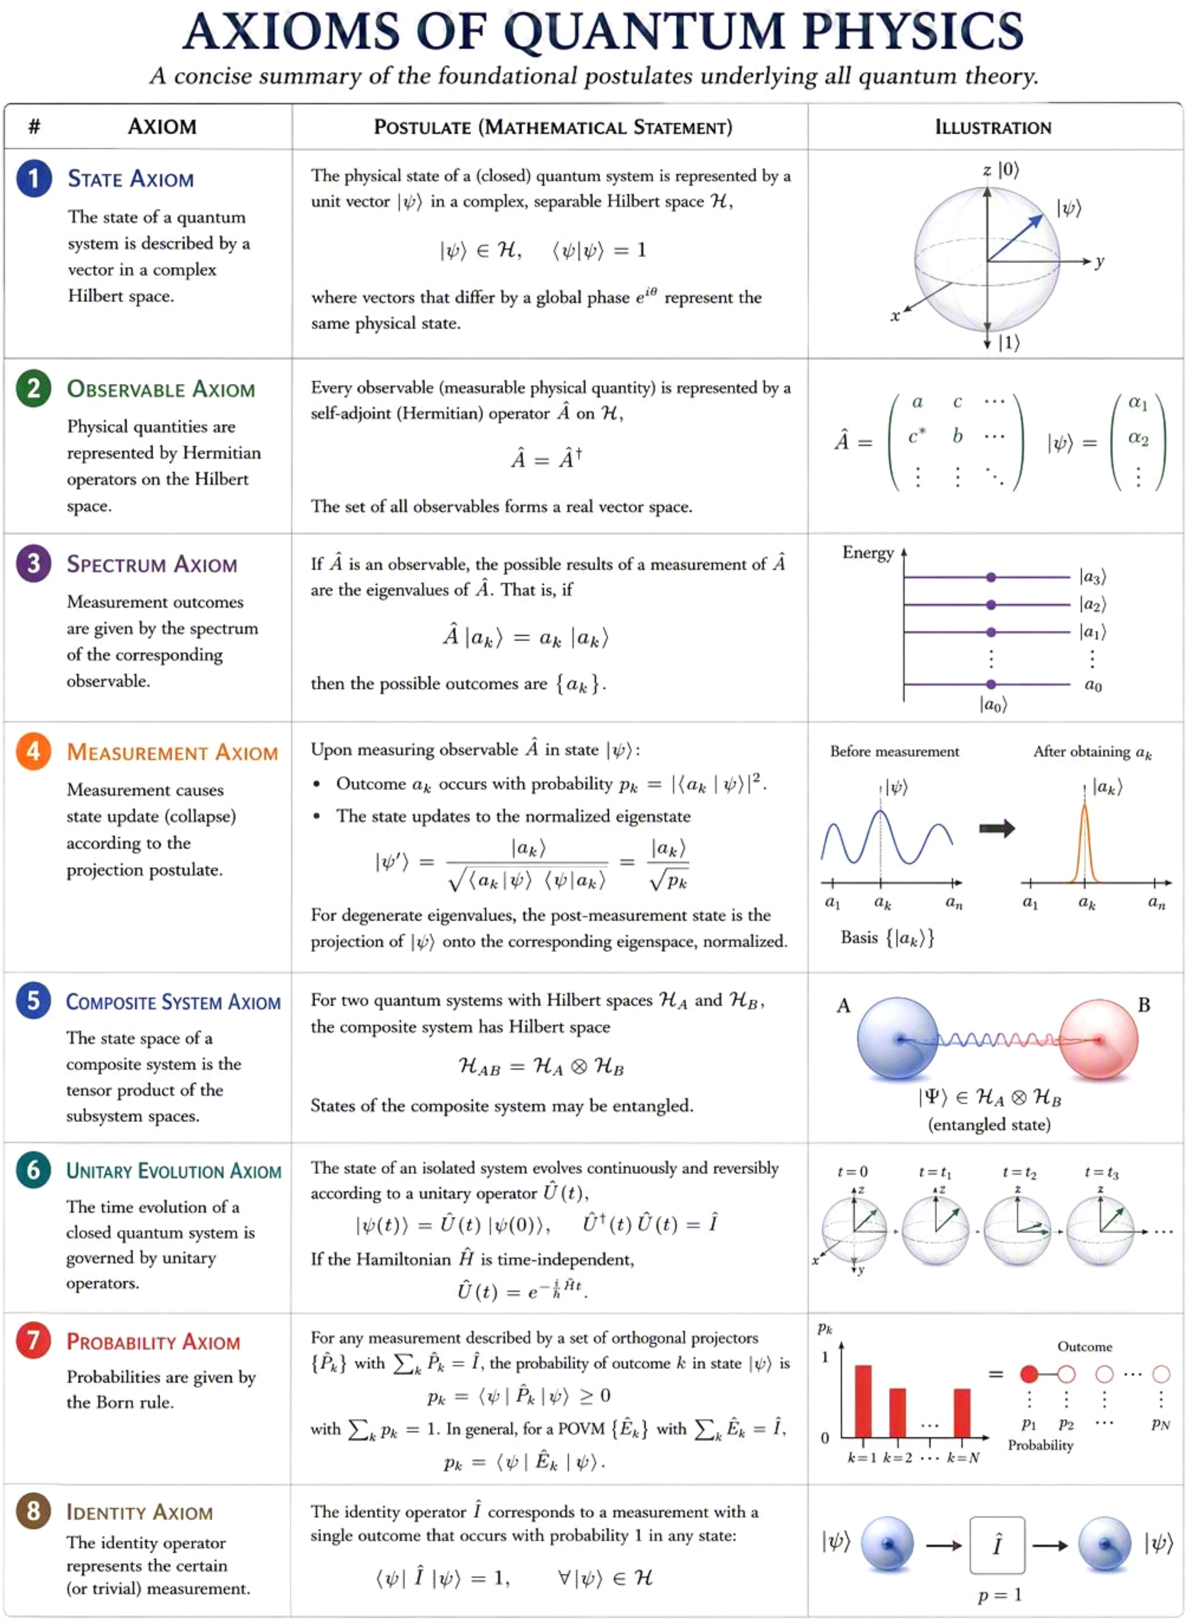
Notice that some textbooks or lectures merge together some of the postulates of the table below and others introduce the Pauli exclusion principle as a postulate (for pedagogical reasons to undergraduate students) even if the latter can be proved with the Spin-Statistics theorem. Also some textbooks and lectures add the "expansion theorem" as a postulate (the eigenfunctions of a linear and hermitian operator form a complete basis set) even if the latter is a property of Hilbert spaces (this is subject to debates...). So a summary of the most common postulates can be given by (the order of the postulates are important for some people so we tried to respect that point):

Number	Postulate	Formalism
P1	**The state vector:** An isolated physical system is represented, at a given time t, by a state vector $\vert\Psi\rangle$ belonging to a Hilbert state space $\mathcal{H}$	$\vert\Psi(\vec{r},t)\rangle \in \mathcal{H}$
P2	**Observable and operators:** Every measurable physical quantity O_k corresponds to a mathematical linear hermitian operator $\hat{O}$	$O_k \rightarrow \hat{O}$ (e.g. $\hat{p} \rightarrow -\mathrm{i}\hbar\nabla$)
P3	**Quantized outcomes:** Every measurable physical quantity $\mathcal{A}$ is described by a Hermitian operator $\mathcal{O}$ acting in the state space $\mathcal{H}$. This operator is an observable, meaning that its eigenvectors form a basis for $\mathcal{H}$. The result of measuring a physical quantity $\mathcal{A}$ must be one of the eigenvalues O_k of the corresponding observable	$\underbrace{\hat{O}}_{\text{operator}} \cdot \underbrace{\psi_k}_{\text{eigenfunction}} = \underbrace{O_k}_{\text{eigenvalue}} \cdot \underbrace{\psi_k}_{\text{eigenfunction}}$
P4	**Collapse rule:** If the measurement of a physical quantity $\mathcal{A}$ of a system in the state $\vert\psi\rangle$ gives the result a_n, then the state of the system immediately after the measurement is the normalized projection of $\vert\psi\rangle$ onto the eigensubspace associated with a_n	$\vert\psi'\rangle = \dfrac{P_n\vert\psi\rangle}{\sqrt{\langle\psi\vert P_n\vert\psi\rangle}} = \dfrac{\vert a_n\rangle\langle a_n\mid\psi\rangle}{\sqrt{\langle\psi\mid a_n\rangle\langle a_n\mid\psi\rangle}}$

P5	**Average of a property:** The expectation value of any property can be found by performing the expectation value integral with respect to its associated wavefunction, a special case being the Born rule when $\varphi_k := \Psi$	$P\left(o_k, t \mid \Psi\right) = \left\lvert\langle\varphi_k \mid \Psi\rangle\right\rvert^2 = \left\lvert\int \bar{\varphi}_k \Psi \mathrm{d}V\right\rvert^2$
P6	**Time evolution:** The time evolution of a closed system (the change of a system's state over time) is a linear transformation via a unitary operator	$\lvert\Psi(t)\rangle = \underbrace{U\left(t, t_0\right)}_{\text{time operator}} \lvert\Psi\left(t_0\right)\rangle$ $\equiv$ $\mathrm{i}\hbar\frac{\mathrm{d}}{\mathrm{d}t}\lvert\psi(t)\rangle = H(t)\lvert\psi(t)\rangle$
P7	**Density operator:** The Hilbert space of a composite system is the Hilbert space tensor product of the state spaces associated with the component systems	$\hat{\rho} = \lvert\phi\rangle \otimes \langle\psi\rvert = \underbrace{\begin{bmatrix} \phi_1\psi_1^* & \phi_1\psi_2^* & \ldots \\ \phi_2\psi_1^* & \phi_1\psi_2^* & \ldots \\ \ldots & \ldots & \phi_n\psi_n^* \end{bmatrix}}_{\text{density matrix}}$

Table 11.6: **Summary of common wave (probabilistic) quantum physics in the orthodox interpretation**

The first five postulates above can be generalized with the density operator!



AXIOMS OF QUANTUM PHYSICS

A concise summary of the foundational postulates underlying all quantum theory.

#	Axiom	Postulate (Mathematical Statement)	Illustration
1	**State Axiom** The state of a quantum system is described by a vector in a complex Hilbert space.	The physical state of a (closed) quantum system is represented by a unit vector $\lvert\psi\rangle$ in a complex, separable Hilbert space $\mathcal{H}$, $$\lvert\psi\rangle \in \mathcal{H}, \quad \langle\psi\vert\psi\rangle = 1$$ where vectors that differ by a global phase $e^{i\theta}$ represent the same physical state.	z $\lvert 0\rangle$ $\lvert\psi\rangle$ y x $\lvert 1\rangle$
2	**Observable Axiom** Physical quantities are represented by Hermitian operators on the Hilbert space.	Every observable (measurable physical quantity) is represented by a self-adjoint (Hermitian) operator $\hat{A}$ on $\mathcal{H}$, $$\hat{A} = \hat{A}^\dagger$$ The set of all observables forms a real vector space.	$\hat{A} = \begin{pmatrix} a & c & \cdots \\ c^* & b & \cdots \\ \vdots & \vdots & \ddots \end{pmatrix} \quad \lvert\psi\rangle = \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \vdots \end{pmatrix}$
3	**Spectrum Axiom** Measurement outcomes are given by the spectrum of the corresponding observable.	If $\hat{A}$ is an observable, the possible results of a measurement of $\hat{A}$ are the eigenvalues of $\hat{A}$. That is, if $$\hat{A}\,\lvert a_k\rangle = a_k\,\lvert a_k\rangle$$ then the possible outcomes are $\{a_k\}$.	Energy $\lvert a_3\rangle$ $\lvert a_2\rangle$ $\lvert a_1\rangle$ $\vdots$ a_0 $\lvert a_0\rangle$
4	**Measurement Axiom** Measurement causes state update (collapse) according to the projection postulate.	Upon measuring observable $\hat{A}$ in state $\lvert\psi\rangle$: • Outcome a_k occurs with probability $p_k = \lvert\langle a_k \mid \psi\rangle\rvert^2$. • The state updates to the normalized eigenstate $$\lvert\psi'\rangle = \frac{\lvert a_k\rangle}{\sqrt{\langle a_k\vert\psi\rangle\ \langle\psi\vert a_k\rangle}} = \frac{\lvert a_k\rangle}{\sqrt{p_k}}$$ For degenerate eigenvalues, the post-measurement state is the projection of $\lvert\psi\rangle$ onto the corresponding eigenspace, normalized.	Before measurement After obtaining a_k $\lvert\psi\rangle$ $\lvert a_k\rangle$ a_1 a_k a_n a_1 a_k a_n Basis $\{\lvert a_k\rangle\}$
5	**Composite System Axiom** The state space of a composite system is the tensor product of the subsystem spaces.	For two quantum systems with Hilbert spaces $\mathcal{H}_A$ and $\mathcal{H}_B$, the composite system has Hilbert space $$\mathcal{H}_{AB} = \mathcal{H}_A \otimes \mathcal{H}_B$$ States of the composite system may be entangled.	A B $\lvert\Psi\rangle \in \mathcal{H}_A \otimes \mathcal{H}_B$ (entangled state)
6	**Unitary Evolution Axiom** The time evolution of a closed quantum system is governed by unitary operators.	The state of an isolated system evolves continuously and reversibly according to a unitary operator $\hat{U}(t)$, $$\lvert\psi(t)\rangle = \hat{U}(t)\,\lvert\psi(0)\rangle, \qquad \hat{U}^\dagger(t)\,\hat{U}(t) = \hat{I}$$ If the Hamiltonian $\hat{H}$ is time-independent, $$\hat{U}(t) = e^{-\frac{i}{\hbar}\hat{H}t}.$$	$t=0$ $t=t_1$ $t=t_2$ $t=t_3$ z z z z x y $\cdots$
7	**Probability Axiom** Probabilities are given by the Born rule.	For any measurement described by a set of orthogonal projectors $\{\hat{P}_k\}$ with $\sum_k \hat{P}_k = \hat{I}$, the probability of outcome k in state $\lvert\psi\rangle$ is $$p_k = \langle\psi \mid \hat{P}_k \mid \psi\rangle \geq 0$$ with $\sum_k p_k = 1$. In general, for a POVM $\{\hat{E}_k\}$ with $\sum_k \hat{E}_k = \hat{I}$, $$p_k = \langle\psi \mid \hat{E}_k \mid \psi\rangle.$$	p_k 1 0 $k=1$ $k=2$ $\cdots$ $k=N$ = Outcome p_1 p_2 $\cdots$ p_N Probability
8	**Identity Axiom** The identity operator represents the certain (or trivial) measurement.	The identity operator $\hat{I}$ corresponds to a measurement with a single outcome that occurs with probability 1 in any state: $$\langle\psi\vert\ \hat{I}\ \vert\psi\rangle = 1, \qquad \forall\,\lvert\psi\rangle \in \mathcal{H}$$	$\lvert\psi\rangle \rightarrow \boxed{\hat{I}} \rightarrow \lvert\psi\rangle$ $p = 1$

11.2.2 Classical principles of uncertainty

Before attacking directly quantum physics in front and the corresponding mathematical tools in-deep (and the pseudo-proofs of the five postulates), we must first introduce a simple classic example in which appears a special type of phenomena: the intrinsic presence of uncertainty in any measurement (as it is intrinsic we don't speak of "statistical uncertainty" as we have already study in the section Statistics!).

This study in classical form is fundamentally not very rigorous (for a more formal and rigorous approach, see below the "Robertson uncertainty relations" at page 4733), it will however normally help the average reader to better understand the quantum uncertainty (at least we hope so...) that we will study and determine further below and that will need no previous experimental considerations! However it seems that it was really one of the approaches used by Werner Heisenberg himself[5]!

Imagine that we would like to measure through a microscope the abscissa x of a particle and the components of its momentum $\vec{p}$. For the measurement of x to be possible, there must be a monochromatic light beam (to simplify...) parallel to the x-axis comes illuminate the particle, and that at least one photon collides the particle and reaches the eye of the observer:

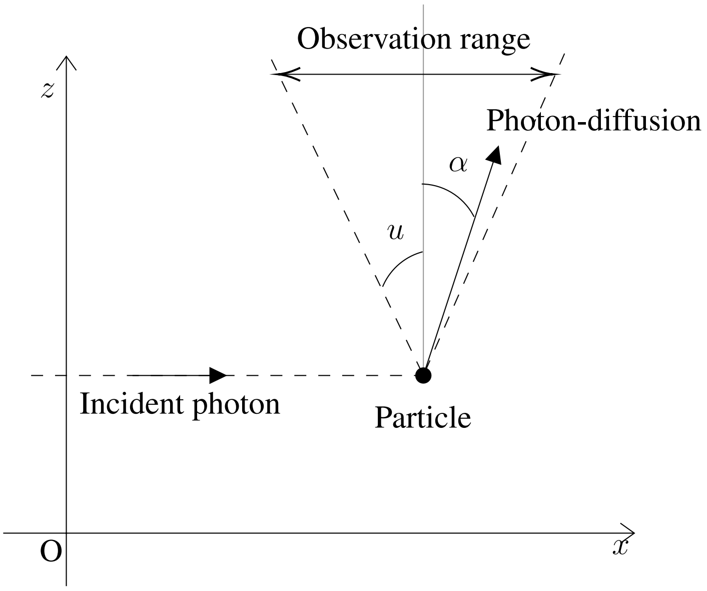


Figure 11.32: Heisenberg's microscope

Remark

Heisenberg's microscope exists only as a thought experiment, one that was proposed by Werner Heisenberg, criticized by his mentor Niels Bohr, and subsequently served as the nucleus of some commonly held ideas, and misunderstandings, about Quantum Mechanics. In particular, it provided an argument for the uncertainty principle on the basis of the principles of classical optics. While the act of measurement does lead to uncertainty, the loss of precision is less than that predicted by Heisenberg's argument when measured at the level of an individual state. The formal mathematical result remains valid.

---

[5] This isn't the way Werner Heisenberg derived the uncertainty relationships in his original book *Die physikalischen Prinzipien der Quantentheorie* (11929 according to holocene calendar). How he did involves the probabilistic wave function and a quite ugly assumption that's why we won't introduce here the original historical way of the proof by Heisenberg.

Once x measured, we can imagine any method for measuring the linear momentum.

Let us put α as the angle that do the direction of the photon after collision with the z-axis. Let us suppose to simplify the calculations that the particle has a relatively high mass so that we can neglect the energy change of the photon. We see that after the collision, the components of the linear momentum of the scattered photon following respectively the x-axis and z-axis are:

$$\frac{h\nu}{c}\sin(\alpha) \qquad \frac{h\nu}{c}\cos(\alpha) \tag{11.2.43}$$

Indeed, let us recall that the relations between the electromagnetic waves, the mass-energy equivalence and the linear momentum (see section Special Relativity page 5679) are:

$$E=mc^2=h\nu\Rightarrow m=\frac{h\nu}{c^2}\Rightarrow p=mv=mc=\frac{h\nu}{c^2}c=\frac{h\nu}{c} \tag{11.2.44}$$

It follows that the particle will see its amount of linear momentum altered. The components of the variation are then (remember that initially it was zero following the z-axes) those of the variation of the photon following:

$$\frac{h\nu}{c}(1-\sin(\alpha)) \qquad -\frac{h\nu}{c}\cos(\alpha) \tag{11.2.45}$$

between it initial and final linear momentum.

The only information we have about the angle α is that it is, in absolute value less than or equal to the opening angle u of the microscope objective (technical restrictions).

This implies that:

$$|\sin(\alpha)|\leq\sin(u) \qquad \cos(u)\leq|\cos(\alpha)|\leq\sin(u) \tag{11.2.46}$$

11.2.2.1 First classical uncertainty relation

When we will have measured the linear momentum $\vec{p}$ at the end of the experiment, we just saw that we will have to make the corrections:

$$\frac{h\nu}{c}(1-\sin(\alpha)),-\frac{h\nu}{c}\cos(\alpha) \tag{11.2.47}$$

of the linear momentum of the photon to know the true value of $\vec{p}$ of the particle just before the start of measurement.

In these corrections, there is an unknown portion corresponding to measurement errors on p_x and p_z of the photon. It is possible to establish that the maximum error Δp_x and Δp_z on the initial linear momentum is given by the x component of the "first classical Heisenberg's uncertainty relation":

$$\boxed{\Delta p_x = \frac{h\nu}{c}\sin(u)} \tag{11.2.48}$$

as we have $|\sin(\alpha)| < \sin(u)$. So it is like a worst error!

11.2.2.2 Second classical uncertainty relation

Let us now see what we can say about the measurement of the position of the particle.

Let us recall now that (see section Wave Optics page 4497) for a rectangular aperture we have by putting $n = 1$:

$$\sin(\theta) = \frac{\lambda}{e} \tag{11.2.49}$$

where θ (in Wave Optics) is the angle to clearly distinguish two diffraction minima (and therefore clearly an object emitting radiation between the same two points). Conversely, from the viewpoint of diffraction, the opening width e is given by:

$$e = \frac{\lambda}{\sin(\theta)} \tag{11.2.50}$$

The value of e may also be seen as the vision area (orthogonal projection of the rectangular aperture on the x axis) of width $x = e$ of the particle. Therefore:

$$x = \frac{\lambda}{\sin(\theta)} \tag{11.2.51}$$

Just as the maximum error of the linear momentum is given by the condition $|\sin(\alpha)| < \sin(u)$, we can also write $|\sin(\theta)| < \sin(u)$, which leads us to write:

$$\Delta x = \frac{\lambda}{\sin(u)} \tag{11.2.52}$$

If we multiply the following relation we just proved before:

$$\Delta p_x = \frac{h\nu}{c}\sin(u) = \frac{h}{\lambda}\sin(u) \tag{11.2.53}$$

with the prior-previous one, we get:

$$\Delta x \Delta p_x = \frac{\lambda}{\sin(u)}\frac{h\nu}{c}\sin(u) = \frac{h}{\lambda}\sin(u) \tag{11.2.54}$$

After simplification we get the "second classical Heisenberg's uncertainty relation" also named "classical spatial uncertainty":

$$\boxed{\Delta x \Delta p_x = h} \tag{11.2.55}$$

which thus represents the maximum experimental error of a small rectangular aperture opening of a microscope. Many quantum physics textbooks show that we fall back on exactly the same expression in many situations.

In his celebrated 11927 (holocene calendar) paper, *Über den anschaulichen Inhalt der quantentheoretischen Kinematik und Mechanik*), Werner Heisenberg established this expression as the minimum amount of unavoidable momentum disturbance caused by any position measurement, but he did not give a precise definition for the uncertainties Δx and Δp. Instead, he gave some plausible estimates in each case separately.

Remark

The reader will easily verify that this relation applied to for a macroscopic object (size of the order of the centimetre), which position would be measurable with a precision of the micrometer gives a ridiculously low uncertainty of linear momentum and thus for the speed. But (!) the same relation applied to the mass of a particle such as that of an electron with a position measurement accuracy assumed of a tenth of a nanometre give an uncertainty about the speed of about $1,000\,[\text{m}\cdot\text{s}^{-1}]$!!

Thus, if we try to locate a particle with an accuracy always bigger, its momentum reaches extreme values. At some point, the magnitude of the linear momentum can be so big that the corresponding energy is sufficient to produce a particle-antiparticle pair. In other words, if we try to confine a particle in an increasingly small box on the one hand, we know less and less its linear momentum and from a certain threshold, we do not even know how many particles there are in the box!

However (!), we will see during our study of commutators applied to quantum physics theory that the true uncertainty relation (whose value differs from the one above as proved at page 4733) only appears naturally from mathematical properties and the definition of the linear momentum.

More generally, for a particle in a volume of dimensions x,y,z, a vector state is characterized by six quantities (x,y,z,p_x,p_y,p_z) in the phase space (phase space which is therefore of 6 dimensions) and the quantum state occupies the "cube" of volume:

$$(\Delta x\Delta p_x)(\Delta y\Delta p_y)(\Delta z\Delta p_z)=h^3 \qquad (11.2.56)$$

What is remarkable in this simplistic approach is that the Planck constant naturally emerges as the unit of minimum universal measurement of uncertainty of experimental physics through the wave-particle dualism! Heisenberg wrote that this result establishes the ultimate failure of causality in quantum physics.

11.2.2.3 Third classical uncertainty relation

In special relativity, we saw that (x, y, z, ct) are the components of a space-time four-vector and also (p_x, p_y, p_z, Ec^{-1}) those of a vector of a four energy-momentum vector.

It is therefore natural to complete the three spatial relation of the type $\Delta x\Delta p_x = h$ by extension:

$$\underbrace{\begin{gathered}x \Rightarrow p_x \rightarrow \Delta x\Delta p_x = h\\ y \Rightarrow p_y \rightarrow \Delta y\Delta p_y = h\\ z \Rightarrow p_z \rightarrow \Delta z\Delta p_z = h\end{gathered}}_{ct\Rightarrow\frac{E}{c}\rightarrow\Delta(ct)\Delta\left(\frac{E}{c}\right)=h} \tag{11.2.57}$$

We obtain thus roughly the "third classical uncertainty relation" also named "classical temporal uncertainty" or "energy-time uncertainty":

$$\boxed{\Delta t\Delta E = h} \tag{11.2.58}$$

However (!), we will see during our study of commutators applied to the theory of quantum physics, that this uncertainty relation (whose value differs from the one above) also appears naturally from only the mathematical properties and the definition of the linear momentum.

Remark

We will come back later on the implications of this temporal uncertainty whose implications are the basis of Quantum Cosmology (and therefore of the creation of our Universe... as seen at page 6083!) and also of Quantum Field Theory and in particular regarding to the Yukawa potential (see section Quantum Field Theory page 5164).

The established classical uncertainties relation will allow us to better understand the "real" uncertainties relations in their modern quantum form. For this, among others, we will have to make use of the necessary mathematical artillery. However, for the sake of clarity, we wanted to present the wave quantum physics in the simplest and least formal way possible as always in this textbook. This presentation may perhaps take the reader to many misinterpretations, he must therefore remain cautious as long as it has not seen the rigorous proof!

Let us now come back as promise in the section of Magnetostatics on the Wilson bubble chamber that obviously seems to be incompatible with Heisenberg' inequalities:

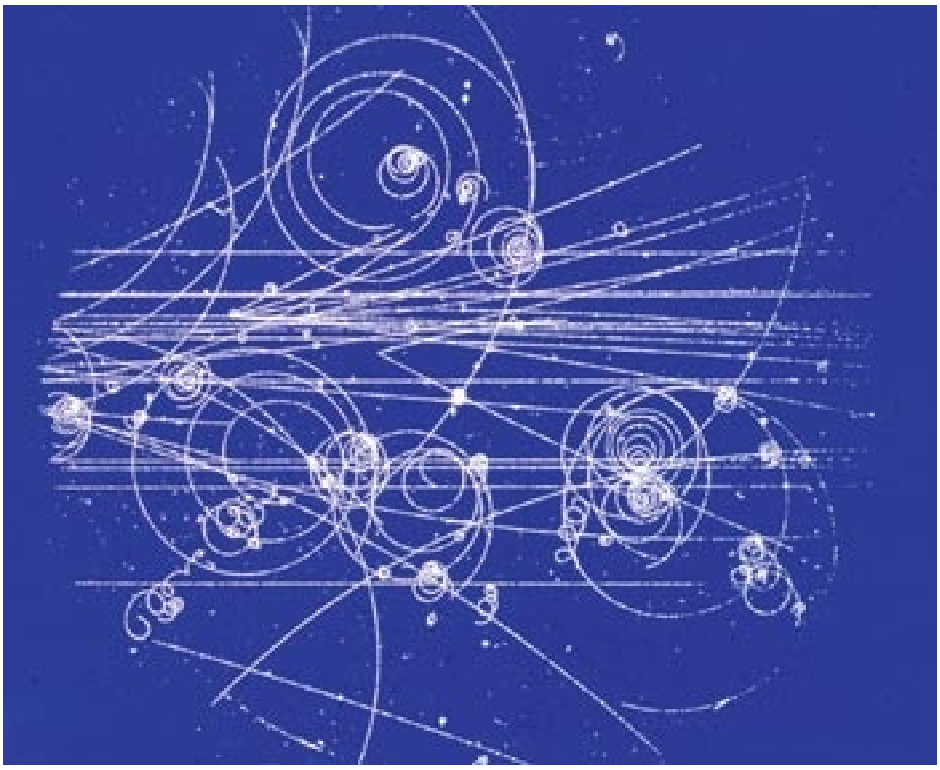

Figure 11.33: Wilson bubble chamber (source: CERN)

The issue of having the possibility to track a particle with such precision and on such a long distance that seems to violate both: Heisenberg's incertitude principle and Wave-Particle duality is named in general the "Mott problem[6]".

The problem was first formulated in 11929 (holocene calendar) by Sir Nevill Francis Mott and Werner Heisenberg, illustrating the paradox of the collapse of a spherically symmetric wave function into the linear tracks seen in a bubble chamber.

In practice, virtually all high energy physics experiments, such as those conducted at particle colliders, involve wave functions which are inherently spherical. Yet, when the results of a particle collision are detected, they are invariably in the form of linear tracks (see, for example, the illustrations accompanying the article on bubble chambers). It is somewhat strange to think that a spherically symmetric wave function should be observed as a straight track, and yet, this occurs on a daily basis in all particle collider experiments.

A related variant formulation was given in 11953 (holocene calendar) by Mauritius Renninger, and is now known as "Renninger's negative-result gedanken experiment". In this formulation, it is noted that the absence of a particle detection can also constitute a quantum measurement; namely, that a measurement can be performed even if no particle whatsoever is detected.

In the original 11929 (holocene calendar) formulation by Mott and Heisenberg, the spherical wave function of an alpha ray emitted from the decay of a radioactive atomic nucleus was considered. It was noted that the result of such a decay is always observed as linear tracks seen in Wilson's cloud chamber (i.e. bubble chamber). Intuitively, one might think that such a wave function should randomly ionize atoms throughout the cloud chamber, but this is not the case. Mott demonstrated that by considering the interaction in configuration space, where all of the atoms of the cloud chamber play a role, it is overwhelmingly probable that all of the condensed droplets in the cloud chamber will lie close to the same straight line. What is uncertain is which straight line the wave packet will reduce to; the probability distribution of straight tracks is spherically symmetric.

---

[6] So a Mott problem is a paradox that illustrates some of the difficulties of understanding the nature of wave function collapse and measurement in quantum mechanics

Remark

Rigorously the "Heisenberg's uncertainty principles" (HUP) should be named "Heisenberg's indetermination theorem" as they can be proven (therefore it is not a principle!) and they are not a limit of the instrumentation of a limit of precision of Nature itself (hence the "indetermination" in place of the "uncertainty").

But this is a detail as many statements in physics are provable and keep the name "principle" because at the time they were discovered they were not provable!

11.2.3 Quantum algebra

Under uncommon and unofficial term of "quantum algebra" (so do not to abuse it!) we wish to introduce and recall to the reader some mathematical tools that will be very useful to solve certain equations of Quantum Physics. It is therefore of prime importance to understand (or to have understand regarding to the reminders) at best what will follow!

Remark

Purists may climb the walls when reading what follows ...

11.2.3.1 Linear functional operators

Definition (#11.2.503): The "linear operators" are mathematical entities acting on functions (see section Functional Analysis page 2209) or vectors (see section Vector Calculus page 1797).

The functions on which can operate on these operators can be functions of a single variable x, such as $f(x)$, or of three coordinates of a point x,y,z such as $f(x,y,z)$ or written briefly $f(\vec{x})$.

We will have to write integrals of these functions, which are often extended to the entire space. In the case of a function of the three-dimensional coordinates of a point, we will adopt the following notation that we already know:

$$\iiint f(x,y,z)\mathrm{d}x\mathrm{d}y\mathrm{d}z=\int f(\vec{x})\mathrm{d}^3\vec{x} \qquad (11.2.59)$$

These notations, that are quite essential to simplify the expressions that we will meet in quantum physics being established, we can go back to our operators.

Starting from a function f, if we associate to it a function g of the same kind, that is to say dependent on the same variables, we can say that g is the result of the action of an operator α on f and write this symbolically as a single product:

$$g=\alpha f \qquad (11.2.60)$$

So α multiply, or better "acts on", f.

But we introduce immediately a fundamental restriction: only interest us linear operators (as in Linear Algebra...), that is to say, such as:

$$\alpha(\lambda_1 f_1+\lambda_2 f_2)=\lambda_1(\alpha f_1)+\lambda_2(\alpha f_2) \qquad (11.2.61)$$

whatever the coefficients λ_1 and λ_2

A very simple category of operator consists simply of the numbers (real or complex scalars). Thus, in the relation:

$$\chi=\lambda f \qquad (11.2.62)$$

χ is a function that depends linearly of f, trough a linear operator that we write λ, λ being a number (typically the position operator in quantum physics).

There are two important special cases to consider:

1. Zero operator: $\lambda=0$ where $\chi=0\cdot f=0$ will be obviously a function equal to zero everywhere...

2. Unit operator (or identity operator): $\lambda=1$ where $\chi=1\cdot f=1$ (which is just as simple...)

Remark

The "nabla" operator ∇ is also a functional linear operator (we will see that a bit later) that in quantum physics is found in the energy operator.

We also check easily for functional operators that they are (see the sections of Set Theory and Linear Algebra if necessary):

- Commutative with respect to the addition
- Associations in relation to the addition and multiplication
- Distributive over addition left and right

So far, nothing distinguishes algebra operators of that of numbers operators. But there are however two properties that we must always keep in mind to not do mistakes when we make calculations with operators:

1. Two operators do not commute in general compared to the multiplication (as in linear algebra ...), that is to say that in general given two functional operators α and β:

$$\alpha\cdot\beta\neq\beta\cdot\alpha \tag{11.2.63}$$

2. If we encounter an expression such as $\alpha_1\beta+\beta\alpha_2$, so we do not have the right to do in general a factorization (there is therefore a particular structure group that is non-commutative)!

✍**Example:**

A simple and important example, as useful for what will follow (very close to a practical case that we will see later), of two operators that do not commute with a function of a single variable is as follows (where f is any).

Let us consider the operator $\mathrm{d}/\mathrm{d}x$ acting on $xf(x)$:

$$\frac{\mathrm{d}}{\mathrm{d}x}(x\cdot f)=1\cdot f+x\frac{\mathrm{d}}{\mathrm{d}x}f \tag{11.2.64}$$

simplifying by f:

$$\frac{\mathrm{d}}{\mathrm{d}x}x=1+x\frac{\mathrm{d}}{\mathrm{d}x} \tag{11.2.65}$$

So we have above an example of two operators that do not commute since:

$$\frac{\mathrm{d}}{\mathrm{d}x}x \neq x\frac{\mathrm{d}}{\mathrm{d}x} \tag{11.2.66}$$

Remarks

R1. If an operator can switch anyhow with another operator is that it is a number (it joined with the concept of measurement which we have mentioned in the postulates).

R2. When a state (a mathematical function in the formal sense) is unchanged by an operator, the sate is then named "eigenstate" or "eigenvector" of the system (we will see practical examples below). The state is then perfectly measurable and is assimilated to the classical observable.

Before going to the next subject, to close this introduction on linear functional operators, consider that we know the three-dimensional Schrödinger equation (which we will prove further below):

$$\frac{\partial^2\Psi}{\partial x^2}+\frac{\partial^2\Psi}{\partial y^2}+\frac{\partial^2\Psi}{\partial z^2}+\frac{8\pi^2 m}{h^2}(E_{\text{tot}}-E_p)\Psi=0 \tag{11.2.67}$$

or written differently (that is more aesthetic ...) with the Laplacian of $\vec{\nabla}^2=\Delta$ of a scalar field (see section Vector Calculus page 1899):

$$\Delta\Psi+\frac{2m}{\hbar^2}(E_{\text{tot}}-E_p)\Psi=\Delta\Psi+\frac{2m}{\hbar^2}(H-V)\Psi=0 \tag{11.2.68}$$

or after rearranging:

$$\frac{2m}{\hbar^2}(E_{\text{tot}}-E_p)\Psi=-\Delta\Psi \tag{11.2.69}$$

or after simplification:

$$\frac{2m}{\hbar^2}(E_{\text{tot}}-E_p)=-\Delta \tag{11.2.70}$$

Then the total energy operator (the Hamiltonian H in other words ...) is expressed as:

$$E_{\text{tot}}=-\frac{\hbar^2}{2m}\Delta+E_p \tag{11.2.71}$$

or in Hamiltonian notation:

$$\boxed{H=-\frac{\hbar^2}{2m}\Delta+V} \tag{11.2.72}$$

Remark

Here we fall back naturally on the second expression given in the second postulate but the notation V for the potential energy can be sometimes confusing with the electrical potential for beginners that have never deal too much with Analytical Mechanics.

On the other hand, we know that:

$$E_{\text{tot}}=E_c+E_p=\frac{p^2}{2m}+E_p \tag{11.2.73}$$

The last two expressions must be identical. The only way to meet these conditions is to put:

$$\boxed{p_x=\frac{1}{\mathrm{i}}\hbar\frac{\partial}{\partial x}=-\mathrm{i}\hbar\frac{\partial}{\partial x}\qquad p_y=\frac{1}{\mathrm{i}}\hbar\frac{\partial}{\partial y}=-\mathrm{i}\hbar\frac{\partial}{\partial y}\qquad p_z=\frac{1}{\mathrm{i}}\hbar\frac{\partial}{\partial z}=-\mathrm{i}\hbar\frac{\partial}{\partial z}} \tag{11.2.74}$$

which are the "Hermitian operators of linear momentum" in wave quantum physics (expressed here in Cartesian coordinates) and that need to be remembered throughout this section of the textbook!

Remark

Here we fall back naturally on one of the operators listed in the third postulate.

We can check the legitimacy of these operators by re-injecting them into the expression of the kinetic energy:

$$\begin{aligned}E_c&=\frac{p^2}{2m}=\frac{p_x^2+p_y^2+p_z^2}{2m}\overset{?}{=}\frac{1}{2m}\left[\left(-\mathrm{i}\hbar\frac{\partial}{\partial x}\right)^2+\left(-\mathrm{i}\hbar\frac{\partial}{\partial y}\right)^2+\left(-\mathrm{i}\hbar\frac{\partial}{\partial z}\right)^2\right]\\&\overset{?}{=}\frac{1}{2m}\left[+\mathrm{i}^2\hbar^2\frac{\partial^2}{\partial x^2}+\mathrm{i}^2\hbar^2\frac{\partial^2}{\partial y^2}+\mathrm{i}^2\hbar^2\frac{\partial^2}{\partial z^2}\right]=-\frac{1}{2m}\hbar^2\left[\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right]\\&=-\frac{1}{2m}\hbar^2\Delta\end{aligned} \tag{11.2.75}$$

Moreover, it is easy to verify that this development is remain correct if we take the complex conjugate of the linear momentum operator!!!

Thus, the total energy operator H (Hamiltonian) is, also, well Hermitian! This result is very important to check such calculations using the orthogonality property of eigenfunctions that we will see further below.

11.2.3.1.1 Hermitian and Self-adjoint operators

Caution!!!! Reading the following lines could be quite abstract... However, if you do not understand much this is not very important because often everything will become evident during the study and the developments of concrete examples that will be give later, after which you will be able to reread the following and understand it at the same time.

Let us consider the two following integrals extended to the whole space (inside the integral it is a multiplication of functions and operators) without trying to understand their utility for the moment:

$$Q=\int\bar{f}(\alpha\cdot\chi)\mathrm{d}\vec{x}\qquad\text{and}\qquad\bar{Q}=\int\bar{\chi}(\beta\cdot f)\mathrm{d}\vec{x} \tag{11.2.76}$$

where let us we recall that the notation $\bar{f}$ is the complex conjugate of f. It should be noted that in these two integrals, α and β represent operators.

We observe in the developments of quantum physics that these two integrals are equal (and for Q and $\bar{Q}$ to be equal we must therefore have $Q \in \mathbb{R}$) and that there is a one-to-one correspondence between the operators α and β, we say then that β is the "adjoint operator" of α (the transpose of the conjugate) or that it is the "hermitian" of α (both terms are customary) and we write:

$$\beta = \alpha^\dagger \tag{11.2.77}$$

if the two previous integrals are satisfied.

From this definition, we deduce the following important identity:

$$\boxed{\int \bar{f}(\alpha \cdot \chi)\mathrm{d}\vec{x} = \overline{\left[\int \bar{\chi}(\alpha^\dagger \cdot f)\mathrm{d}\vec{x}\right]}} \tag{11.2.78}$$

✍**Example:**

Let us consider the operator:

$$\alpha = \frac{\mathrm{d}}{\mathrm{d}x} \tag{11.2.79}$$

Then by integration by parts:

$$\begin{aligned}\int_{-\infty}^{+\infty} \bar{f}(\alpha\chi)\mathrm{d}x &= \int_{-\infty}^{+\infty} \bar{f}\left(\frac{\mathrm{d}\chi}{\mathrm{d}x}\right)\mathrm{d}x = (\bar{f}\chi(+\infty) - \bar{f}\chi(-\infty)) - \int_{-\infty}^{+\infty} \left(\frac{\mathrm{d}}{\mathrm{d}x}\bar{f}\right)\chi\mathrm{d}x \\ &= -\int_{-\infty}^{+\infty} \chi\left(\frac{\mathrm{d}}{\mathrm{d}x}\bar{f}\right)\mathrm{d}x = \int_{-\infty}^{+\infty} \chi\overline{\left(-\frac{d}{\mathrm{d}x}\bar{f}\right)}\mathrm{d}x = \int_{-\infty}^{+\infty} \chi\overline{\left(\alpha^\dagger f\right)}\mathrm{d}x \\ &= \int_{-\infty}^{+\infty} \overline{\bar{\chi}\left(\alpha^\dagger f\right)}\mathrm{d}x = \overline{\int_{-\infty}^{+\infty} \bar{\chi}\left(\alpha^\dagger f\right)\mathrm{d}x}\end{aligned} \tag{11.2.80}$$

Remark

We will prove the relation above in a concrete but particular example in our study of Quantum Field Theory (see the next section) and we will return to this in a more rigorous way in our presentation of the Dirac formalism in the section Relativistic Quantum Physics.

The adjoint operator has several properties, the only ones that will interest us in this section are:

P1. $(\alpha^\dagger)^\dagger$ which it is unnecessary to prove, since this relation comes from the very definition of the adjoint operator.

P2. α being considered as a complex number (special case of operator such as the linear momentum one that we have seen before) then we have $\alpha^{\dagger}=\bar{\alpha}$.

An extremely important category of operators is thus constituted by the "self-adjoint Hermitian operators", or simply "self-adjoint operators" equal by definition to their adjoint:

$$\alpha=\alpha^{\dagger} \tag{11.2.81}$$

It must be known to the reader that sadly some teachers and physicists say that "self-adjoint" and "hermitian" are equivalent concepts. This is an abusive language used by physicists that you will never found by mathematicians.

Remark

Remember that these operators can also be matrices!

We also notice that if we take a Hermitian operator (such as that of the linear momentum to make a simple example) and that we multiply that latter by the unitary imaginary number i then it becomes non-Hermitian (being not in $\mathbb{C}$ anymore) but at the same time it becomes self-adjoint as it will be a real operator (belonging to $\mathbb{R}$).

Theorem 11.2. Any operator, that we will denote by ξ, can be decomposed in a unique way into Hermitian (self-ajdoint) α and non-Hermitian (non-self-adjoint) $\mathrm{i}\beta$ parts, that is, we can write:

$$\xi=\alpha+\mathrm{i}\beta \tag{11.2.82}$$

where α and β are Hermitian (self-adjoints).

Proof 11.2.1. If:

$$\xi=\alpha+\mathrm{i}\beta \tag{11.2.83}$$

then:

$$\xi^{\dagger}=\alpha-\mathrm{i}\beta \tag{11.2.84}$$

as it is a simple complex number, then:

$$\alpha=\frac{1}{2}(\xi+\xi^{\dagger}) \qquad \beta=\frac{1}{2}(\xi-\xi^{\dagger}) \tag{11.2.85}$$

The sum or the difference of the operator and its adjoint is therefore a self-adjoint operator (the sum or subtraction between self-adjoints operators, hence remains self-adjoints).

■ Q.E.D.

In general, it is quite obvious that the product of two self-adjoints operators α and β is not necessarily itself self-adjoint operator, that is:

$$\alpha\beta=(\alpha\beta)^{\dagger} \tag{11.2.86}$$

since we can verify that the condition for which the product of two self-adjoint operators is itself self-adjoint is that the two operators "commute" (see below):

Theorem 11.3. The product of two self-adjoint operators is self-adjoint if and only if the two operators commute.

Proof 11.3.1. First remember that by definition and explicitly:

$$\xi^\dagger = \bar{\xi}^T \tag{11.2.87}$$

Therefore (see section Linear Algebra page 1951):

$$(\alpha\beta)^\dagger = \left(\overline{\alpha\beta}\right)^T = \bar{\beta}^T\bar{\alpha}^T = \beta^\dagger\alpha^\dagger \tag{11.2.88}$$

Therefore we see that:

$$(\alpha\beta)^\dagger = \alpha^\dagger\beta^\dagger \tag{11.2.89}$$

if and only if $\alpha^\dagger$ and $\beta^\dagger$ commute or equivalently, if and only if:

$$(\alpha\beta)^\dagger = (\beta\alpha)^\dagger \tag{11.2.90}$$

That is to say if and only if:

$$\alpha\beta = \beta\alpha \tag{11.2.91}$$

■ Q.E.D.

✍**Example:**

In the Schrödinger picture we will see later that we have:

$$\mathrm{i}\partial_t|\psi(t)\rangle = \hat{H}|\psi(t)\rangle \tag{11.2.92}$$

where $\hat{H}$ (which may be explicitly time dependent or not) is the Hamilton operator, which must be selfadjoint.

Taking the adjoint of this equation, you get:

$$-\mathrm{i}\partial_t\langle\psi(t)| = \langle\psi(t)|\hat{H}^\dagger = \langle\psi(t)|\hat{H} = \langle\hat{H}\psi(t)| \tag{11.2.93}$$

11.2.3.1.2 Commutators and Anticommutators

In mathematics, a "commutator" gives an indication of the extent to which a certain binary operation fails to be commutative. There are different definitions used in group theory and ring theory. **Definitions (#11.2.504):**

D1. The "commutator" of two operators α and β, is written:

$$\boxed{[\alpha,\beta]=\alpha\beta-\beta\alpha=[\alpha,\beta]_-} \tag{11.2.94}$$

D2. The "anticommutator" of two operators α and β, is written:

$$\boxed{[\alpha,\beta]_+=\alpha\beta+\beta\alpha} \tag{11.2.95}$$

Which is generally written in the following form:

$$\{\alpha,\beta\}=\alpha\beta+\beta\alpha \tag{11.2.96}$$

Remarks

R1. As the commutator is much more common in developments than the anticommutator, if there is no possible confusion, we denote it simply $[\alpha,\beta]$.

R2. Concrete and trivial examples of these commutators in our study of Quantum Physics will be presented in the text that follows.

Let us mention some obvious properties of commutators (those that we will use the most in this textbook):

P1. Anticommutativity:

$$[\alpha,\beta]=-[\beta,\alpha] \tag{11.2.97}$$

P2. Left-linearity:

$$[\lambda_1\alpha_1+\lambda_2\alpha_2,\beta]=\lambda_1[\alpha_1,\beta]+\lambda_2[\alpha_2,\beta] \tag{11.2.98}$$

P3. Right-linearity:

$$[\alpha,\lambda_1\beta_1+\lambda_2\beta_2]=\lambda_1[\alpha,\beta_1]+\lambda_2[\alpha,\beta_2] \tag{11.2.99}$$

where λ_1, λ_2 are any number (proofs are made - if necessary - during the development of practical examples further below).

Let us look for the adjoint of $[\alpha,\beta]$:

$$[\alpha,\beta]^\dagger=(\alpha\beta-\beta\alpha)^\dagger=(\alpha\beta)^\dagger-(\beta\alpha)^\dagger=(\beta^\dagger\alpha^\dagger-\alpha^\dagger\beta^\dagger) \tag{11.2.100}$$

Hence a very simple result:

$$[\alpha,\beta]^{\dagger}=[\alpha^{\dagger},\beta^{\dagger}] \tag{11.2.101}$$

The following relation is very useful in practice (trivial, but as usual if necessary we can add the detailed proof on request):

$$[\alpha_1\alpha_2,\beta]=\alpha_1[\alpha_2,\beta]+[\alpha_1,\beta]\alpha_2 \tag{11.2.102}$$

We also have:

$$[\alpha,\beta_1\beta_2]=\beta_1[\alpha,\beta_2]+[\alpha,\beta_1]\beta_2 \tag{11.2.103}$$

We will prove later with a concrete case that if two operators do not commute, then it is impossible to have a state having a precise and unique value for both operators at the same time (in quantum physics there is an experimental configuration where the first operator represents the linear momentum and the second the spatial coordinate), this is why the operators are often referred to as "observables".

Let us take a moment to look at a concrete example of commutators and whose one of the results is absolutely fundamental!

We have proved earlier above the relations:

$$p_x=\frac{1}{\mathrm{i}}\hbar\frac{\partial}{\partial x}\qquad p_y=\frac{1}{\mathrm{i}}\hbar\frac{\partial}{\partial y}\qquad p_z=\frac{1}{\mathrm{i}}\hbar\frac{\partial}{\partial z} \tag{11.2.104}$$

Consider the relation (simple usual mathematical differential):

$$\frac{\partial}{\partial x}[x\psi(x)]=x\frac{\partial}{\partial x}\psi(x)+\psi(x) \tag{11.2.105}$$

If we divide by ψ on both sides of the equality and then multiply by $\hbar/\mathrm{i}$, then we get:

$$\frac{\hbar}{\mathrm{i}}\frac{\partial}{\partial x}x=x\frac{\hbar}{\mathrm{i}}\frac{\partial}{\partial x}+\frac{\hbar}{\mathrm{i}} \tag{11.2.106}$$

what give us:

$$p_x x=xp_x-\mathrm{i}\hbar\Leftrightarrow xp_x-p_x x=\mathrm{i}\hbar \tag{11.2.107}$$

therefore it comes that the commutator of x and p_x is equal to $\mathrm{i}\hbar$ and therefore that the quantities do not commute. We therefore have the following non-commuting relation:

$$\boxed{[x,p_x]_{\text{cycl.}}=\mathrm{i}\hbar} \tag{11.2.108}$$

that we often find in literature in the form (with the symbol of Kronecker):

$$[x_\mu,p_\nu]=\mathrm{i}\hbar\delta_{\mu\nu} \tag{11.2.109}$$

Thus (in the context of the second postulate), the two observables x and p_x, whose operators do not commute, do not have a common eigenvector basis. They are therefore not simultaneously measurable with precision and therefore constitute an Heisenberg uncertainty (see proof after the remark)!

Remarks

R1. The abbreviation (cycl.) means that the letters (x, y, z) can be circularly changed and the result remains the same.

R2. Although this result may seem surprising, it is none the less extremely correct as it results from mathematical reasoning. We can not make it more simpler and rigorous.

Theorem 11.4. Operators that do not commute, do not have a common eigenvector (eigenfunction) basis or conversely operators that do commute, have a common eigenvector (eigenfunction) basis.

In other words, given A and B two hermitian operators (i.e. matrices $M_{nn}(\mathbb{C})$) such that $[A,B]=0$. We can the found a basis $\mathcal{H}$ made by common eigenvectors of A and B.

Proof 11.4.1. Let us consider two operators A and B which represent observables and are therefore Hermitian. If there is a ψ such that:

$$A\psi=a\psi \qquad \text{and} \qquad B\psi=b\psi \tag{11.2.110}$$

then ψ is a simultaneous (common) eigenfunction (eigenvector) of A and B, belonging to eigenvalues a and b, respectively. Hence:

$$\begin{aligned}BA\psi=B(a\psi)=aB\psi=ab\psi\\AB\psi=A(b\psi)=bA\psi=ba\psi\end{aligned} \tag{11.2.111}$$

and therefore:

$$(AB-BA)\psi=0 \tag{11.2.112}$$

■ Q.E.D.

Let us now also consider the relation:

$$\frac{\partial}{\partial x}[y\psi(x)]=y\frac{\partial}{\partial x}\psi(x) \tag{11.2.113}$$

and proceeding in the same way as before, we get:

$$\boxed{[y,p_x]_{\text{cycl.}}=0} \tag{11.2.114}$$

The two relations:

$$[x,p_x]_{\text{cycl.}}=\mathrm{i}\hbar \qquad \text{and} \qquad [y,p_x]_{\text{cycl.}}=0 \tag{11.2.115}$$

can be summarized as follows:

$$\boxed{[q_k,p_l]=[q_k,p_l]_{\_}=q_kp_l-p_lq_k=\mathrm{i}\hbar\delta_{kl}} \tag{11.2.116}$$

using the generalized coordinates and generalized moments (see section Analytical Mechanics page 3156 and page 3180) and are remarkable from several point of views:

1. First, because from purely theoretical and mathematical considerations we fall back on an equivalent (but not equal) uncertainty to that obtained during our study of the classical Heisenberg's uncertainty principles seen earlier above (which we recall was equal to h rather than $\hbar$).

   Indeed, if we take the module of the left commutator, then we get the "spatial uncertainty relation of Heisenberg":

   $$\boxed{|[x,p_x]|_{\text{cycl.}}=\hbar} \tag{11.2.117}$$

   which for recall, can also be written in the form:

   $$|[x,v_x]|_{\text{cycl.}}=\frac{\hbar}{m} \tag{11.2.118}$$

   The Planck constant being extremely small, this explains why this effect is impossible to detect on our macroscopic scale. By cons, the mass of the electrons being extremely small too, the above fraction becomes noticeable for an electron and the effect of this uncertainty is then important!

   Finally, by the commutation of the components of the linear momentum quadrivector (see section Special Relativity page 5684), we get the "temporal uncertainty relation of Heisenberg" or "energy-time uncertainty":

   $$\boxed{|[t,E]|=\hbar} \tag{11.2.119}$$

   Caution!!!! The time-energy uncertainty relation (and other time-"observable" uncertainty relations that can be constructed) is (considered) not to have same meaning as canonical uncertainty relations. Meaning uncertainty relations constructed from canonical dynamical variables/observables (in the Hamiltonian sense), like position and momentum, since time parameter is not an observable and also not an operator in QM/QFT formalisms.

   Remark

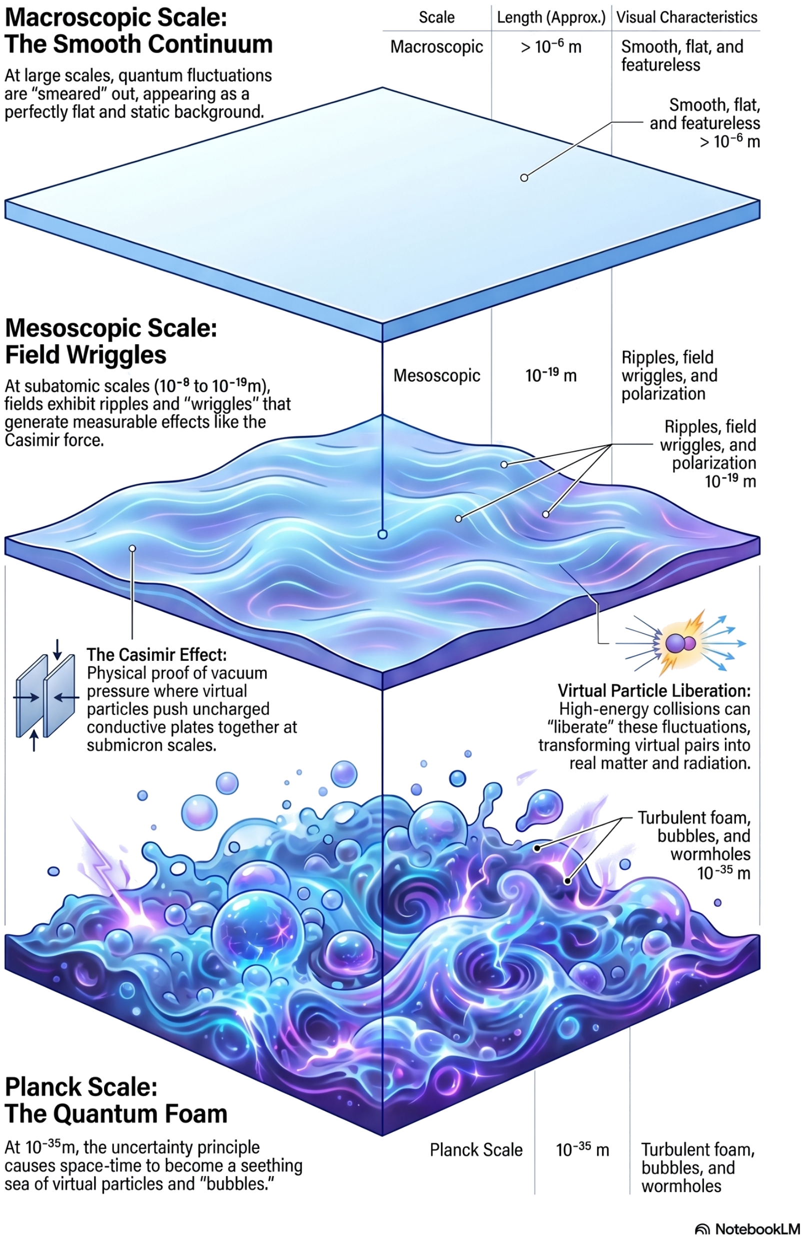
   With the use of more advanced mathematics we can prove that in fact a factor $1/2$ is missing in front of the $\hbar$ (see further below page 4733).

   There is a quite fantastic consequence from the uncertainty about time and energy and relativity. Imagine the most complete vacuum (quantum vacuum[7]) and suppose that we look at what happens at a given point in space for a very short time. Then the principle of temporal uncertainty tells us that the energy of this state (the vacuum!) is very imprecise. But Special Relativity says that energy is also mass (and therefore also a field), and therefore particles. So, during this very short time particles can spontaneously appear from the vacuum (see [382])! We name them "virtual particles" (even if they are real because we can measure their consequences in particles accelerators) because they disappear very quickly and are generated by the "vacuum quantum fluctuations". We will come back on virtual particles later in the section of Quantum Field Theory.

---

[7] As we already know it from our study of Probabilities and as we will see now from the Quantum Physics point of view the "nothingness" (see page 4742) in the philosophical sense is a physical impossibility. So, a professional scientist who talks about "nothingness" is actually talking most of the time about a quantum vacuum!

Definition (#11.2.505): A "quantum fluctuation" refers to the fact that when a physical system is prepared in a given state and some property or quantity is measured, and this procedure is repeated many times, then the measured outcomes may fluctuate even though the system was prepared each time in the same state.



Macroscopic Scale:
The Smooth Continuum
At large scales, quantum fluctuations are "smeared" out, appearing as a perfectly flat and static background.
Scale
Length (Approx.)
Visual Characteristics
Macroscopic
> 10^{-6} m
Smooth, flat, and featureless
Smooth, flat, and featureless > 10^{-6} m
Mesoscopic Scale:
Field Wriggles
At subatomic scales (10^{-8} to 10^{-19}m), fields exhibit ripples and "wriggles" that generate measurable effects like the Casimir force.
Mesoscopic
10^{-19} m
Ripples, field wriggles, and polarization
Ripples, field wriggles, and polarization 10^{-19} m
The Casimir Effect:
Physical proof of vacuum pressure where virtual particles push uncharged conductive plates together at submicron scales.
Virtual Particle Liberation:
High-energy collisions can "liberate" these fluctuations, transforming virtual pairs into real matter and radiation.
Turbulent foam, bubbles, and wormholes 10^{-35} m
Planck Scale:
The Quantum Foam
At 10^{-35}m, the uncertainty principle causes space-time to become a seething sea of virtual particles and "bubbles."
Planck Scale
10^{-35} m
Turbulent foam, bubbles, and wormholes
NotebookLM

Figure 11.34: **Conceptual (artistic) representation of vacuum quantum fluctuations (source: ?)**

However (!!!) the above "time-energy uncertainty relation" (and other time-"observable" uncertainty relations that can be constructed) is (considered) not to have same meaning as previous "canonical uncertainty relations". Meaning uncertainty relations constructed from canonical dynamical variables/observables (in the Hamiltonian sense), like position and momentum, since time parameter is not an observable and also not an operator in

Quantum Mechanics or Quantum Field Theory formalisms.

In fact, there are various approaches and interpretations of time-energy uncertainty. For example:

- Energy dispersion (ΔE) of a state and lifetime (Δt) of the state itself
- Energy exchange (ΔE) and time-frame (Δt) during which this can happen
- Energy measurement (ΔE) and time (Δt) it needs for accuracy (although this is rigorously disputed)

...other similar or specialized formulations of the above.

2. Secondly, these relations are remarkable because uncertainty is a complex value. This leads us to consider that the set $\mathbb{C}$ of complexes number is inherent to the real structure of our Universe (space-time) at the level of the quantum world (as confirmed by the Casimir effect where the sum to infinity of integers prolongation with the Riemann Zeta function is equal to $-1/12$ as seen in the section of Sequences and Series at page 1683). The quantum world is therefore a world of complex uncertainty. And this probability does not seem to be a consequence of our vagueness or ignorance but seems to be an intrinsic property of Nature!

Caution!!!! We can say that the quantum fluctuations are caused by the quantum zero-point energy, although that's somewhat tautological. Quantum fluctuations exist on the paper because quantum theory is a wave theory, from which the Heisenberg uncertainty principle is a natural consequence. There is no further understanding of how this came to be! Because quantum theory was developed to describe certain phenomena, and thus is a descriptive framework, not an explanatory framework!

It is also interesting to notice that time plays an unusual and subtle role in quantum physics. Unlike position, time is not usually treated as an operator; rather it is a simple parameter!

Remark

The relations and properties of commutators and anti-commutators will be indispensable to develop the quantified theory of angular momentum and spin further below.

11.2.3.1.3 Representatives

Let us now introduce contemporary quantum notations, which we will consider for now as abbreviations of integrals relating to wave functions, we will write (for the future purpose of calculating probability densities):

$$\langle\psi\,|\,\chi\rangle=\int\bar{\psi}\cdot\chi\mathrm{d}\vec{x}\qquad\text{and}\qquad\langle\psi\,|\,\alpha\,|\,\chi\rangle=\int\bar{\psi}(\alpha\cdot\chi)\mathrm{d}\vec{x}\tag{11.2.120}$$

since it is a complex functional dot product (see section Functional Analysis page 2379 and Vector Calculus page 1821).

With this notation, the relation that we presented earlier in our study of operators:

$$\int \bar{\psi}\cdot(\alpha\cdot\chi)\mathrm{d}\vec{x}=\overline{\left[\int \bar{\chi}\cdot(\alpha^{\dagger}\cdot\psi)\mathrm{d}\vec{x}\right]} \tag{11.2.121}$$

becomes (it is lighter already ... but less pedagogical):

$$\langle\psi\,|\,\alpha\,|\,\chi\rangle=\overline{\langle\chi\,|\,\alpha^{\dagger}\,|\,\psi\rangle} \tag{11.2.122}$$

That said, the set E of the functions ψ that interest us in Wave Quantum Physics constitutes a linear functional space. Indeed, in Quantum Physics, the differential equations that we have to solve (Schrödinger's equation) to describe the behaviour of a particle are such that the general solution can be very often decomposed into the sum of the particular solutions (we will prove this later!). In mathematics, we say that "the states are linear", that is, every combination of states is still a state!

Thus, the state of a particle is, as will be proved later, represented by a "quantum state" or a "state vector" denoted $|\Psi\rangle$ which also corresponds to a mathematical function describing it completely.

For example, if $|\Psi_1\rangle$ and $|\Psi_2\rangle$ are two possible states, then:

$$|\,\Psi_1\rangle+|\,\Psi_2\rangle \tag{11.2.123}$$

is also a possible state for the system (due to the property of linear functional spaces).

Let us now return to our linear functional space (or "linear space of states"). The fact that the set E of the functions ψ that interest us constitutes a "linear functional space" means that if $\psi\in E$, $\chi\in E$ we have:

$$(\lambda\psi+\mu\chi)\in E \tag{11.2.124}$$

regardless of the coefficients λ and μ, and also that:

$$\langle\varphi_i\,|\,\varphi_j\rangle=\delta_{ij} \tag{11.2.125}$$

where for recall, δ_{ij} is the Kronecker symbol (see section Tensor Calculus page 2044).

Definition (#11.2.506): The base is name a "complete base" if of course any $\psi\in E$ can be develop in series of eigenfunctions such as:

$$\psi=\sum_i c_i\Phi_i \tag{11.2.126}$$

where c_i is an arbitrary number (it is in part here that we have to return back to the 4th and 5th postulates of Wave Quantum Physics).

Let us now calculate the functional scalar product (see section Functional Analysis page 2379):

$$\int\bar{\varphi}_j\cdot\psi\mathrm{d}\vec{x}=\langle\varphi_i\,|\,\psi\rangle=\int\bar{\varphi}_j\cdot\sum_i c_i\varphi_i\mathrm{d}\vec{x}=\sum_i c_i\int\bar{\varphi}_j\cdot\varphi_i\mathrm{d}\vec{x}=\sum_i c_i\delta_{ij}=c_j \tag{11.2.127}$$

This last relation shows that we have identically (we change the notation of the indices):

$$\langle\varphi_j\,|\,\psi\rangle=\sum_i c_i\delta_{ij} \tag{11.2.128}$$

Thus, in a complete orthonormal basis $(\varphi_i$, an function ψ will be well described by the data of the coefficients c_i. It will often be useful to put them in the format of the representative matrix of ψ in the basis (φ_i):

$$\begin{bmatrix} c_1\\ c_2\\ \ldots\\ \ldots\\ c_i \end{bmatrix} \tag{11.2.129}$$

Let us consider now an operator α such that:

$$\chi=\alpha\cdot\psi=\alpha\cdot\sum_i c_i\varphi_i \tag{11.2.130}$$

But we can also write (notice the apostrophe in the relation!):

$$\chi=\sum_i\alpha\cdot c_i\cdot\varphi_i=\sum_i c_i'\cdot\varphi_i \tag{11.2.131}$$

Let us multiply this last relation by $\bar{\varphi}_j$ and calculate the functional scalar product:

$$\int\bar{\varphi}_j\cdot\chi\mathrm{d}\vec{x}=\int\bar{\varphi}_j\cdot\sum_i c_i'\cdot\varphi_i\mathrm{d}\vec{x}=\sum_i c_i'\int\bar{\varphi}_j\cdot\alpha\cdot\varphi_i\mathrm{d}\vec{x}=\sum_i c_i'\langle\varphi_j\,|\,\alpha\,|\,\varphi_i\rangle=\sum_i c_i'A_{ij} \tag{11.2.132}$$

To be compared with (obtained above):

$$\langle\varphi_j\,|\,\psi\rangle=\sum_i c_i\delta_{ij} \tag{11.2.133}$$

By noting A_{ij}, the "representative matrix" of α in the basis φ_i, we can thanks to the relation:

$$\langle\psi\,|\,\alpha\,|\,\chi\rangle=\overline{\langle\chi\,|\,\alpha^\dagger\,|\,\psi\rangle} \tag{11.2.134}$$

write finally:

$$\langle\varphi_j\,|\,\alpha\,|\,\varphi_i\rangle=A_{ij}=\overline{\langle\varphi_i\,|\,\alpha^\dagger\,|\,\varphi_j\rangle}=\bar{A}_{ij} \tag{11.2.135}$$

11.2.3.1.4 Eigenvalues and Eigenfunctions

Given an operator α (hermitian or not). The number a is named the "eigenvalue of the operator" of α, if there exists a function φ not identically zero such that (for a reminder of similar notions see the section of Linear Algebra):

$$\alpha\cdot\varphi=a\cdot\varphi \tag{11.2.136}$$

$\varphi$is then say to be the "eigenfunction" (in analogy with the "eigenvectors") of α, associated with the eigenvalue of a. Notice that a may very well be equal to zero (you will understand this better when we move on to the study of concrete cases).

In more physical terms, this means that when a state (a mathematical function in the formal sense such as φ) is unchanged by an operator, then the state is named an "eigenstate" or "eigenvector" of the system.

Let us consider the set E_a of eigenfunctions associated to a and a functional linear space which we will name "sub-eigenspace" associated to a. The number of dimensions of E_a is named the "multiplicity" or "degeneracy order" of the eigenvalue a, and we denote it g.

Let us consider now a a being a simple eigenvalue, or non degenerated: $g=1$. This means that there is only one eigenfunction associated with a, with a non-zero multiplicative coefficient.

If $g=2$ (double eigenvalue), we can find two non-proportional eigenfunctions (unbounded) associated with a, etc.

✍**Example:**

Let us see a particular example of an eigenfunction with an eigenvalue other than the classical case using the Energy.

Given:

$$\alpha\cdot\Psi=a\cdot\Psi \tag{11.2.137}$$

with $\alpha=-\mathrm{i}\hbar\dfrac{\partial}{\partial x}$ (operator that we have already seen previously) and a an eigenvalue.

The equation becomes:

$$-\mathrm{i}\hbar\frac{\partial\Psi}{\partial x}=a\cdot\Psi \tag{11.2.138}$$

which is easily verified if:

$$\boxed{\Psi=e^{\frac{\mathrm{i}ax}{k}}} \tag{11.2.139}$$

which is indeed an eigenfunction of the previously mentioned operator and which will be useful to us in the following developments!

11.2.3.1.4.1 Orthogonality of eigenfunctions

Two eigenfunctions (eigenvectors) φ and φ' associated with two different eigenvalues of the same Hermitian operator are orthogonal, that is to say:

$$\langle\varphi\,|\,\varphi'\rangle=0 \tag{11.2.140}$$

Proof 11.4.2. Let us start this time first with the Dirac notation with two eigenfunctions and two associated eigenvalues:

$$\begin{gathered}\alpha\cdot\varphi=a\cdot\varphi\\ \alpha\varphi'=a'\cdot\varphi'\end{gathered} \tag{11.2.141}$$

with $a\neq a'$.

We multiply the two previous relations by $\bar{\varphi}'$ and $\bar{\varphi}$ and we integrate to get the functional scalar product:

$$\begin{aligned}\langle\varphi'\,|\,\alpha\,|\,\varphi\rangle &= a\langle\varphi'\,|\,\varphi\rangle \qquad (a)\\ \langle\varphi\,|\,\alpha\,|\,\varphi'\rangle &= a'\langle\varphi\,|\,\varphi'\rangle \qquad (b)\end{aligned} \tag{11.2.142}$$

Let us recall to continue that we have proved earlier above that:

$$\langle\psi\,|\,\alpha\,|\,\chi\rangle=\overline{\langle\chi\,|\,\alpha^\dagger\,|\,\psi\rangle} \tag{11.2.143}$$

So if the operator α is self-adjoint (which is the case of the Hamiltonian as we have shown it), that is to say that $\alpha=\alpha^\dagger$, we have:

$$\langle\psi\,|\,\alpha\,|\,\chi\rangle=\overline{\langle\chi\,|\,\alpha\,|\,\psi\rangle} \tag{11.2.144}$$

Hence, by subtracting from the relation (11.2.142a) the conjugate complex of relation (11.2.142b), the eigenvalue a being assumed real (or an integer...), we have:

$$\begin{gathered}\langle\varphi'\,|\,\alpha\,|\,\varphi\rangle-\overline{\langle\varphi\,|\,\alpha\,|\,\varphi'\rangle}=a\langle\varphi'\,|\,\varphi\rangle-a'\overline{\langle\varphi\,|\,\varphi'\rangle}\\ \langle\varphi'\,|\,\alpha\,|\,\varphi\rangle-\langle\varphi'\,|\,\alpha\,|\,\varphi\rangle=0=a\langle\varphi'\,|\,\varphi\rangle-a'\langle\varphi'\,|\,\varphi\rangle=(a-a')\langle\varphi'\,|\,\varphi\rangle\end{gathered} \tag{11.2.145}$$

which proves indeed that:

$$\langle\varphi'\,|\,\varphi\rangle=0 \tag{11.2.146}$$

since $a\neq a'$.

Let us now make the same proof with but using the classical algebraic notation and a different approach. We start from:

$$\begin{aligned}\int\bar{\varphi}'\alpha\varphi dV &= a\int\bar{\varphi}'\varphi\mathrm{d}V \qquad (a)\\ \int\bar{\varphi}\alpha\varphi' dV &= a'\int\bar{\varphi}\varphi'\mathrm{d}V \qquad (b)\end{aligned} \tag{11.2.147}$$

and as we have proved earlier above that:

$$\overline{\int\bar{\varphi}'\alpha\varphi\mathrm{d}V}=\int\bar{\varphi}\alpha^\dagger\varphi'\mathrm{d}V \tag{11.2.148}$$

So if the operator α is self-adjoint (which is the case of the Hamiltonian as we have shown it), that is to say that $\alpha=\alpha^{\dagger}$, we have:

$$\overline{\int \bar{\varphi}'\alpha\varphi\mathrm{d}V}=\int \bar{\varphi}\alpha\varphi'\mathrm{d}V \tag{11.2.149}$$

It follows that the two relations (11.2.147a) and (11.2.147b) are equal (do not forget that the eigenvalue is assumed to be real!). As we can write:

$$a\int \bar{\varphi}'\varphi\mathrm{d}V=a'\int \bar{\varphi}\varphi'\mathrm{d}V \tag{11.2.150}$$

We can then write:

$$(a-a')\int \bar{\varphi}'\varphi\mathrm{d}V=0 \tag{11.2.151}$$

So if the eigenvalues are not equal it is forced that it is the integral that is zero (the functional scalar product) and therefore that the two eigenfunctions are orthogonal!

■ Q.E.D.

The same proof, but with the traditional and more pedagogical notation gives:

$$\begin{gathered}H\Psi_1=E_1\Psi_1\\ H\Psi_2=E_2\Psi_2\end{gathered} \tag{11.2.152}$$

If we multiply the first equation on the left by $\bar{\Psi}_2$, and the second equation by $\bar{\Psi}_1$, and that we integrate over the totality of space, we get the following two expressions (corresponding to mean values):

$$\begin{gathered}\int\limits_{-\infty}^{+\infty}\bar{\Psi}_2 H\Psi_1\mathrm{d}x\mathrm{d}y\mathrm{d}z=\int\limits_{-\infty}^{+\infty}\bar{\Psi}_2 E_1\Psi_1\mathrm{d}x\mathrm{d}y\mathrm{d}z=E_1\int\limits_{-\infty}^{+\infty}\bar{\Psi}_2\Psi_1\mathrm{d}x\mathrm{d}y\mathrm{d}z\\ \int\limits_{-\infty}^{+\infty}\bar{\Psi}_1 H\Psi_2\mathrm{d}x\mathrm{d}y\mathrm{d}z=\int\limits_{-\infty}^{+\infty}\bar{\Psi}_1 E_1\Psi_2\mathrm{d}x\mathrm{d}y\mathrm{d}z=E_2\int\limits_{-\infty}^{+\infty}\bar{\Psi}_1\Psi_2\mathrm{d}x\mathrm{d}y\mathrm{d}z\end{gathered} \tag{11.2.153}$$

If we take the case of real functions, we can write:

$$\begin{gathered}\int\limits_{-\infty}^{+\infty}\Psi_2 H\Psi_1\mathrm{d}x\mathrm{d}y\mathrm{d}z=E_1\int\limits_{-\infty}^{+\infty}\Psi_2\Psi_1\mathrm{d}x\mathrm{d}y\mathrm{d}z\\ \int\limits_{-\infty}^{+\infty}\Psi_1 H\Psi_2\mathrm{d}x\mathrm{d}y\mathrm{d}z=E_2\int\limits_{-\infty}^{+\infty}\Psi_1\Psi_2\mathrm{d}x\mathrm{d}y\mathrm{d}z\end{gathered} \tag{11.2.154}$$

Since the operator H is Hermitian (self-adjoint) as we have proved it above, we have:

$$\overline{\int\limits_{-\infty}^{+\infty}\Psi_1 H\Psi_2\mathrm{d}x\mathrm{d}y\mathrm{d}z}=\int\limits_{-\infty}^{+\infty}\Psi_2 H\Psi_1\mathrm{d}x\mathrm{d}y\mathrm{d}z \tag{11.2.155}$$

and as E_2, Ψ_1, Ψ_2 are admitted as real functions, we also have:

$$\overline{E_2\int_{-\infty}^{+\infty}\Psi_1\Psi_2 \mathrm{d}x\mathrm{d}y\mathrm{d}z}=E_2\int_{-\infty}^{+\infty}\Psi_1\Psi_2 \mathrm{d}x\mathrm{d}y\mathrm{d}z=E_2\int_{-\infty}^{+\infty}\Psi_2\Psi_1 \mathrm{d}x\mathrm{d}y\mathrm{d}z \tag{11.2.156}$$

Therefore:

$$\int_{-\infty}^{+\infty}\Psi_2 H\Psi_1 \mathrm{d}x\mathrm{d}y\mathrm{d}z-\overline{\int_{-\infty}^{+\infty}\Psi_1 H\Psi_2 \mathrm{d}x\mathrm{d}y\mathrm{d}z}=E_1\int_{-\infty}^{+\infty}\Psi_2\Psi_1 \mathrm{d}x\mathrm{d}y\mathrm{d}z-\overline{E_2\int_{-\infty}^{+\infty}\Psi_1\Psi_2 \mathrm{d}x\mathrm{d}y\mathrm{d}z} \tag{11.2.157}$$

can be written:

$$\int_{-\infty}^{+\infty}\Psi_2 H\Psi_1 \mathrm{d}x\mathrm{d}y\mathrm{d}z-\int_{-\infty}^{+\infty}\Psi_2 H\Psi_1 \mathrm{d}x\mathrm{d}y\mathrm{d}z=E_1\int_{-\infty}^{+\infty}\Psi_2\Psi_1 \mathrm{d}x\mathrm{d}y\mathrm{d}z-E_2\int_{-\infty}^{+\infty}\Psi_2\Psi_1 \mathrm{d}x\mathrm{d}y\mathrm{d}z \tag{11.2.158}$$

Therefore it comes:

$$(E_1-E_2)\int_{-\infty}^{+\infty}\Psi_2\Psi_1 \mathrm{d}x\mathrm{d}y\mathrm{d}z=0 \tag{11.2.159}$$

which shows well that Ψ_1, Ψ_2 are orthogonal according to the definition of the functional scalar product.

11.2.3.1.5 Dirac formalism

Dirac has conceived a very practical general formalism, world-wide used by physicists, of which we will give the essential elements. The notations used have already been partially introduced in the preceding paragraphs.

We will use the Dirac formalism for two points, the first being to better understand what has been seen so far when introducing to functional operators, the second being to introduce a notation and a method of solving that we can find in some textbooks. Moreover, in this textbook by simplification of writing, we will sometimes use this formalism.

11.2.3.1.5.1 Kets and Bras

We consider a vector space E_n with n dimensions where n can very well be infinite (Hilbert space). A vector is defined by n components x_i with $i=1,2,\ldots,n$ which we can store in column to form a column-matrix:

$$\begin{vmatrix} x_1 \\ x_2 \\ \ldots \\ x_n \end{vmatrix} \tag{11.2.160}$$

We will say that this matrix describes the "right vector" or the "ket $|x\rangle$" (this must remind the "representatives"). It is possible to associate with the column-matrix the adjoint matrix (conjugated transpose for recall...):

$$\overline{\bar{x}_1\,\bar{x}_2\,\ldots\,\bar{x}_n} \tag{11.2.161}$$

where the $\bar{x}_i$ are the conjugate complexes of the x_i. We will say that the adjoint line matrix describes the "left vector" or the "bra $\langle x|$" (this must also remind you the "representatives").

The addition and multiplication by a number λ are evident. Notice that if:

$$|y\rangle=\lambda|x\rangle \tag{11.2.162}$$

we have trivially:

$$\langle y|=\bar{\lambda}\langle x| \tag{11.2.163}$$

With two vectors of components x_i and y_i, we can then form the following quantity, named "Hermitian scalar product" or "Hermitian inner product":

$$\overline{\bar{x}_1\,\bar{x}_2\,\ldots\,\bar{x}_n}\begin{vmatrix} y_1 \\ y_2 \\ \ldots \\ y_n \end{vmatrix}=\sum_i \bar{x}_i y_i \tag{11.2.164}$$

We agree to write it $\langle x|y\rangle$. Notice that:

$$\langle x\,|\,y\rangle=\overline{\langle y\,|\,x\rangle} \tag{11.2.165}$$

the Hermitian scalar product is therefore not simply commutative!

The product $\langle x|y\rangle$ depends linearly on $\langle x|$ and $|y\rangle$. Conversely, if a number Q depends linearly on a ket $|x\rangle$, there exists a bra $\langle a|$ such that:

$$Q=\langle a\,|\,x\rangle \tag{11.2.166}$$

In quantum physics, $\langle x|y\rangle$ is associated to the "amplitude" of being in the state x if the system is in the state y. This Hermitian scalar product will be interpreted as the probability that the physical system is projected into the state x if it is in the state y.

An orthonormal basis of the studied space is constituted by n vectors $|i\rangle$ such that (see section Vector Calculus page 1833):

$$\langle i\,|\,j\rangle=\delta_{ij} \tag{11.2.167}$$

where for recall, δ_{ij} is the Kronecker symbol (see section Tensor Calculus page 2044).

Any vector (or function if we generalize vector space to function space) $|x\rangle$ of E_n can be developed on this basis according to (see section Vector Calculus page 1806):

$$|x\rangle=\sum_i x_i|i\rangle \tag{11.2.168}$$

where the x_i are the components of $|x\rangle$ in the chosen base. We can easily verify that (already seen many times in the section of Vector Calculus):

$$x_i = \langle i|x\rangle \tag{11.2.169}$$

If a ket $|y\rangle$ depends linearly on a ket $|x\rangle$, we write symbolically:

$$|\,y\rangle = \alpha\,|\,x\rangle \tag{11.2.170}$$

where α is a linear operator.

Given a linear operator defined by the preceding relation and a bra $\langle u|$, the Hermitian scalar product:

$$\langle u\,|\,y\rangle = \langle u\,|\,\big[\alpha\,|\,x\rangle\big]\rangle = Q \tag{11.2.171}$$

is a number Q which depends linearly on $|x\rangle$. From what has been seen above, there is a bra $\langle v|$ such as $Q = \langle v|x\rangle$. Then $\langle v|$ obviously depends of $\langle u|$ linearly. We agree to put:

$$\langle v\,| = \langle u\,|\,\alpha \tag{11.2.172}$$

Using this convention we can write:

$$\langle u\,|\,\big[\alpha\,|\,x\rangle\big]\rangle = \big[\langle u\,|\,\alpha\big]\,|\,x\rangle = \langle u\,|\,\alpha\,|\,x\rangle \tag{11.2.173}$$

If $|y\rangle = \alpha|x\rangle$, depends linearly on $\langle x|$. By definition, we will write:

$$\langle y\,| = \langle x\,|\,\alpha^\dagger \tag{11.2.174}$$

where for recall $\alpha^\dagger$ is the adjoint of α.

Let us form with a bra $\langle u|$ the Hermitian scalar product:

$$\langle u\,|\,y\rangle = \langle u\,|\,\alpha\,|\,x\rangle \tag{11.2.175}$$

and we can write (as we have proved it previously):

$$\overline{\langle u\,|\,y\rangle} = \langle y\,|\,u\rangle = \langle x\,|\,\alpha^\dagger\,|\,u\rangle \tag{11.2.176}$$

Hence the relation of the first importance which we have already met several times without really explaining its origin:

$$\boxed{\langle x\,|\,\alpha^\dagger\,|\,u\rangle = \overline{\langle u\,|\,\alpha\,|\,x\rangle}} \tag{11.2.177}$$

We simply recall with this relation that a Hermitian (self-adjoint) operator is an operator equal to its adjoint.

Thanks to Dirac's formalism, what was before abstract definitions have now become more obvious!

To summarize:

Classic formalism	Dirac formalism
$\int \bar{\varphi}_i\varphi_j \mathrm{d}V$	$\langle\varphi_i\vert\varphi_j\rangle$
$\int \bar{\varphi}_i\alpha\varphi_j \mathrm{d}V$	$\langle\varphi_i\vert\alpha\vert\varphi_j\rangle$
$\overline{\int \bar{\varphi}_i\varphi_j \mathrm{d}V} = \int \bar{\varphi}_j\varphi_i \mathrm{d}V$	$\overline{\langle\varphi_i\vert\varphi_j\rangle} = \langle\varphi_j\vert\varphi_i\rangle$
$\overline{\int \bar{\varphi}_i\alpha\varphi_j \mathrm{d}V} = \int \bar{\varphi}_j\alpha^\dagger\varphi_i \mathrm{d}V = \int \bar{\varphi}_j\alpha\varphi_i \mathrm{d}V$	$\overline{\langle\varphi_i\vert\alpha\vert\varphi_j\rangle} = \langle\varphi_j\vert\alpha\vert\varphi_i\rangle$
$\Psi = \sum\limits_i c_i\varphi_i$	$\vert\Psi\rangle = \sum_i c_i\vert\varphi_i\rangle$
$\sum\limits_i c_i' \int \bar{\varphi}_j\alpha\varphi_i \mathrm{d}\vec{x}$	$\sum\limits_i c_i'\langle\varphi_i\vert\psi\rangle$
$c_i = \int \bar{\varphi}_j\psi \mathrm{d}V$	$c_i = \langle\varphi_i\vert\psi\rangle$

Table 11.7: **Comparison between Classic and Dirac formalism**

So the reader has probably noticed that Dirac bra-kets and their algebra are very much like the Linear Algebra.

A ket is like a vector, a bra is like the conjugate transpose of a vector, a bra-ket is like a complex inner product, a ket-bra is like an outer product, and operator is like a matrix, and operator acting on a state is like matrix product. Even we speak about eigenstates which are very much like eigenvectors.

So how did it happened that we invented a new notation for Linear Algebra instead of sticking to the usual notation of vectors and matrices as usual?

In fact it is not that it's "like Linear Algebra" but it is exactly Linear Algebra!!!! At the time of Dirac Linear Algebra was not taught to all undergraduates[8]. So he invented his own notation. Physicists found them convenient for the questions they consider. The clear evidence of this is that Heisenberg had to invent matrix multiplication when he created quantum mechanics... Actually there is probably a causal relation between the invention of quantum mechanics and the spread of linear algebra as a part of the standard curriculum.

Remark

Again, an excellent practical example of the application of the Dirac formalism for engineers is proposed in the section on Quantum Computing (see page 7263).

---

[8] In the first decade (when they were all students) of 120th century (holocene calendar) matrix multiplication was not taught to students on a regular basis in the best European universities.

11.2.3.2 Robertson uncertainty relations

The reader remember maybe that we have derived earlier (see page 4704) the classical Heisenberg's uncertainty relations (and also based on the wave-packet approach at page 4791). However, now that we have a better mathematical quantum toolbox, we can go a bit further! Indeed, the most common general form of the classical Heisenberg's uncertainty principle is the Robertson uncertainty relation established in 11929 (holocene calendar) by... Howard P. Robertson that we will derive now.

For an arbitrary Hermitian operator $\hat{\mathcal{O}}$ we can associate a standard deviation:

$$\sigma_{\hat{\mathcal{O}}}^2=\left\langle\left(\hat{\mathcal{O}}-\langle\hat{\mathcal{O}}\rangle\right)^2\right\rangle \tag{11.2.178}$$

where as we know it already, the brackets $\langle\hat{\mathcal{O}}\rangle$ indicate an expectation value. For recall, the expected mean of $\hat{\mathcal{O}}$ in the state ψ is defined as:

$$\langle\hat{\mathcal{O}}\rangle_\Psi=\langle\Psi|\hat{\mathcal{O}}|\Psi\rangle=\int\limits_{-\infty}^{+\infty} x\,|\Psi(x)|^2\mathrm{d}x \tag{11.2.179}$$

So we have therefore:

$$\langle\sigma_{\hat{\mathcal{O}}}^2\rangle_\Psi=\langle\Psi|\hat{\mathcal{O}}|\Psi\rangle=\int\limits_{-\infty}^{\infty} x\,|\Psi(x)|^2\mathrm{d}x \tag{11.2.180}$$

For any Hermitian operator $\hat{A}$, based upon the definition of variance, we have:

$$\sigma_{\hat{A}}^2=\langle(\hat{A}-\langle\hat{A}\rangle)\Psi|(\hat{A}-\langle\hat{A}\rangle)\Psi\rangle \tag{11.2.181}$$

we let $|f\rangle=|(\hat{A}-\langle\hat{A}\rangle)\Psi\rangle$ and thus:

$$\sigma_{\hat{A}}^2=\langle f\,|\,f\rangle \tag{11.2.182}$$

Similarly, for any other Hermitian operator $\hat{B}$ in the same state:

$$\sigma_{\hat{B}}^2=\langle(\hat{B}-\langle\hat{B}\rangle)\Psi|(\hat{B}-\langle\hat{B}\rangle)\Psi\rangle=\langle g\,|\,g\rangle \tag{11.2.183}$$

for $|g\rangle=|(\hat{B}-\langle\hat{B}\rangle)\Psi\rangle$.

The product of the two deviations can thus be expressed as:

$$\sigma_A^2\sigma_B^2=\langle f\,|\,f\rangle\langle g\,|\,g\rangle \tag{11.2.184}$$

In order to relate the two vectors $|f\rangle$ and $|g\rangle$, we use the Cauchy–Schwarz integral inequality (see section Functional Analysis page 2388) which is defined for recall as:

$$\langle f\,|\,f\rangle\langle g\,|\,g\rangle\geq|\langle f\,|\,g\rangle|^2 \tag{11.2.185}$$

and thus the prior-previous can be written as:

$$\sigma_{\hat{A}}^2\sigma_{\hat{B}}^2\geq|\langle f\,|\,g\rangle|^2 \tag{11.2.186}$$

Since $\langle f\,|\,g\rangle$ is in general a complex number, we use the fact that the modulus squared of any complex number z is defined as $|z|^2=z\bar{z}$, where $\bar{z}$ is the complex conjugate of z. The modulus squared can also be expressed as:

$$|z|^2=(\Re(z))^2+(\Im(z))^2=\left(\frac{z+\bar{z}}{2}\right)^2+\left(\frac{z-\bar{z}}{2\mathrm{i}}\right)^2 \tag{11.2.187}$$

we let $z=\langle f\,|\,g\rangle$ and $\bar{z}=\langle g\,|\,f\rangle$ and substitute these into the equation above to get:

$$|\langle f\,|\,g\rangle|^2=\left(\frac{\langle f\,|\,g\rangle+\langle g\,|\,f\rangle}{2}\right)^2+\left(\frac{\langle f\,|\,g\rangle-\langle g\,|\,f\rangle}{2\mathrm{i}}\right)^2 \tag{11.2.188}$$

The inner product $\langle f\,|\,g\rangle$ is written out explicitly as:

$$\langle f\,|\,g\rangle=\langle(\hat{A}-\langle\hat{A}\rangle)\Psi|(\hat{B}-\langle\hat{B}\rangle)\Psi\rangle \tag{11.2.189}$$

and using the fact that $\hat{A}$ and $\hat{B}$ are Hermitian operators, we find:

$$\begin{aligned}\langle f\,|\,g\rangle&=\langle\Psi|(\hat{A}-\langle\hat{A}\rangle)(\hat{B}-\langle\hat{B}\rangle)\Psi\rangle\\&=\langle\Psi\,|\,(\hat{A}\hat{B}-\hat{A}\langle\hat{B}\rangle-\hat{B}\langle\hat{A}\rangle+\langle\hat{A}\rangle\langle\hat{B}\rangle)\Psi\rangle\\&=\langle\Psi\,|\,\hat{A}\hat{B}\Psi\rangle-\langle\Psi\,|\,\hat{A}\langle\hat{B}\rangle\Psi\rangle-\langle\Psi\,|\,\hat{B}\langle\hat{A}\rangle\Psi\rangle+\langle\Psi\,|\,\langle\hat{A}\rangle\langle\hat{B}\rangle\Psi\rangle\\&=\langle\hat{A}\hat{B}\rangle-\langle\hat{A}\rangle\langle\hat{B}\rangle-\langle\hat{A}\rangle\langle\hat{B}\rangle+\langle\hat{A}\rangle\langle\hat{B}\rangle\\&=\langle\hat{A}\hat{B}\rangle-\langle\hat{A}\rangle\langle\hat{B}\rangle\end{aligned} \tag{11.2.190}$$

Similarly it can be shown that $\langle g\,|\,f\rangle=\langle\hat{B}\hat{A}\rangle-\langle\hat{A}\rangle\langle\hat{B}\rangle$.

Thus we have:

$$\langle f\,|\,g\rangle-\langle g\,|\,f\rangle=\langle\hat{A}\hat{B}\rangle-\langle\hat{A}\rangle\langle\hat{B}\rangle-\langle\hat{B}\hat{A}\rangle+\langle\hat{A}\rangle\langle\hat{B}\rangle=\langle[\hat{A},\hat{B}]\rangle \tag{11.2.191}$$

and:

$$\langle f\,|\,g\rangle+\langle g\,|\,f\rangle=\langle\hat{A}\hat{B}\rangle-\langle\hat{A}\rangle\langle\hat{B}\rangle+\langle\hat{B}\hat{A}\rangle-\langle\hat{A}\rangle\langle\hat{B}\rangle=\langle\{\hat{A},\hat{B}\}\rangle-2\langle\hat{A}\rangle\langle\hat{B}\rangle \tag{11.2.192}$$

where we have introduced the anticommutator:

$$\{\hat{A},\hat{B}\}=\hat{A}\hat{B}+\hat{B}\hat{A} \tag{11.2.193}$$

We now substitute the above two relations above back into:

$$|\langle f\,|\,g\rangle|^2=\left(\frac{\langle f\,|\,g\rangle+\langle g\,|\,f\rangle}{2}\right)^2+\left(\frac{\langle f\,|\,g\rangle-\langle g\,|\,f\rangle}{2\mathrm{i}}\right)^2 \tag{11.2.194}$$

and get:

$$|\langle f\,|\,g\rangle|^2=\left(\frac{1}{2}\langle\{\hat{A},\hat{B}\}\rangle-\langle\hat{A}\rangle\langle\hat{B}\rangle\right)^2+\left(\frac{1}{2\mathrm{i}}\langle[\hat{A},\hat{B}]\rangle\right)^2 \tag{11.2.195}$$

Substituting the above into:

$$\sigma_{\hat{A}}^2\sigma_{\hat{B}}^2\geq|\langle f\,|\,g\rangle|^2 \tag{11.2.196}$$

we get the "Roberston-Schrödinger uncertainty relation":

$$\boxed{\sigma_{\hat{A}}\sigma_{\hat{B}} \geq \sqrt{\left(\frac{1}{2}\langle\{\hat{A},\hat{B}\}\rangle - \langle\hat{A}\rangle\langle\hat{B}\rangle\right)^2 + \left(\frac{1}{2\mathrm{i}}\langle[\hat{A},\hat{B}]\rangle\right)^2}} \tag{11.2.197}$$

Notice that in some textbooks, the relation:

$$|z|^2 = (\Re(z))^2 + (\Im(z))^2 = \left(\frac{z+\bar{z}}{2}\right)^2 + \left(\frac{z-\bar{z}}{2\mathrm{i}}\right)^2 \tag{11.2.198}$$

is simplified as we may have $\Re(z) \geq 0$:

$$|z|^2 \geq (\Im(z))^2 = \left(\frac{z-\bar{z}}{2\mathrm{i}}\right)^2 \tag{11.2.199}$$

Therefore the Roberston-Schrödinger uncertainty relation is simplified to:

$$\sigma_{\hat{A}}\sigma_{\hat{B}} \geq \sqrt{\left(\frac{1}{2\mathrm{i}}\langle[\hat{A},\hat{B}]\rangle\right)^2} \tag{11.2.200}$$

Hence (the vertical bars are the absolute value, not the modulus!):

$$\sigma_{\hat{A}}\sigma_{\hat{B}} \geq \left|\frac{1}{2\mathrm{i}}\langle[\hat{A},\hat{B}]\rangle\right| \tag{11.2.201}$$

✍**Example:**

For position and linear momentum, the canonical commutation relation:

$$[\hat{x},\hat{p}] = \mathrm{i}\hbar \tag{11.2.202}$$

we get:

$$\left|\frac{1}{2\mathrm{i}}\langle[\hat{A},\hat{B}]\rangle\right| = \left|\frac{1}{2\mathrm{i}}\langle\mathrm{i}\hbar\rangle\right| = \left|\frac{1}{2\mathrm{i}}\mathrm{i}\hbar\right| = \frac{1}{2}\hbar \tag{11.2.203}$$

Therefore:

$$\sigma_{\hat{p}}\sigma_{\hat{x}} \geq \frac{1}{2}\hbar \tag{11.2.204}$$

And we then get the same for energy and time:

$$\sigma_{\hat{E}}\sigma_t \geq \frac{1}{2}\hbar \tag{11.2.205}$$

Notice that this inequality is quite smaller (one order of magnitude) than the classical Heisenberg's uncertainty relations that we get before:

$$(\Delta x\Delta p = h) \gg \left(\sigma_{\hat{p}}\sigma_{\hat{x}} \geq \frac{1}{2}\hbar\right) \tag{11.2.206}$$

For energy and time, the relation:

$$\sigma_{\hat{E}}\sigma_t \geq \frac{1}{2}\hbar \tag{11.2.207}$$

is often found in various textbooks and videos under the following form (for an alternative derivation of his inequality see further below):

$$\boxed{\Delta t \Delta E \geq \frac{\hbar}{2} \cong 5.27286 \cdot 10^{-35}\,[\mathrm{J}\cdot\mathrm{s}]} \tag{11.2.208}$$

Caution!!!! Remember that the time-energy uncertainty relation (and other time-"observable" uncertainty relations that can be constructed) is (considered) not to have same meaning as canonical uncertainty relations. Meaning uncertainty relations constructed from canonical dynamical variables/observables (in the Hamiltonian sense), like position and momentum, since time parameter is not an observable and also not an operator in QM/QFT formalisms.

This is the relation that leads to the concept of "quantum vacuum fluctuation" also simply named "quantum fluctuation". The quantum fluctuations - i.e. zero-point fluctuations - have no cause[9] (not even with hidden variables) and are experimentally verified with:

- Speed of light (electric permittivity)
- Spontaneous light emission (Wigner-Weisskopf spontaneous decay)
- Radioactivity
- Casimir effect
- Lamb shift
- Anomalous electron g-factor
- Anomalous muon g-factor
- Josephson tunnel junctions
- False vacuum decay
- Vacuum polarization
- Vacuum birefringence
- Quantum critical point (quantum phase transition)
- Fine-structure constant variation
- LIGO Interferometer squeezed quantum vacuum
- Neutrino oscillation in vacuum
- Fulling–Davies–Unruh effect
- Spontaneous Parametric Down-Conversion (SPDC)

Let's us quote a two physicists on the topic (on of them is a Nobel Price in Physics):

---

[9] See the definition of "cause" in the section Mechanics at page 3206.

> ❞ *What causes the universe to pop out of nothing? No cause is needed. If you have a radioactive atom, it will decay, and quantum mechanics gives the decay probability in a given interval of time, say, a minute. There is no reason why the atom decayed at this particular moment and not another. The process is completely random. No cause is needed for the quantum creation of the universe.* ❞
>
> Alexander Vilenkin

quote 11.2:4736.#65

> ❞ *The discovery that individual events are irreducibly random is probably one of the most significant findings of the twentieth century. ... for the individual event in quantum physics, not only do we not know the cause, there is no cause! The instant when a radioactive atom decays, or the path taken by a photon behind a half-silvered beamsplitter are objectively random.* ❞
>
> Anton Zeilinger (Nobel Price)

quote 11.2:4737.#66

Or as stated by the philosopher S. Quentin in [499]:

quote
11.2:4738.#67

> *There is sufficient evidence at present to justify the belief that the universe began to exist without being caused to do so. This evidence includes the Hawking-Penrose singularity theorems that are based on Einstein's General Theory of Relativity, and the recently introduced Quantum Cosmological Models of the early universe.*
>
> Smith Quentin

The Heisenberg position-momentum uncertainty principle has obviously been tested and confirmed experimentally like in *On the experimental verification of the uncertainty principle of position and momentum* ([485]) where we have the following conclusive figure:

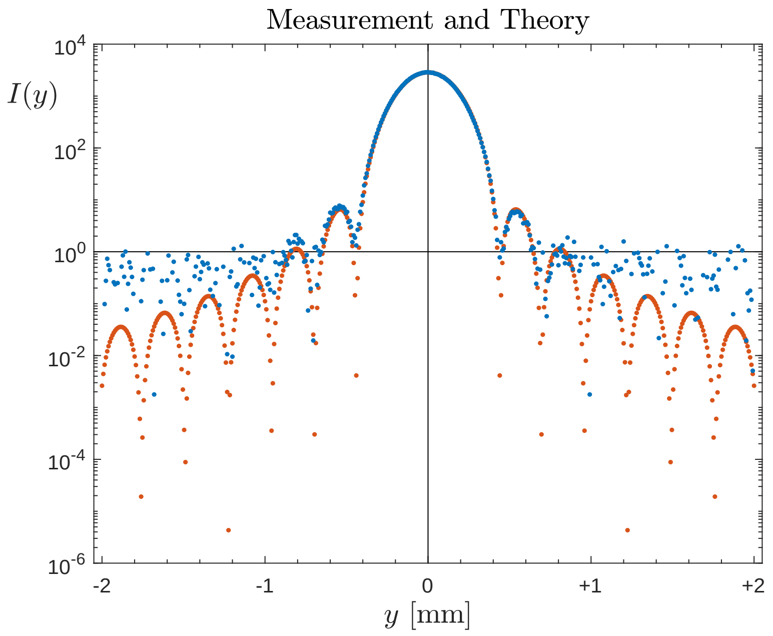


Figure 11.35: Measured (blue) versus theoretical (orange) density in semi-logarithmic representation. The signal-to-noise ratio outside the range of $y_c = \pm 1$ mm is almost zero and therefore of minor relevance for the computation of expectation values under consideration.

11.2.3.2.1 Energy-Time Heisenberg's uncertainty principle

The text that follows is almost a copy/paste of the content of the video on YouTube made by Sam Dietterich!

Under normal circumstances, when we say uncertainty in quantum mechanics, we mean the standard deviation. This can be calculated for a given quantum state and observable from the quantum state's wave function and the observable's operator. This is done using the following formula:

$$\sigma_A = \sqrt{\langle A^2 \rangle - \langle A \rangle^2} \qquad (11.2.209)$$

When considering the energy-time uncertainty principle, the situation is a little more complicated than this. While there is an energy operator (the Hamiltonian) that can be used to evaluate the above formula, there is no such thing as a time operator. When making a measurement of some observable, the naturally relevant concept of time uncertainty is the time it takes for the average (expectation value) $\langle Q \rangle$ of a given observable Q to change by one standard deviation σ_Q, given that the standard deviation is the uncertainty for that observable. So, we can make the following definition:

$$\Delta t := \frac{\sigma_Q}{|\mathrm{d}\langle Q \rangle / \mathrm{d}t|} \qquad (11.2.210)$$

Or put another way: the temporal uncertainty Δt is the number of times that we can put the variation of the temporal magnitude of the mean of the observable $\mathrm{d}\langle Q \rangle / \mathrm{d}t$ in a standard deviation of the latter σ_Q.

The reader that is careful will notice that this definition is made by anticipation of the result we want. Therefore it is a circular reasoning!

If we then take the definition of the energy uncertainty to be the usual one:

$$\Delta E = \sigma_H = \sqrt{\langle H^2 \rangle - \langle H \rangle^2} \qquad (11.2.211)$$

We can actually use the generalized Heisenberg uncertainty relation to construct an energy-time uncertainty relation. The generalized Heisenberg uncertainty relation is as proven earlier above:

$$\sigma_A \sigma_B \geq \left| \frac{1}{2\mathrm{i}} \langle [A, B] \rangle \right| \qquad (11.2.212)$$

Doing this requires the assistance of the generalized Ehrenfest theorem (see page 4874), which is for recall:

$$\frac{\mathrm{d}}{\mathrm{d}t} \langle Q \rangle = \frac{\mathrm{i}}{\hbar} \langle [H, Q] \rangle + \left\langle \frac{\partial Q}{\partial t} \right\rangle \qquad (11.2.213)$$

The energy time uncertainty principle is usually considered for cases where Q is not explicitly time dependent, so the Ehrenfest Theorem reduces to:

$$\frac{\mathrm{d}}{\mathrm{d}t} \langle Q \rangle = \frac{\mathrm{i}}{\hbar} \langle [H, Q] \rangle \qquad (11.2.214)$$

Rearranging:

$$\langle[H,Q]\rangle=\frac{\hbar}{\mathrm{i}}\frac{\mathrm{d}}{\mathrm{d}t}\langle Q\rangle \tag{11.2.215}$$

We can now insert this into the generalized uncertainty relation for the case of the Hamiltonian and the observable whose operator is Q :

$$\sigma_H\sigma_Q\geq\left|\frac{1}{2i}\frac{\hbar}{\mathrm{i}}\frac{\mathrm{d}}{\mathrm{d}t}\langle Q\rangle\right|=\frac{\hbar}{2}\left|\frac{\mathrm{d}}{\mathrm{d}t}\langle Q\rangle\right| \tag{11.2.216}$$

Hence:

$$\sigma_H\sigma_Q\geq\frac{\hbar}{2}\left|\frac{\mathrm{d}}{\mathrm{d}t}\langle Q\rangle\right| \tag{11.2.217}$$

We can then divide by the rate of change of the average:

$$\sigma_H\frac{\sigma_Q}{|\mathrm{d}\langle Q\rangle/\mathrm{d}t|}\geq\frac{\hbar}{2} \tag{11.2.218}$$

We thus have the famous energy-time uncertainty relation:

$$\boxed{\Delta E\Delta t\geq\frac{\hbar}{2}} \tag{11.2.219}$$

11.2.3.2.2 Zero-Point Energy from the uncertainty principles

It is a well-known deduction from quantum mechanics, confirmed by experimental data, that a minimum vibrational energy exists for an atomic oscillator undergoing simple harmonic vibratory motion (see further below page 4807). This minimum energy, or the zero-point vibrational energy is as we have already seen given by:

$$E_0=\frac{1}{2}\hbar\omega_0=\frac{1}{2}h\nu_0 \tag{11.2.220}$$

The value above which cannot so far be deduced from classical theory arises as we have already proved it from the solution of the Schrödinger equation given for reminder by:

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2}+\frac{8\pi^2m}{h^2}\left(E_{\text{tot}}-E_{\text{p}}\right)\Psi=\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2}+\frac{8\pi^2m}{h^2}\left(E_{\text{tot}}-\frac{1}{2}kx^2\right)\Psi=0\,[\mathrm{m}^{-5/2}] \tag{11.2.221}$$

in which m is the mass of the oscillator, E_{tot} its total vibrational energy; and its potential energy is $\frac{1}{2}kx^2$, where k is the force constant and x the displacement from the equilibrium position x_0.

Some researchers who discuss this problem then go on to state that the zero-point energy, $\frac{1}{2}h\nu_0$, when $n=0$, is a necessary consequence of the uncertainty principle, because the position, x, and momentum, $p=mv$, cannot both be known exactly at the same instant; and therefore the particle in question cannot be merely standing at rest at $x=0$ and $p=0$.

We will now show that the zero-point vibrational energy, like the ground-energy and size of the H atom can be deduced quite simply, and without solving the Schrödinger equation, if we assume the uncertainty principle, in its most rigorous form, as a fundamental postulate!

The total energy of the oscillator is the sum of its potential and kinetic energies:

$$E_{\text{tot}} = E_p + E_c = \frac{1}{2}kx^2 + \frac{1}{2}mv^2 = \frac{1}{2}kx^2 + \frac{p^2}{2m} \tag{11.2.222}$$

It is seen that the total energy will be at its minimum value when x and p are as small as possible, or when the derivation of the (Robertson) uncertainty principle states that:

$$\Delta x \Delta p \geq \frac{h}{4\pi} \tag{11.2.223}$$

where Δx and Δp are, respectively, the uncertainty in position and momentum of the particle.

But the average values of the distance, $\bar{x}$, from equilibrium, and the momentum, $\bar{p}$, cannot be less than the uncertainty, Δx and Δp, in these quantities:

$$\begin{aligned} \bar{x} &\geq \Delta x \\ \bar{p} &\geq \Delta p \end{aligned} \tag{11.2.224}$$

The smallest average value of the product $\bar{x}\bar{p}$ is therefore:

$$\bar{x}\bar{p} = \Delta x \Delta p = \frac{h}{4\pi} \tag{11.2.225}$$

and:

$$\bar{p} = \frac{h}{4\pi\bar{x}} \tag{11.2.226}$$

If we substitute this value of $\bar{p}$ in the equation for the total energy we get:

$$E_{\text{tot}} = E_p + E_c = \frac{1}{2}kx^2 + \frac{p^2}{2m} = \frac{1}{2}k\bar{x}^2 + \frac{h^2}{32\pi^2 m\bar{x}^2} \tag{11.2.227}$$

Differentiating the above relation with respect to $\bar{x}$, and setting the derivative equal to zero, we get the value of $\bar{x}$ for which E_{tot} is a minimum:

$$\frac{\mathrm{d}E_{\text{tot}}}{\mathrm{d}\bar{x}} = 0 = k\bar{x} - \frac{h^2}{16\pi^2 m\bar{x}^3} \tag{11.2.228}$$

Therefore:

$$\bar{x}^2_{\text{min}} = \frac{h}{4\pi\sqrt{mk}} \tag{11.2.229}$$

The minimum E_{tot} is obtained by substituting this value of $\bar{x}^2_{\text{min}}$ in the total energy relation:

$$\begin{aligned} E_{\text{min}} &= \frac{1}{2}kx^2 + \frac{p^2}{2m} = \frac{1}{2}k\frac{h}{4\pi\sqrt{mk}} + \frac{h^2}{32\pi^2 m}\frac{4\pi\sqrt{mK}}{h} \\ &= \frac{h}{8\pi}\sqrt{\frac{k}{m}} + \frac{h}{8\pi}\sqrt{\frac{k}{m}} = \frac{h}{4\pi}\sqrt{\frac{k}{m}} \end{aligned} \tag{11.2.230}$$

For the harmonic oscillator the force constant is related to the vibration frequency by (see section Social Sciences page 8224):

$$2\pi\nu = \sqrt{\frac{k}{m}} \tag{11.2.231}$$

and therefore:

$$E_{\min}=\left(\frac{h}{4\pi}\right)\cdot(2\pi\nu)=\frac{1}{2}h\nu \tag{11.2.232}$$

which is the zero-point energy! For the anharmonic oscillator Heisenberg also derived a more complicated expression, also involving a zero-point energy.

If a harmonic oscillator were to have zero energy, both its potential and kinetic energy would have to be zero. The case $E_p=\frac{1}{2}kx^2=0$ would correspond to a precise knowledge of the position of the particle $(x=0)$ and thus imply that the momentum p is completely uncertain. However, then the mean value of $E_c=p^2/2m$ would be infinite. Conversely, for E_c to be zero, E_p would have to be infinite.

Definition (#11.2.507): As absolute zero is the point at which a quantum system has minimal vibrational motion, retaining only quantum mechanical zero-point energy (ZPE)-induced particle motion, we define usually in quantum physics "nothing" as the smallest relative energy to the zero-point energy that satisfies $\Delta E_0\Delta t\geq {}^1\!/\!{}_2\hbar$ for a given quantum system (remember that energy is defined by a "quantity which is conversed or not depending on invariance under time translations" by Noether theorem and that time multiplied by a given speed is equal to a space distance!). Formerly in quantum physics:

$$\varnothing_{\text{Q.Ph.}}:=E_0\geq\frac{\hbar}{2\Delta t} \tag{11.2.233}$$

This can be found sometimes in a more technical notation in some textbooks as:

$$\varnothing_{\text{Q.Ph.}}:=\sigma_H\geq\frac{\hbar}{2\sigma_Q}|\mathrm{d}\langle Q\rangle/\mathrm{d}t| \tag{11.2.234}$$

As illustrated in the figure below, the concept of nothingness is (as for everything) more complex than it seems[10]:

---

[10] Notice that the levels are empirical and are not based on any international scientific consensus

Popular concept of "Nothing": We take out everything made of matter that is visible by the human eyes from a given space (a ball, a car, a house, a glass, etc.)

Greek concept of "Nothing" (antiquity... almost 2,500 years ago): We take also out everything made of matter that is not visible by the human eye (bacteries, viruses, gas, cosmic particles, atoms, protons, electrons, strings, black holes, etc.)

119th century concept of "Nothing" (almost 200 years ago): We take also out everything made of radiations, ie – at least approximatively - masless particles (photons, gluons, graviton, neutrinos).

Early 120th century concept of "Nothing" (almost 80 years ago): We take also out all the quantum fields that have a lowest non-zero energy level and that are responsisble of quantum vacuum fluctuations (pais of virtual particles that appear as observed experimentally).

Middle 120th century concept of "Nothing": We take also out all of the the space-time structure and therefore laws of physics.

Supernatural concept of "Nothing": We take also out all the supernatural concepts like the deities of all the 26 monotheistic religions or the 33 millions of deities of the polytheist religions.

Late 120th century concept of "Nothing": We take also out all the information and concepts like "math", "numbers", "probability", "value", "sets" and therefore even... "nothing" (as the latter is ill defined)!

Figure 11.36: The seven levels of nothingness

If we go for the etymology of "nothingness" as the "negation of everything", we essentially construct the set:

$$\{P \mid P = \neg Q, \forall Q\} \tag{11.2.235}$$

where P, Q are statements.

Interestingly, via Russell's paradox (see section Set Theory page 138) the inconsistency of this set is swiftly established via the statement "*The above set exists*". Then it must contain its negation and its double negation. Hence nothingness as by the definition of the word itself leads to an impossibility. Or in the form a syllogism:

- Premise 1: Something exists.
- Premise 2: Something cannot come from nothing.
- Conclusion: Therefore, a state of "absolute nothingness" never existed.

For people who want to know more on the topic we recommend the following paper *Is zero-point energy physical? A toy model for Casimir-like effect* (see [416]).

> *If something doesn't come from nothing and something exists, therefore there was never nothing!*

11.2.3.3 Fourier uncertainty principle

Let us see that there is another way quite similar to the above one but slightly different and interesting that leads to the same result!

Let us rewrite the Fourier transform pair as following (Fourier transform first and inverse Fourier transform in second as seen in the section of Sequences and Series page 1758):

$$\begin{aligned} g(k)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} f(x)e^{-\mathrm{i}kx}\mathrm{d}x \\ f(x)&=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{+\infty} g(k)e^{\mathrm{i}kx}\mathrm{d}k \end{aligned} \tag{11.2.236}$$

Let us assume that the both functions above are normalized such that:

$$\int\limits_{-\infty}^{+\infty}|f(x)|^2\mathrm{d}x=1 \qquad \int\limits_{-\infty}^{+\infty}|g(k)|^2\mathrm{d}k=1 \tag{11.2.237}$$

As f and g are complex functions, let us define the following mean inspired from our knowledge of the definition of mean during our study of Statistics for a continuous variable:

$$\begin{aligned} \mu_x=\langle x\rangle &=\int\limits_{-\infty}^{+\infty}\bar{f}(x)xf(x)\mathrm{d}x \\ \mu_k=\langle k\rangle &=\int\limits_{-\infty}^{+\infty}\bar{g}(k)kg(k)\mathrm{d}k \end{aligned} \tag{11.2.238}$$

Without loss in generality, let us put that:

$$\begin{aligned}\langle x\rangle &= \int\limits_{-\infty}^{+\infty} \bar{f}(x)xf(x)\mathrm{d}x := 0\\ \langle k\rangle &= \int\limits_{-\infty}^{+\infty} \bar{g}(k)kg(k)\mathrm{d}k := 0\end{aligned} \tag{11.2.239}$$

Now again as f and g are complex functions, let us define the following variance inspired from our knowledge of the definition of the variance during our study of Statistics for a continuous variable:

$$\sigma_x^2 = \left\langle (x-\mu_x)^2\right\rangle = \int\limits_{-\infty}^{+\infty} f^*(x)(x-\mu_x)^2 f(x)\mathrm{d}x\sigma_k^2 = \left\langle (k-\mu_k)^2\right\rangle \quad = \int\limits_{-\infty}^{+\infty} \bar{g}(k)(k-\mu_k)^2 g(k)\mathrm{d}k \tag{11.2.240}$$

However as we have assumed without loss of generality that $\mu_x = \mu_k = 0$, we have (remember that $z\cdot\bar{z} = a^2+b^2 = |z|^2$):

$$\begin{aligned}\sigma_x^2 &= \left\langle (x-\mu_x)^2\right\rangle = \int\limits_{-\infty}^{+\infty} \bar{f}(x)(x-\mu_x)^2 f(x)\mathrm{d}x = \int\limits_{-\infty}^{+\infty} |xf(x)|^2\mathrm{d}x\\ \sigma_k^2 &= \left\langle (k-\mu_k)^2\right\rangle = \int\limits_{-\infty}^{+\infty} \bar{g}(k)(k-\mu_k)^2 g(k)\mathrm{d}k = \int_{-\infty}^{+\infty} |kg(k)|^2\mathrm{d}k\end{aligned} \tag{11.2.241}$$

Now let us computer the standard deviation product:

$$\sigma_x^2\sigma_k^2 = \int\limits_{-\infty}^{+\infty} |xf(x)|^2\mathrm{d}x \int\limits_{-\infty}^{+\infty} |kg(k)|^2\mathrm{d}k \tag{11.2.242}$$

Remember the propery of time derivative (see page 2316):

$$\mathcal{F}\left(\frac{\mathrm{d}}{\mathrm{d}t}x(t)\right) = \mathrm{i}\omega X(\mathrm{i}\omega) \tag{11.2.243}$$

Let us adapt the notation and rearrange to our study case that we have here:

$$-\mathrm{i}\frac{\mathrm{d}f(x)}{\mathrm{d}x} \leftrightarrow kg(k) \tag{11.2.244}$$

Hence:

$$\sigma_x^2\sigma_k^2 = \int\limits_{-\infty}^{+\infty} |xf(x)|^2\mathrm{d}tx \int\limits_{-\infty}^{+\infty} \left|-\mathrm{i}\frac{\mathrm{d}f(x)}{\mathrm{d}x}\right|^2 \mathrm{d}x \tag{11.2.245}$$

Using the Cauchy-Schwarz hermitian inequality for integrals (see section Numerical Methods page 2388):

$$\sigma_x^2\sigma_k^2=\int\limits_{-\infty}^{+\infty}|xf(x)|^2\mathrm{d}tx\int\limits_{-\infty}^{+\infty}\left|-\mathrm{i}\frac{\mathrm{d}f(x)}{\mathrm{d}x}\right|^2\mathrm{d}x\geq\left|\int\limits_{-\infty}^{+\infty}-\mathrm{i}\frac{\mathrm{d}f(x)}{\mathrm{d}x}x\bar{f}(x)\mathrm{d}x\right|^2 \tag{11.2.246}$$

Developing the last term (as $z\bar{z}=|z|^2$):

$$\left|\int\limits_{-\infty}^{+\infty}-\mathrm{i}\frac{\mathrm{d}f(x)}{\mathrm{d}x}x\bar{f}(x)\mathrm{d}x\right|^2=\underbrace{\left(\int\limits_{-\infty}^{+\infty}\mathrm{i}\frac{\mathrm{d}\bar{f}(x)}{\mathrm{d}x}xf(x)\mathrm{d}x\right)}_{:=\bar{z}}\underbrace{\left(\int\limits_{-\infty}^{+\infty}-\mathrm{i}\frac{\mathrm{d}f(x)}{\mathrm{d}x}x\bar{f}(x)\mathrm{d}x\right)}_{:=z} \tag{11.2.247}$$

And as we we have proven in our study of complex numbers (see page 245) that:

$$|\Im(z)|\leq|z|\Leftrightarrow\bar{z}z=|z|^2\geq|\Im(z)|^2 \tag{11.2.248}$$

Therefore:

$$\sigma_x^2\sigma_k^2=\underbrace{\left(\int\limits_{-\infty}^{+\infty}\mathrm{i}\frac{\mathrm{d}\bar{f}(x)}{\mathrm{d}x}xf(x)\mathrm{d}x\right)}_{\bar{z}}\underbrace{\left(\int\limits_{-\infty}^{+\infty}-\mathrm{i}\frac{\mathrm{d}f(x)}{\mathrm{d}x}x\bar{f}(x)\mathrm{d}x\right)}_{z}\geq|\Im(z)|^2 \tag{11.2.249}$$

We will now simplify this relation. First remember that we have just put:

$$z=\int\limits_{-\infty}^{+\infty}-\mathrm{i}\frac{\mathrm{d}f(x)}{\mathrm{d}x}x\bar{f}(x)\mathrm{d}x \tag{11.2.250}$$

Using integration by parts and our normalization assumption we have:

$$\begin{aligned}\mathrm{i}z=\int\limits_{-\infty}^{+\infty}x\bar{f}(x)\frac{\mathrm{d}f(x)}{\mathrm{d}x}\mathrm{d}x&=x\bar{f}(x)f(x)\Big|_{-\infty}^{+\infty}-\int\limits_{-\infty}^{\infty}\frac{\mathrm{d}}{\mathrm{d}x}\left[x\bar{f}(x)\right]f(x)\mathrm{d}x\\&=0-\int\limits_{-\infty}^{+\infty}\left[\bar{f}(x)+x\frac{\mathrm{d}\bar{f}x)}{\mathrm{d}x}\right]f(x)\mathrm{d}x\\&=-\int\limits_{-\infty}^{+\infty}|f(x)|^2\mathrm{d}x-\int\limits_{-\infty}^{+\infty}xf(x)\frac{\mathrm{d}\bar{f}(x)}{\mathrm{d}x}\mathrm{d}x\qquad=-1+\mathrm{i}\bar{z}\end{aligned} \tag{11.2.251}$$

Therefore:

$$z-\bar{z}=\mathrm{i} \tag{11.2.252}$$

As we have :

$$\sigma_x^2\sigma_k^2\geq|\Im(z)|^2 \tag{11.2.253}$$

We know from our study of complex numbers that:

$$|\Im(z)|=\left[\frac{1}{2\mathrm{i}}(z-\bar{z})\right]^2 \tag{11.2.254}$$

Injecting into it the result $z-\bar{z}=\mathrm{i}$, this leads us to:

$$\sigma_x^2\sigma_k^2\geq\frac{1}{4} \tag{11.2.255}$$

So finally we get the "Fourier uncertainty principle":

$$\sigma_x\sigma_k\geq\frac{1}{2} \tag{11.2.256}$$

We see that the latter has almost the same form as the Heisenberg's uncertainty principle given for recall by:

$$\sigma_x\sigma_k\geq\frac{\hbar}{2} \tag{11.2.257}$$

This similarity is not a coincidence! Indeed, if we do in our previous developments the change of variable $p=\hbar k$, the we fall back on Heisenberg's uncertainty principle!

So to summarize the big picture:

1. Wave function tells you location of object, with uncertainty in position Δx.
2. Wave functions can be made out of sines and cosines.
3. Fourier Transforms connect uncertainty in position and uncertainty in the wavenumber (i.e. the number of waves or cycles per unit distance)
4. Momentum is related to wavelength

HEISENBERG UNCERTAINTY PRINCIPLE

You cannot simultaneously know both the position and momentum of a particle with arbitrary precision.

Werner Heisenberg
1901–1976

THE PRINCIPLE (MATHEMATICAL FORM)

For any quantum state:

$$\boxed{\Delta x\, \Delta p \geq \frac{\hbar}{2}}$$

Δx : Uncertainty (standard deviation) in position

Δp : Uncertainty (standard deviation) in momentum

$\hbar$: Reduced Planck constant $= \frac{h}{2\pi} \approx 1.055 \times 10^{-34}$ Js

The more precisely you know a particle's position, the less precisely you can know its momentum — and vice versa.

GENERAL UNCERTAINTY RELATION

For any two observables A and B:

$$\Delta A\, \Delta B \geq \frac{1}{2} |\langle [A, B] \rangle|$$

where $[A, B] = AB - BA$ is the commutator.

Special case:

$$[x, p] = i\hbar \quad \Rightarrow \quad \Delta x\, \Delta p \geq \frac{\hbar}{2}$$

WHY THIS HAPPENS: WAVE NATURE

1. WELL-DEFINED POSITION

A very localized wave packet (narrow in space) requires many wavelengths combined together.

This means a wide range of momenta.

2. WELL-DEFINED MOMENTUM

A narrow range of momenta (narrow in momentum space) produces a spread-out wave packet in position space.

PHYSICAL MEANING

- Not a limitation of measurement technology.
- It is a fundamental property of nature.
- Arises from the wave nature of particles and the structure of quantum mechanics.

IMPORTANT CONSEQUENCES

- Zero-point energy in atoms
- Stability of matter
- Limits in measurement precision
- Basis of quantum mechanics

OTHER UNCERTAINTY RELATIONS

$$\Delta y\, \Delta p_y \geq \frac{\hbar}{2}$$

$$\Delta z\, \Delta p_z \geq \frac{\hbar}{2}$$

$$\Delta E\, \Delta t \geq \frac{\hbar}{2} \quad \text{(energy–time)}$$

$$\Delta L_z\, \Delta \phi \geq \frac{\hbar}{2} \quad \text{(angular variables)}$$

EXAMPLE: ELECTRON

Localization Δx	Minimum momentum uncertainty Δp	Minimum speed uncertainty $\Delta v = \Delta p / m_e$
1 nm	$\geq 5.27 \times 10^{-26}$ kgm/s	$\geq 5.8 \times 10^{5}$ m/s
1 pm	$\geq 5.27 \times 10^{-25}$ kgm/s	$\geq 5.8 \times 10^{6}$ m/s
1 fm	$\geq 5.27 \times 10^{-22}$ kgm/s	$\geq 5.8 \times 10^{9}$ m/s

($m_e = 9.11 \times 10^{-31}$ kg)

VISUALIZING THE TRADE-OFF

The shaded surface represents the boundary $\Delta x\, \Delta p = \hbar/2$.

The region above the surface is allowed.

QUANTUM SCALE (TYPICAL)

For an electron confined to the size of a hydrogen atom (~ 0.1 nm):
$\Delta v \sim 10^{6}$ m/s

For a proton in a nucleus (~ 1 fm $= 10^{-15}$ m):
$\Delta v \sim 10^{9}$ m/s (relativistic)

KEY TAKEAWAY

Nature does not allow infinite precision in complementary properties. The uncertainty principle lies at the heart of the quantum world.

Symbols

x : position

p : momentum

Δ : standard deviation

$\hbar$: reduced Planck constant

11.2.4 Schrödinger Model

Experiments (Compton effect, photoelectric effect, Young's slits, geometric / wave optics, etc.) have shown that waves can be treated as corpuscles (and vice versa). It is these observations which led Niels Bohr to state his "principle of complementarity" which says that, according to the experiments carried out, we must consider matter either as a wave or as corpuscles. These two aspects complement each other.

11.2.4.1 de Broglie associated wave

In 11924 (holocene calendar), the French physicist Louis Victor de Broglie suggested that particles (electrons, protons, and others, and even atoms and molecules) could also, in some cases, exhibit wave properties in the same way as the light! De Broglie then expressed the idea that there existed between the associated fictitious wavelength of a particle of matter and its momentum a relation similar to that of a photon, that is to say (ν is the notation for the frequency for recall...):

$$E_{\text{tot}}=h\nu=h\frac{\omega}{2\pi}=\hbar\omega=mc^2 \tag{11.2.258}$$

so we can write using the relation established in the section of Wave Mechanics (see page 3479):

$$p=mc=\frac{E_{\text{tot}}}{c}=\frac{h\nu}{c}=\frac{\hbar\omega}{c}=\frac{\hbar kc}{c}=\hbar k=\frac{h}{\lambda} \tag{11.2.259}$$

Where:

$$\boxed{p=\hbar k} \tag{11.2.260}$$

is named the "de Broglie relation".

Hence the ratio:

$$\lambda=\frac{h}{p} \tag{11.2.261}$$

De Broglie then made the hypothesis that for a corpuscle of mass m and velocity v we have:

$$\boxed{\lambda=\frac{h}{m\nu}} \tag{11.2.262}$$

where λ is named the "associated de Broglie wavelength" and also denoted sometimes λ_{db}.

The moving matter would therefore have an associated wavelength!? It is an extremely small wavelength for masses of the order of a kilogram. If the speed is for example of the order of $1\;[\text{m}\cdot\text{s}^{-1}]$ then $\lambda\cong 10^{-34}$ [m].

As we have seen it, the phenomena of interference and diffraction are important only when the size of the objects or slits is not much greater than the wavelength. It is therefore impossible to detect the wave properties of everyday objects. It is not the same for elementary particles, the electrons in particular.

The electrons can therefore have wavelengths of the order of 10^{-10} [m] which corresponds to the spacing of the atoms of a crystal. C. J. Davisson and L. H. Germer carried out a crucial experiment: they scattered electrons on the surface of a crystal and in early 11927 (holocene calendar) observed that the ejected electrons were distributed in regular peaks. When they interpreted these peaks as diffraction peaks, they found that the wavelength of the diffracted electron was exactly that predicted by de Broglie!

But then what is an electron?? The illustrations that show an electron as a minuscule negatively charged sphere are only convenient but inaccurate images. In fact, we have to use the corpuscular or wave model, the one that works best according to the situation so that we can understand what is happening. But we must not conclude that an electron is a wave or a particle. Rather, we should say that an electron is "all of its measurable properties". Some physicists still use the term "quanton" to describe any system behaving either as a wave or as a particle.

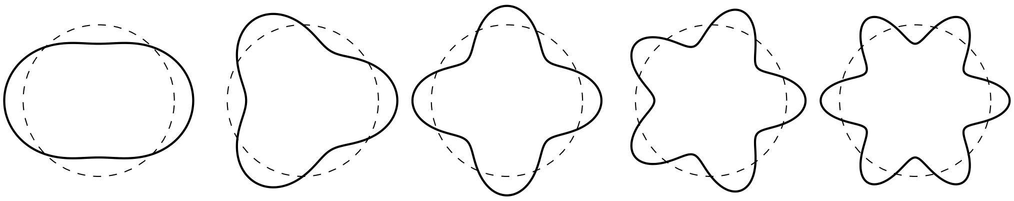
De Broglie was then able to suggest that each quantified electron orbit (according to Bohr's quantization postulate) is then a stationary wave and that an electron can only occupy orbits that can accept an integer number of wavelengths of its associated fictitious wave (today we assimilated this to the fact that the electron is trapped in a potential wells). If there was no exact coincidence, there could be no stationary wave, and therefore no stationary orbit either.

Consequently, as for the resonant modes of a string (standing waves), only the waves whose circumference of the circular orbit contains an integer number of λ exist, or (the amplitude will be calculated by particular techniques which will be seen further):

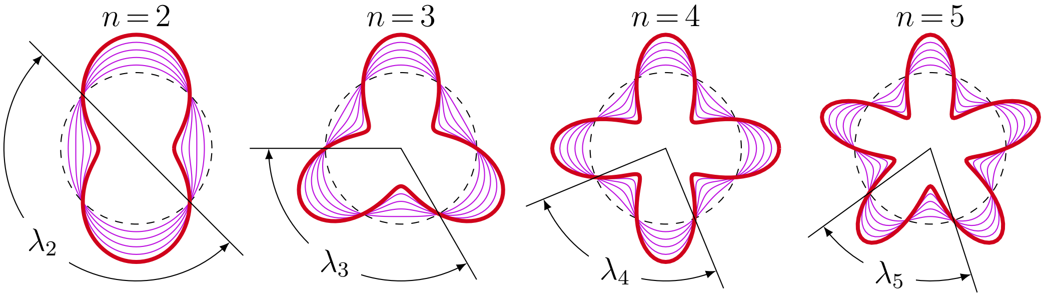
$$2\pi r_n = n\lambda \tag{11.2.263}$$

with $n \in \mathbb{N}^*$.

Visually for $n = 2, \ldots, 5$, we have for example:



And a more complete version by Juan Castaño:



and respecting the idea of growing scale of orbital radius (for $n = 2, \ldots, 4$):

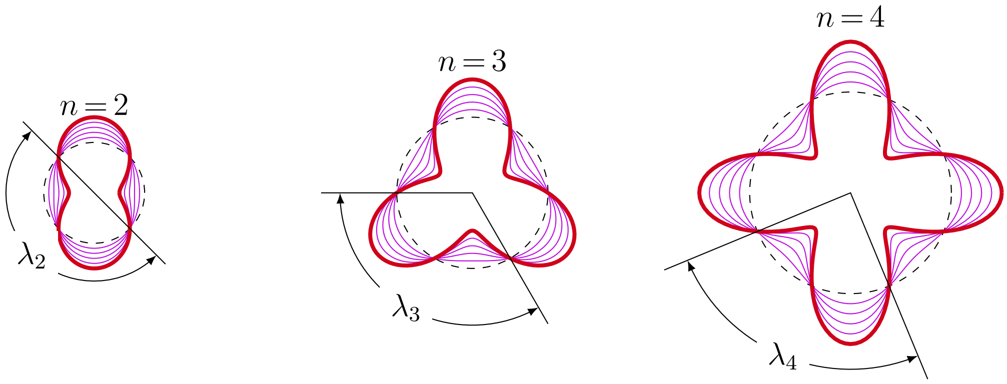


Figure 11.37: **Approach to the wave aspect of orbits by de Broglie**

By replacing λ by h/mv, we get:

$$2\pi r_n=\frac{nh}{mv}\Leftrightarrow mvr_n=\frac{nh}{2\pi} \tag{11.2.264}$$

That is indeed the quantum condition proposed by Bohr (see section Corpuscular Quantum Physics page 4626). The orbits and the quantized energy states of the Bohr model are due to the wave nature of the electron and to the fact that only resonant stationary waves persist. This supposes that the wave-particle duality is the basis of the structure of the atom.

The wave notion of the particle then allowed the physicist Erwin Schrödinger to develop a "wave equation" to describe the wave properties of particles.

Let us do a small sympathetic interlude... since the associated wave of de Broglie known and given the result seen during our study of the virial theorem in the section of Continuum Mechanics, we can relate together:

$$\lambda=\frac{h}{p}=\frac{h}{mv}\qquad E_c=\frac{1}{2}mv^2=\frac{1}{2}pv=\frac{3}{2}kT\Rightarrow v=\sqrt{\frac{3kT}{m}} \tag{11.2.265}$$

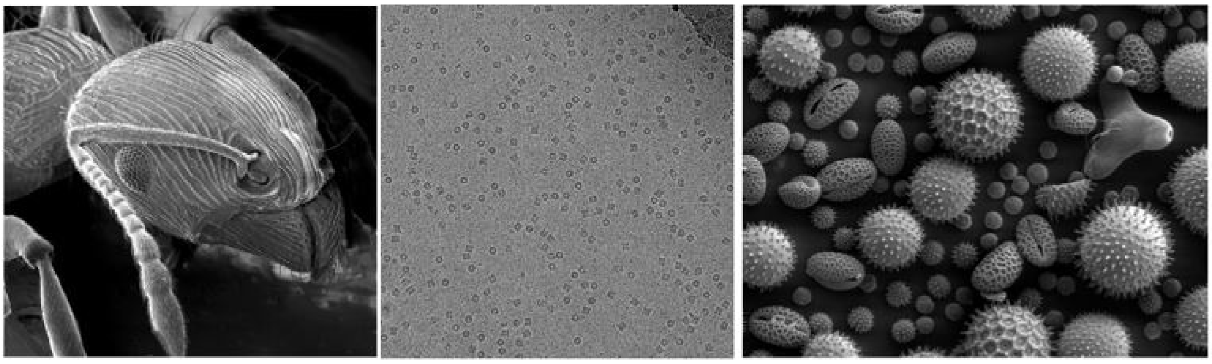
Thus, for a fluid (liquid), we can get the value of the associated "de Broglie thermal wave". Which gives us:

$$\lambda=\frac{h}{mv}=\frac{h}{m\sqrt{\frac{3kT}{m}}}=\frac{h}{\sqrt{3mkT}} \tag{11.2.266}$$

We will come back to this relation during our study of superfluids in the section of Continuum Mechanics.

11.2.4.1.1 Electronic microscopy

Usually, we see the world using photons in certain wavelengths[11]. Our eyes can see only a very limited width of the electromagnetic spectrum. The quantum revolution taught us that we can use other particles (and other wavelengths) to see the world and the Universe in ways we could have never ever imagined. This fact is even more general and can be thought valid even for gravitational waves (bunches of gravitons!).



There are several types of electron microscopes:

1. Transmission electron microscopy. The original form of the electron microscope, the transmission electron microscope (TEM), uses a high voltage electron beam to illuminate the specimen and generate an image. From Wikipedia, The resolution of TEMs is limited primarily by spherical aberration, but a new generation of hardware correctors can reduce spherical aberration to increase the resolution in high-resolution transmission electron microscopy (HRTEM) to below 0.5 Angstrom, enabling magnifications above 50 million times. The ability of HRTEM to determine the positions of atoms within materials is useful for nano-technologies research and development. TEM consists of an emission source or cathode, which may be a tungsten filament or needle, or a lanthanum hexaboride. Cryo-TEM is the cryoscopic modification of TEM in order to do EM for biology and precision TEM imaging. Samples cooled to cryogenic temperatures and embedded in an environment of vitreous water allows useful biological studies, and it deserved a Nobel Prize in 12017 (holocene calendar), to Jacques Dubochet, Joachim Frank, and Richard Henderson for developing cryo-electron microscopy for the high-resolution structure determination of biomolecules in solution.

2. Scanning electron microscopy (SEM). The scanning electron microscope (SEM) is a type of electron microscope that produces images of a sample by scanning the surface with a focused beam of electrons. The electrons interact with atoms in the sample, producing various signals that contain information about the surface topography and composition of the sample. The electron beam is scanned in a raster scan pattern, and the position of the beam is combined with the intensity of the detected signal to produce an image. In the most common SEM mode, secondary electrons emitted by atoms excited by the electron beam are detected using an Everhart-Thornley detector. The number of secondary electrons that can be detected, and thus the signal intensity, depends, among other things, on

---

specimen topography. SEM can achieve resolution better than 1 nanometer. It can also made cryoscopic, as Wikipedia says: «(...)Scanning electron cryomicroscopy (CryoSEM) is a form of electron microscopy where a hydrated but cryogenically fixed sample is imaged on a scanning electron microscope's cold stage in a cryogenic chamber. The cooling is usually achieved with liquid nitrogen. CryoSEM of biological samples with a high moisture content can be done faster with fewer sample preparation steps than conventional SEM. In addition, the dehydration processes needed to prepare a biological sample for a conventional SEM chamber generate numerous distortions in the tissue leading to structural artefacts during imaging(...)».

3. Reflection electron microscopy (REM). In the reflection electron microscope (REM) as in the TEM, an electron beam is incident on a surface but instead of using the transmission (TEM) or secondary electrons (SEM), the reflected beam of elastically scattered electrons is detected. This technique is typically coupled with reflection high energy electron diffraction (RHEED) and reflection high-energy loss spectroscopy (RHELS). Another variation is spin-polarized low-energy electron microscopy (SPLEEM), which is used for looking at the microstructure of magnetic domains.

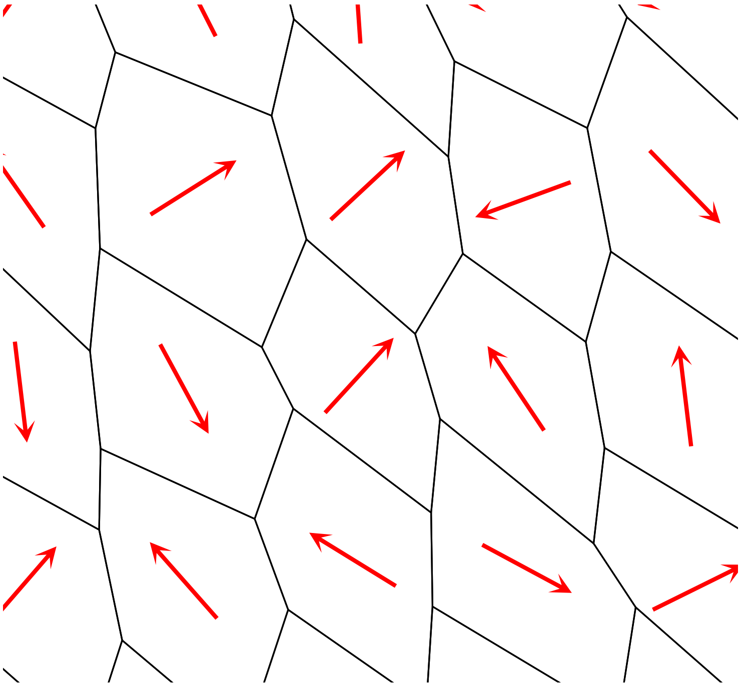

Figure 11.38: Schematic magnetic domains randomly assigned

4. ...

First, let us recall that simple non-relativistic electrons have a kinetic energy of:

$$E_c = \frac{1}{2} m_e v^2 \tag{11.2.267}$$

Any electron that is accelerated by a voltage ΔU change its kinetic energy in a conservative way, so:

$$\Delta E_c = -\Delta E_p = -q_e \Delta U \tag{11.2.268}$$

Suppose that initially $v_0=0\,[\text{m}\cdot\text{s}^{-1}]$ and $U_0=0$ [V], $U_f=U$. Then, the final kinetic energy reads:

$$E_{c,f}=\frac{1}{2}mv_f^2=\frac{p^2}{2m_e}=q_eU \tag{11.2.269}$$

where $p=mv$ is the non-relativistic linear momentum. In the quantum realm, any particle like the electron has an associated wave and wavelength. It is the de Broglie wavelength. And it reads:

$$\lambda_{\text{db}}=\frac{h}{mv} \tag{11.2.270}$$

Using the energy equation above, we can derive that:

$$p=\sqrt{2m_eq_eU} \tag{11.2.271}$$

and thus, we can derive the wavelength of the (non-relativistic) electron microscopy:

$$\lambda_e=\frac{h}{\sqrt{2m_eq_eU}} \tag{11.2.272}$$

We can generalize this relation to microscope of X-particles, where X-particles are particles with mass m_X and electric charger $q_X=Zq_e$ as follows:

$$\boxed{\lambda_X=\frac{h}{\sqrt{2m_XZq_eU}}} \tag{11.2.273}$$

Good!!!! Now, some numerology. We can use the value of the Planck constant as roughly $h\cong 6.63\cdot 10^{-34}\,[\text{J}\cdot\text{s}^{-1}]$, and then we can write:

$$\lambda_e=\frac{12.25\cdot 10^{-10}\,[\text{m}]}{\sqrt{U}}=\frac{1.225\,[\text{nm}]}{\sqrt{U}} \tag{11.2.274}$$

Or more generally:

$$\lambda_X=\frac{12.25\cdot 10^{-10}\,[\text{m}]}{\sqrt{N_XZ_XV}}=\frac{1.225\,[\text{nm}]}{\sqrt{N_XZ_XU}} \tag{11.2.275}$$

and where we wrote $m_X=N_Xm_e$ and $q_X=Z_Xq_e$. If, in particular, the energy is given in [eV] (electron-volts), then we get:

$$\begin{aligned}\lambda_e&=3.88\,[\text{pm}]\text{ at }E=100\,[\text{keV}]\\ \lambda_e&=2.74\,[\text{pm}]\text{ at }E=200\,[\text{keV}]\\ \lambda_e&=2.24\,[\text{pm}]\text{ at }E=300\,[\text{keV}]\\ \lambda_e&=1.23\,[\text{pm}]\text{ at }E=1\,[\text{keV}]\end{aligned} \tag{11.2.276}$$

Imagine muon microscopy, tau particle microscopy or W boson microscopy...

Now, we can enter the special relativistic electron microscope realm. Just as we have for photons (or any massless particle)

$$E=pc\quad\text{and}\quad\lambda=\frac{hc}{E} \tag{11.2.277}$$

for any relativistic particle with relativistic mass $M = m_0\gamma$ and energy:

$$E = Mc^2 = m_0\gamma c^2 \tag{11.2.278}$$

(rest mass $E_0 = m_0c^2$), the kinetic energy reads:

$$E_c = E - m_0c^2 = m_0c^2(\gamma - 1) \tag{11.2.279}$$

since:

$$E = E_c + m_0c^2 \tag{11.2.280}$$

Again, for a conservative force set-up:

$$\Delta E_c = -\Delta E_p = -q_e\Delta U = +q_eU \tag{11.2.281}$$

Taking into account that:

$$\gamma = \frac{1}{\sqrt{1-\dfrac{v^2}{c^2}}} \tag{11.2.282}$$

the special relativity theory generalizes the de Broglie relationship (indeed, de Broglie himself used SR in his wave-particle duality!):

$$\lambda = \frac{h}{m_0\gamma v} = \frac{h}{m_0 v}\sqrt{1-\frac{v^2}{c^2}} \tag{11.2.283}$$

From $E = m_0c^2\gamma$ we get:

$$1-\frac{v^2}{c^2} = \left(\frac{m_0c^2}{E}\right)^2 \tag{11.2.284}$$

From Einstein's relation we get:

$$p^2 = \frac{1}{c^2}\left(E^2-(m_0c^2)^2\right) \tag{11.2.285}$$

Therefore:

$$\begin{aligned} p &= \sqrt{\frac{1}{c^2}\left(E^2-(m_0c^2)^2\right)} = \sqrt{\frac{1}{c^2}\left((E_c+m_0c^2)^2-(m_0c^2)^2\right)} = \sqrt{\frac{1}{c^2}\left(E_c^2+2E_cm_0c^2\right)} \\ &= \sqrt{2E_cm\left(1+\frac{E_c}{2m_0c^2}\right)} \end{aligned} \tag{11.2.286}$$

Inserting this momentum into the relativistic de Broglie wavelength we finally derive the full relativistic electron microscope equation:

$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{2E_cm\left(1+\dfrac{E_c}{2m_0c^2}\right)}} \tag{11.2.287}$$

or inserting E_c as q_eU units, we also get equivalently:

$$\boxed{\lambda=\frac{h}{p}=\frac{h}{\sqrt{2q_eUm\left(1+\dfrac{q_eU}{2m_0c^2}\right)}}} \tag{11.2.288}$$

Some numbers:

Voltage U [kV]	λ_{nr} [nm]	λ_r [nm]	mass $(\cdot m_e)$	$v\ (\cdot 10^8\ [\mathrm{m}\cdot\mathrm{s}^{-1}])$
100	0.00386	0.00370	1.196	1.644
200	0.00274	0.00251	1.391	2.086
400	0.00193	0.00164	1.783	2.484
1000	0.00122	0.00087	2.957	2.823

(11.2.289)

and where λ_{nr} is the non-relativistic wavelength and λ_r is the full relativistic wavelength. They are linked through the following expressions:

$$\begin{gathered}\lambda_{nr}=\frac{h}{\sqrt{2m_eq_eU}}\\ \Xi=\frac{1}{\sqrt{\left(1+\dfrac{E_c}{2m_0c^2}\right)}}\\ \lambda_r=\lambda_{nr}\Xi\end{gathered} \tag{11.2.290}$$

With simple scaling rules, we can extended the relativistic electron microscopes to relativistic X-particle microscopes as follows:

$$\boxed{\lambda=\frac{h}{p}=h\left[2m_XZ_Xq_eU\left(1+\frac{Z_Xq_eU}{2m_Xc^2}\right)\right]^{-1/2}} \tag{11.2.291}$$

11.2.4.2 Classical (time independent) Schrödinger Wave Equation

The physicist Peter Debye found the de Broglie model a bit far fetched. He argued that the physics of waves, from the sound waves to the electromagnetic waves, even the waves propagating on a string requires an equation that describes them. There was no wave equation for de Broglie's atomic model (for the simple reason that the latter had never tried and Albert Einstein either). The physicist Erwin Schrödinger then took it upon himself to find the missing equation and did it brilliantly.

Let us recall the one-dimensional form of the wave equation (see section Wave Mechanics page 3476):

$$\frac{\partial^2 f(x,t)}{\partial x^2}=\frac{1}{v^2}\frac{\partial^2 f(x,t)}{\partial t^2} \tag{11.2.292}$$

To simplify, let us look for a particular solution of the form (see the section on Wave mechanics or the section on Electrodynamics for the analogy):

$$f(x,t)=\Psi(x)\sin(\omega t) \tag{11.2.293}$$

$\Psi(x)$ is the amplitude of the field associated with the particle. It is important to notice that the periodic part does not contain any displacement parameter k (as is the case in Electrodynamics, for example) because the function must describe "static" solutions (be careful not to take this literally).

For historical reasons this amplitude is as we know commonly named "wave function" although this name is misleading. It might be better to name it simply "amplitude field associated with matter".

It is the search for the expression of this function that will lead us during the study of a special case (see much further below in text) to the well-known expression of the ionisation energy of an electron of given main quantum number n and for its atom of given atomic number N.

If we introduce 11.2.293 into 11.2.292, we get:

$$\begin{aligned}&\cancel{\sin(\omega t)}\frac{\partial^2\Psi(x)}{\partial x^2}=-\frac{\omega^2}{v^2}\Psi(x)\cancel{\sin(\omega t)}\\&\Rightarrow\frac{\partial^2\Psi(x)}{\partial x^2}=-\frac{\omega^2}{c^2}\Psi(x)\Rightarrow\frac{\partial^2\Psi(x)}{\partial x^2}=-\frac{(2\pi v)^2}{c^2}\Psi(x)\\&\Rightarrow\frac{\partial^2\Psi(x)}{\partial x^2}=-\frac{\left(2\pi\dfrac{c}{\lambda}\right)^2}{c^2}\Psi(x)\Rightarrow\frac{\partial^2\Psi(x)}{\partial x^2}=-\frac{4\pi^2}{\lambda^2}\Psi(x)\\&\Rightarrow\frac{\partial^2\Psi(x)}{\partial x^2}+\frac{4\pi^2}{\lambda^2}\Psi(x)=0\end{aligned} \tag{11.2.294}$$

We have also:

$$E_c=\frac{1}{2}mv^2=\frac{1}{2m}p^2=\frac{1}{2m}\left(\frac{h}{\lambda}\right)^2=E_{\text{tot}}-E_p \tag{11.2.295}$$

Hence:

$$\frac{1}{\lambda^2}=\frac{2mE_c}{h^2}=\frac{2m(E_{\text{tot}}-E_p)}{h^2} \tag{11.2.296}$$

if we introduce 11.2.296 into 11.2.294 then we get the (time-independent) "classical one-dimensional Schrödinger equation" (in the absence of magnetic field ...):

$$\frac{\partial^2\Psi}{\partial x^2}+\frac{8\pi^2 m(E_{\text{tot}}-E_p)}{h^2}\Psi(x)=0\,[\text{m}^{-5/2}] \tag{11.2.297}$$

Remark

The potential energy could be gravitational as well as electric or both combined (therefore of any kind). But gravity is assumed to be so small at such scales compared to electrostatic forces that it is neglected.

We can rewrite the preceding equation by generalizing it to a three-dimensional system and using the reduced Planck constant. What ultimately gives us:

$$\boxed{\Delta\Psi+\frac{2m}{\hbar}(E_{\text{tot}}-E_p)\Psi=0\,[\text{m}^{-7/2}]} \tag{11.2.298}$$

where for recall Δ is the Laplacian of a scalar field (see section Vector Calculus page 1899):

$$\Delta=\frac{\partial^2}{\partial^2 x}+\frac{\partial^2}{\partial^2 y}+\frac{\partial^2}{\partial^2 z} \tag{11.2.299}$$

The above relation is also often denoted after expliciting the Laplacian and rearranging the terms:

$$\left(-\frac{\hbar}{2m}\nabla^2+E_p\right)\Psi=E_{\text{tot}}\Psi \tag{11.2.300}$$

Let $\vec{r}_i$ be the position vector of electron i and $\vec{R}_j$ be the position vector of proton j. Then, taking into account the electric force between all charged particles and neglecting the motions of the protons and neutrons in the nucleus, which are very slow compared to the electrons, Schrödinger's equation becomes:

$$\left\{-\frac{\hbar^2}{2m_e}\sum_{i=1}^{z}\nabla_i^2-\sum_{i=1}^{z-1}\sum_{j=1+1}^{z}\frac{k_E e^2}{||\vec{r}_i-\vec{R}_j||^2}+\sum_{i}^{z-1}\sum_{k=i+1}^{z}\frac{k_E e^2}{||\vec{r}_i-\vec{r}_k||^2}\right\}\Psi=E_{\text{tot}}\Psi \tag{11.2.301}$$

This is complicated, but it is completely explicit. It describes every atom in the periodic table! Note that we have taken care of not only the electrical force between each electron and each proton in the nucleus but also the forces between each electron pair. The neutron has a small magnetic interaction with the electron and protons, but this can be neglected for most chemical purposes.

Remarks

R1. This equation is not a Lorentz invariant given that it was established from the classical expression of energy (and not the relativistic one).

R2. The plane wave function that we have taken at the beginning does not have a physical significance since it carries an infinite energy. A better solution is to consider a wave packet. However, the wave packets generally employed consist of a superposition of plane waves (see proof further below). Hence, by studying its effects on one of the plane waves, we can still accept the physical conclusions which we can deduce from them...

However as simple as it may seem, it took all the skill and experience of Schrödinger to be the first to write this wave equation and it was the foundation upon which he built the mathematical edifice of Wave Quantum Physics in the following months. But first it had to prove that it was indeed the wave equation sought by applying it to the hydrogen atom for which some results were well known thanks to Sommerfeld results (see section Corpuscular Quantum Physics page 4648). His model eliminated all the successive and empirical tinkering of Corpuscular Quantum Physics.

Some physicists judged Schrödinger's model to be pure madness (in particular Sommerfeld), but they changed mind shortly afterwards... The model was effective and replaced advantageously the horrible abstract matrix model of Heisenberg on which even Pauli had failed to use to explain the experimental results of the hydrogen atom. Soon after Max Born described the wave model as the deepest form of quantum laws, which obviously did not please his close friend Heisenberg...

However, the Heisenberg model describes particles as Schrodinger describes waves. The advantage of having two different formalisms - but equivalent - in quantum physics quickly became evident. For most of the problems physicists encounter, wave mechanics offers the easiest way to the solution. However, for others, such as those involving spin, Heisenberg's matrix approach proves (or rather "defines") its value (see section Relativistic Quantum Physics page 4985).

11.2.4.2.1 Schrödinger Hamiltonian

The Schrödinger equation can also be written as (after a few small elementary factorizations) as follows:

$$\left(E_p-\frac{\hbar}{2m}\Delta\right)\Psi=E_{\text{tot}}\Psi \tag{11.2.302}$$

We write this in quantum physics in the form (the units are given for the three dimensional case):

$$\boxed{H\cdot\Psi=E_{\text{tot}}\cdot\Psi\;[\mathrm{J}\cdot\mathrm{m}^{-3/2}]} \tag{11.2.303}$$

Where H is therefore the Hamiltonian of the system (or total energy) and constitutes a functional operator and where the total energy E_{tot} is its eigenvalue.

The Schrödinger equation is therefore an equation with partial derivatives of the second order, homogeneous linear. Whatever the total energy, it admits solutions (phew!), but we show that in general these solutions grow very rapidly (exponential growth) when we go to infinity in certain directions and are therefore physically unacceptable. There are only particular values of the total energy which give rise to physically acceptable solutions and in general all of these values include discrete values (trigonometric functions at the source with integer parameters) which are the "linked levels" of the system (because their eigenfunction decreases rapidly to infinity) and a continuum of values which are the "unbound levels" (their eigenfunction remaining finite at infinity). More precisely, if W is the lower limit of the potential energy values at infinity, the bounded levels lie below W, while the values greater than W constitute the continuum of the unbound levels.

For example, in the study of the harmonic oscillator (one of the most difficult practical cases in terms of formalism) that we will do later, we will prove that we have:

$$E_p=\frac{Cx^2}{2} \tag{11.2.304}$$

with $W=+\infty$. So there are only linked levels.

For the hydrogen atom:

$$E_p=\frac{-e^2}{4\pi\varepsilon_0 r} \tag{11.2.305}$$

with $W=0$. Linked levels are negative, therefore all positive energy values will be unbound levels.

This having been said, let us also consider as an example (very important) how to determine the Hamiltonian H of the Schrödinger equation of a non-relativistic charged particle in an electromagnetic field!

We have seen in the section of Analytical Mechanics (see page 3155) that the (classical) Lagrangian was defined by the subtraction of kinetic and potential energy according to the relation:

$$L=T-V \tag{11.2.306}$$

We have proved in the section of Electrodynamics that the Lagrangian of the relativistic field-current interaction was given by (see page 4124):

$$L=L_0+L_1=-m_0c^2\sqrt{1-\frac{v^2}{c^2}}+q\vec{A}\circ\vec{v}-q\phi \tag{11.2.307}$$

where for recall ϕ is the vector potential of the electric field (whose gradient is the electric field $\vec{E}$) and $\vec{A}$ is the vector potential of the magnetic field (whose curl is the magnetic field $\vec{B}$).

If we add an electric field (and therefore an electrostatic potential U) in addition to the electromagnetic field, the Lagrangian is then written (since the potential is subtracted according to the Lagrangian definition):

$$L=L_0+L_1=-m_0c^2\sqrt{1-\frac{v^2}{c^2}}-qU+q\vec{A}\circ\vec{v}-q\phi \tag{11.2.308}$$

In the classical (non-relativistic) approximation we know that we have $v/c\ll 1$ and using the Maclaurin series of (see section Sequences and Series page 1703):

$$\sqrt{1+x}\cong 1+\frac{1}{2}x \tag{11.2.309}$$

we can then write:

$$L=-m_0c^2+\frac{1}{2}m_0v^2-qU+q\vec{A}\circ\vec{v}-q\phi \tag{11.2.310}$$

As we restrict ourselves to the non-relativistic case, we can eliminate the constant term of energy of the mass at rest such that:

$$L=\frac{1}{2}m_0v^2-qU+q\vec{A}\circ\vec{v}-q\phi \tag{11.2.311}$$

Still in the section of Analytical Mechanics, we showed that the Hamiltonian was given by:

$$H=\sum_i \dot{x}_ip_i-L \tag{11.2.312}$$

Therefore we have

$$H=\sum_i \dot{x}_ip_i-\frac{1}{2}m_0v^2+qU-q\vec{A}\circ\vec{v}+q\phi \tag{11.2.313}$$

Moreover, we have seen in the section of Analytical Mechanics (see page 3155) that:

$$p_i=\frac{\partial L}{\partial \dot{x}_i} \tag{11.2.314}$$

It therefore comes that:

$$p_i=\frac{\partial}{\partial \dot{x}_i}\left(\frac{1}{2}m_0v_i^2-qU+q\vec{A}\circ\vec{v}-q\phi\right)=m_0v_i+qA_i \tag{11.2.315}$$

Finally:

$$H=m_0v^2+q\vec{A}\circ\vec{v}-\frac{1}{2}m_0v^2+qU-q\vec{A}\circ\vec{v}+q\phi \tag{11.2.316}$$

Either after simplification:

$$H=\frac{1}{2}m_0v^2+qU+q\phi=\frac{1}{2}m_0v^2+qU+V \tag{11.2.317}$$

H therefore contains the kinetic energy and total potential energy. There is no magnetic term because the Laplace force, as we proved it in the section of Magnetostatic, does not work (there are some who are lucky...). H is indeed the total energy of the classical system, but the preceding relation is not really adapted to Hamilton's formalism because the conjugate moments do not appear. But it is very simple to introduce them from the result obtained previously which was:

$$p_i=m_0v_i+qA_i\Rightarrow v_i=\frac{p_i-qA_i}{m_0} \tag{11.2.318}$$

Therefore:

$$H=\frac{1}{2}m_0v^2+q\cdot U+V=\frac{1}{2}m_0\left(\frac{p_i-qA_i}{m_0}\right)^2+qU+V=\frac{(p_i-qA_i)^2}{2m_0}+qU+V \tag{11.2.319}$$

If we go into Quantum Physics, we have to replace the p_i by their respective operators:

$$p_i=-\mathrm{i}\hbar\partial_i \tag{11.2.320}$$

of which we have already proved the origin earlier above. Thus, we have that:

$$H=\frac{(p_i-qA_i)^2}{2m_0}+qU+V \tag{11.2.321}$$

which must be written in the general case (as we do not know if the vector potential commutes with the linear momentum operator, we will assume that it does not commute):

$$H_i = \frac{p_i^2}{2m_0} - \frac{q(p_iA_i + A_ip_i)}{2m_0} + \frac{q^2A_i^2}{2m_0} + qU + V \tag{11.2.322}$$

What is traditionally written in the form (sic!):

$$\boxed{H = \frac{p^2}{2m_0} - q\frac{(pA + Ap)}{2m_0} + \frac{q^2A^2}{2m_0} + qU + V} \tag{11.2.323}$$

This last relation is very often found in the following simplified form in textbooks in the absence of potential U and by making V explicit:

$$H = \frac{1}{2m_0}(p - qA)^2 + q\phi \tag{11.2.324}$$

Remark

In the section of Relativistic Quantum Physics we will prove the relativistic form of this Hamiltonian associated with the generalized Klein-Gordon equation (see page 4924) or that of Dirac (see page 4978) which includes the $1/2$ spin!

Fortunately, we will not discuss examples where we will have to find solutions to the Schrödinger equation with such a Hamiltonian in this textbook...

In the academic case, however, when application premises are addressed ..., we cancel either the vector potential (i.e. the particle is not immersed in a magnetic field) or the scalar potential (i.e. the particle is not immersed in an electric field). Moreover, when one of the fields is chosen as being non-zero, we take the case where it is constant and in a single dimension... Thus, if we want a constant electric field along a single axis (for example the x-axis), we take as scalar potential:

$$\phi(x,t) = E_0 \cdot x \tag{11.2.325}$$

since its gradient will give a constant according to x. In the case of a constant magnetic field along a single axis (for example the z-axis), we will arrange to take the vector potential:

$$A = \frac{B_0}{2}\begin{pmatrix} -y \\ x \\ 0 \end{pmatrix} \tag{11.2.326}$$

whose rotational (curl) gives a constant magnetic field according to z.

11.2.4.2.2 De Broglie normalization condition

In general, in a given dynamic state, the particle (if it is a one-particle system) described by the resolution of the Schrödinger equation for well-defined parameters is badly localized because x, y and z are not well defined by Heisenberg's principle of uncertainty. It is therefore necessary to define a probability $\mathrm{d}P$ of finding the particle in the volume element $\mathrm{d}x\mathrm{d}y\mathrm{d}z$ surrounding a point (x,y,z), hence the existence of a distribution function of the coordinates such that:

$$\mathrm{d}P=\rho(x,y,z)\mathrm{d}x\mathrm{d}y\mathrm{d}z \tag{11.2.327}$$

where $\rho(x,y,z)$ is therefore an essentially positive or zero quantity (probabilities obliged!) which must be expressed by means of the Schrödinger equation function $\Psi(x,y,z)$. We have, moreover, such very detailed examples in this section and at the end of that of Quantum Chemistry.

Analogies with Classical Wave Physics, more precisely with Electrodynamics, have led us to admit that since the density of energy of an electromagnetic wave is proportional to the square of its amplitude (see section Electrodynamics page 4156), the volumetric density probability must be proportional to the square of the intensity of the associated field such that:

$$\rho(x,y,z)=c^{te}\cdot|\Psi(x,y,z)|^2 \tag{11.2.328}$$

where we use the Schrödinger function module as an amplitude analogy and where the constant is a real number. In the framework of Quantum Physics, it is much more common to find this last relation in the following obvious form:

$$\rho(x,y,z)=\frac{|\Psi(x,y,z)|^2}{\displaystyle\int|\Psi(x,y,z)|^2\mathrm{d}x\mathrm{d}y\mathrm{d}z}=\left|\frac{\Psi(x,y,z)}{\sqrt{\displaystyle\int|\Psi(x,y,z)|^2\mathrm{d}x\mathrm{d}y\mathrm{d}z}}\right|^2=c^{te}|\Psi(x,y,z)|^2 \tag{11.2.329}$$

which highlights the necessary normalization of the Schrödinger equation.

Finally, it is important to know that during mathematical developments, the huge majority of physicists have the habit of keeping the same notation for the non-normalized Schrödinger function as for the normalized one (which can lead to some confusion) such as:

$$|\Psi(x,y,z)|^2=\left|\frac{\Psi(x,y,z)}{\sqrt{\displaystyle\int|\Psi(x,y,z)|^2\mathrm{d}x\mathrm{d}y\mathrm{d}z}}\right|^2 \tag{11.2.330}$$

where $|\Psi(x,y,z)|^2$ then represents the density probability of finding the particle at a certain point in space.

It is evident then that with this way of writing things we have then over all space:

$$\boxed{\iiint_V\rho(x,y,z)\mathrm{d}x\mathrm{d}y\mathrm{d}z=\iiint_V|\Psi(x,y,z)|^2\mathrm{d}x\mathrm{d}y\mathrm{d}z=1} \tag{11.2.331}$$

We can now consider the physical significance which may be attached to the intensity of the field associated with matter. Since this field describes the motion of a particle, we can say that the regions of space in which the particle is most likely to be found are those in which the $|\Psi(x,y,z)|^2$ is maximum.

Figure 11.41: **Atomic model evolution (source: ?)**

Let us also inform you that the prior-previous relation is often written using the Dirac ket-bra notation in the very refined (and very common...) way:

$$\| \Psi\rangle |^2 = \left| \frac{|\Psi\rangle}{\sqrt{\langle\Psi \mid \Psi\rangle}} \right|^2 = \frac{\| \Psi\rangle |^2}{\langle\Psi \mid \Psi\rangle} \tag{11.2.332}$$

where the module in the denominator disappears, since, for recall, the integral is a real number. Or in the following way (it is simply the square root of the previous one):

$$|\Psi\rangle = \frac{|\Psi\rangle}{\sqrt{\langle\Psi \mid \Psi\rangle}} \tag{11.2.333}$$

It should never be forgotten that physicists, for the vast majority, note in a similar way the non-normalized and normalized Schrödinger function as this last relation reminds us.

As we have already said, we will see many detailed examples of this normalization in this section with one-dimensional spaces and in the context of volumes in the section on Quantum Chemistry.

✍**Example:**

A ball is constrained to move along a line inside a tube of length L. The ball is equally likely to be found anywhere in the tube at some time t. What is the probability of finding the ball in the left half of the tube at that time? (the answer is 50%, of course, but how do we get this answer by using the probabilistic interpretation of the quantum mechanical wave function?)

The first step to the answer is to write down the wave function. The ball is equally like to be found anywhere in the box, so one way to describe the ball with a constant wave function:

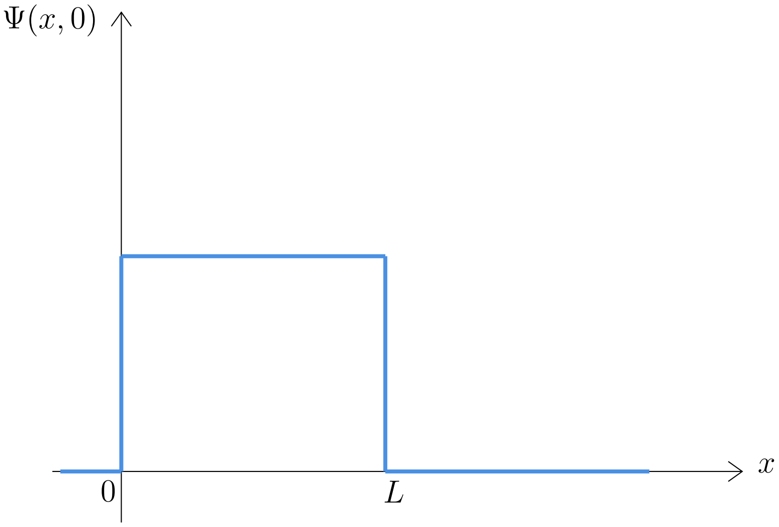

Figure 11.42: **Wave function for a ball in a tube of length L**

The normalization condition can be used to find the value of the function and a simple integration over half of the box yields the final answer.

The wave function of the ball can be written as:

$$\Psi(x,t)=C^{te}(0\leq x\leq L) \tag{11.2.334}$$

where c^{te} is a constant, and $\Psi(x,t)=0$ otherwise. We can determine the constant C^{te} by applying the normalization condition (we set $t=0$ to simplify the notation):

$$P(-\infty\leq x\leq +\infty)=\int\limits_{-\infty}^{+\infty}\Psi\bar{\Psi}\mathrm{d}x=\int\limits_{-\infty}^{+\infty}|C^{te}|^2\mathrm{d}x=1 \tag{11.2.335}$$

This integral can be broken into three parts: (1) negative infinity to zero, (2) zero toL, and (3) L to infinity. The particle is constrained to be in the tube, so $C^{te}=0$ outside the tube and the first and last integrations are zero. The above equation can therefore be written:

$$P(x=0,L)=\int\limits_{0}^{L}|C^{te}|^2\mathrm{d}x=1 \tag{11.2.336}$$

The constant C^{te} does not depend on x and can be taken out of the integral, so we obtain:

$$P(x=0,L)=|C^{te}|^2\int_0^L \mathrm{d}x=1 \tag{11.2.337}$$

Integration gives obviously:

$$C^{te}=\sqrt{\frac{1}{L}} \tag{11.2.338}$$

To determine the probability of finding the ball in the first half of the box $(0\leq x\leq L)$, we have:

$$P(x=0,L/2)=\int_0^{L/2}\left|\sqrt{\frac{1}{L}}\right|^2\mathrm{d}x=\left(\frac{1}{L}\right)\frac{L}{2}=0.5 \tag{11.2.339}$$

The probability of finding the ball in the first half of the tube is 50%, as expected. Two observations are noteworthy. First, this result corresponds to the area under the constant function from $x=0$ to $L/2$ (the area of a square left of $L/2$). Second, this calculation requires an integration of the square of the wave function. A common mistake in performing such calculations is to forget to square the wave function before integration.

Let us say one more thing about normalization. If you observe the Hamiltonian expression of the Schrödinger equations seen so far, then if λ is a real or complex constant we always have:

$$H(\lambda\Psi)=\lambda H(\Psi) \tag{11.2.340}$$

If we assume that Ψ is a solution of the Schrödinger equation, we see that $\lambda\Psi$ is also a solution of the equation. Indeed, we get:

$$H(\lambda\Psi)=\lambda H(\Psi)=\lambda E\Psi=E(\lambda\Psi) \tag{11.2.341}$$

Taking into account the fact that the function $\lambda\Psi$ is normalized, we then get:

$$\int|\lambda\Psi|^2\,\mathrm{d}x=1\Rightarrow|\lambda|^2\int|\Psi|^2\,\mathrm{d}x=1\Rightarrow|\lambda|^2=1 \tag{11.2.342}$$

hence (some textbooks restrict themselves to these solutions for pedagogical reasons):

$$\lambda=\pm 1\qquad\text{or}\qquad\lambda=\pm\mathrm{i} \tag{11.2.343}$$

Or rigorously we have more generally:

$$\lambda=e^{\mathrm{i}\theta} \tag{11.2.344}$$

where θ is a real number. This is what we name the "phase arbitrariness" which we had already mentioned at the beginning of this section without proof. We will also come back on this in the section of Quantum Field Theory for our study of Gauge theories applied to Quantum Physics.

These solutions are normalized and correspond to the same energy value E as the same probability density. This shows that it is not useful to look for the meaning of a negative or complex value of Ψ (if we take the particular pedagogical case of $\lambda=-1$), because $|\Psi|^2$ is real and is not negative (but nothing prevent us that the fact we require a result in $\mathbb{R}$ is wrong...). Only the square of a wave function, which corresponds to the probability density, seems to be interesting from a physical point of view.

11.2.4.2.3 Bound and unbound states

Let us suppose that $\Psi(x,y,z)$ decreases rapidly to infinity, so that the integral:

$$\int\limits_{-\infty}^{+\infty} |\,\Psi(x,y,z)\,|^2 \, \mathrm{d}x\mathrm{d}y\mathrm{d}z \tag{11.2.345}$$

converge. It is then possible to take advantage of the arbitrariness prevailing on the wave function (the fact that Ψ and $\lambda\Psi$ describe the same state) to make this integral equal to unity. We then say that Ψ is a "standardized field state function":

$$\int\limits_{-\infty}^{+\infty} |\,\Psi(x,y,z)\,|^2 \, \mathrm{d}x\mathrm{d}y\mathrm{d}z = 1 \tag{11.2.346}$$

We notice that there is still an arbitrary on Ψ by a complex number of module 1, $e^{\mathrm{i}\theta}$, without the condition of normalization being altered. We know that this is the "phase arbitrariness" and we have already introduced it just before!

Such a dynamic state is named "bound state" or "bound level", because the particle manifests itself in a limited region of space because of a potential. When, for example, the hydrogen atom is located on a fundamental level, it is in a bound state. We know that there is no chance of finding the electron at more than a few Angstroms of the proton, treated as infinitely heavy and originally placed as we have seen in the study of the Bohr model. Here is a good schematic view of the thing (bound state):

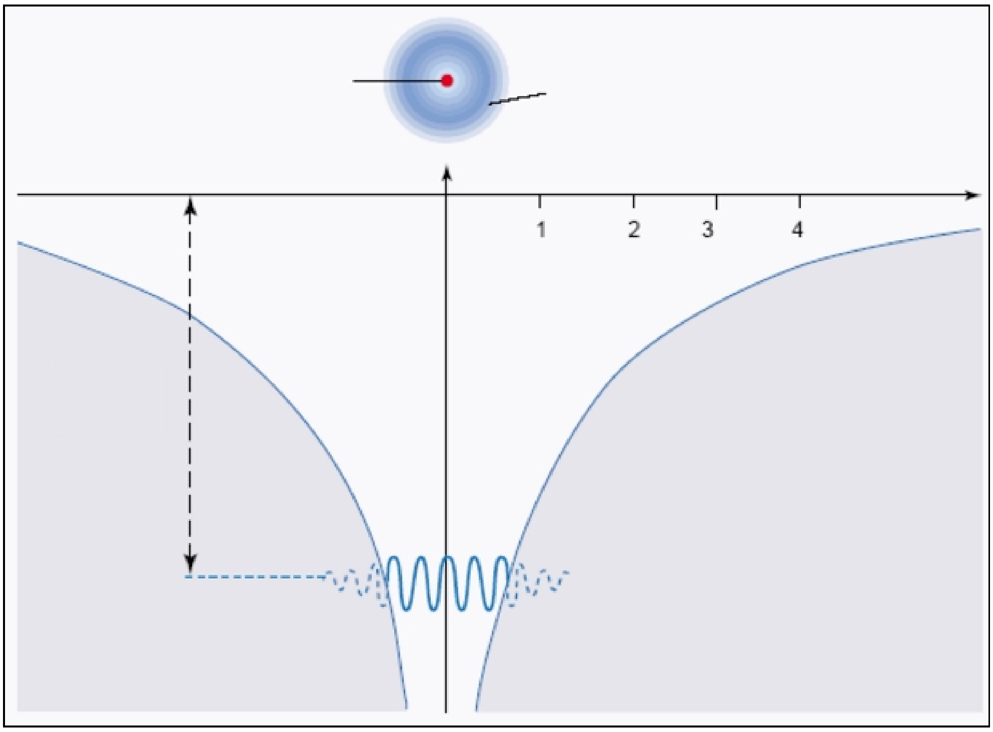

Figure 11.43: **Pictorial representation of a bound state (source: Pour la science)**

An example of an "unbounded (default) state" is the free particle that can propagate indefinitely in all directions of space (by the way, for the latter example it is a little more complicated ... but we will deal with it later).

Remark

It is perhaps good to know that these bound state concepts have classical analogues. Thus, the bound levels of the hydrogen atom correspond to the elliptic orbits, the unbound (positive energy) levels correspond to the hyperbolic orbits.

11.2.4.3 Classical Shrödinger equation of evolution

We know that in Classical Mechanics the dynamic state of a system evolves, in general, in time. This means that the position and the linear momentum (for example) are a function of time. For a given Hamiltonian system, knowledge of the initial dynamic state makes it possible to predict exactly the future evolution of this system due to the well-known properties of Hamilton's equations.

In Quantum Physics, dynamic states will generally evolve over time. The wave function describing a dynamic state will then not only depend on the coordinates of the particles constituting the system, but it will also depend on time and be written:

$$\Psi(x,y,z,t) \tag{11.2.347}$$

It is quite natural to assume, by analogy with Classical Mechanics, that for a given Hamiltonian system the knowledge of the initial dynamic state at the instant t_0 allows us to predict what will be the dynamic state of the system at a later time $t>t_0$.

On the way let us notice that this is equivalent to say that an initially "pure set" remains a pure set in the during the subsequent evolution of the systems which constitute it without external action. It would therefore cease to be true if all the systems of the whole had not exactly the same Hamiltonian.

Let us indicate that there are at least two simple possible approaches to determine the time-dependent functions:

- The first one, common in many fields of application of Quantum Physics, consists in using an "evolution operator" and makes it possible to make explicit the Schrödinger equation of evolution. We will begin with this one even if it is the most complicated or abstract approach in our point of view.
- The second, which is widely used for educational purposes, allows the time-dependent functions to be obtained by means of the technique of separation of the variables of differential equations (see section Differential and Integral Calculus page 1617) but requires to admit the Schrödinger equation of evolution as a postulate.

11.2.4.3.1 Operator of evolution

Given $\Psi(t)$ the normalized wave function describing the dynamic state of the system at time t (we do not write the other variables on which equation depends for simplicity, i.e. the spatial coordinates of the system's particles!). From the above, if $\Psi(t_0)$ is known, $\Psi(t)$ is also known. Then we have the correspondence:

$$\Psi(t) \rightarrow \Psi(t_0) \qquad (11.2.348)$$

and we will admit that this dependence is linear! There is therefore an operator $T(t,t_0)$, named "evolution operator", such that:

$$\Psi(t) = T(t,t_0)\Psi(t_0) \qquad (11.2.349)$$

The function $\Psi(t+\mathrm{d}t)$ depends also linearly on $\Psi(t)$. Then the same applies to:

$$\frac{\Psi(t+\mathrm{d}t)-\Psi(t)}{\mathrm{d}t} \qquad (11.2.350)$$

Therefore we assume that it exist a linear operator K, such that:

$$\frac{\partial\Psi}{\partial t} = \mathrm{i}K\Psi \qquad (11.2.351)$$

where the pure imaginary complex number i simply comes from the fact that we intuitively guess that the result will be a complex wave function. What also led the physicists to write the latter equality thus were the known results of the wave equation describing a dynamic state according to the idea of de Broglie. We will then show why writing this equality is justified.

We have to determine K. Since the knowledge of the Hamiltonian H controls the evolution of the system, so K must probably depend on H. To define the law that binds K to H, we will examine a particular case, that of the free particle (for which e will make a detailed study later). In this case, H is identifies with kinetic energy only.

According to de Broglie's ideas it is natural to assume that the wave function describing a dynamic state in which the linear momentum is well-defined, i.e. $p=\hbar k$ (relation proved during the study of the free particle), and where the total energy is thus also well defined, i.e. equal $E=\hbar\omega$, is a plane wave of the classical form:

$$\Psi(x,y,z,t)=\Psi_0 e^{\mathrm{i}(\vec{k}\circ\vec{r}+\omega\cdot t)} \tag{11.2.352}$$

where as we already know, and for recall, $\vec{k}$ is the wave vector of the wave and $\vec{r}=(x,y,z)$ its spatial coordinates.

It is common in Quantum Physics to take a wave that propagates in the $+X$ direction. Therefore (see section Wave Mechanics 3476) using the De Broglie relation ($E=\hbar\omega$):

$$\frac{\partial\Psi}{\partial t}=\frac{\partial\Psi_0 e^{\mathrm{i}(\vec{k}\circ\vec{r}-\omega\cdot t)}}{\partial t}=-\mathrm{i}\omega\Psi=\frac{E}{\hbar\mathrm{i}}\Psi \tag{11.2.353}$$

But we have the relation between the Hamiltonian operator and the corresponding eigenvalue:

$$H\Psi=E\Psi \tag{11.2.354}$$

The two preceding equations lead us to write:

$$\frac{\partial\Psi}{\partial t}=\frac{H}{\hbar\mathrm{i}}\Psi \tag{11.2.355}$$

By comparing this last relation with:

$$\frac{\partial\Psi}{\partial t}=\mathrm{i}K\Psi \tag{11.2.356}$$

We are led to put:

$$K=-\frac{H}{\hbar} \tag{11.2.357}$$

Physicists assume that this relation between K and H is general. Then the equation:

$$\frac{\partial\Psi}{\partial t}=\mathrm{i}K\Psi \tag{11.2.358}$$

In which K is replaced by its expression:

$$K=-\frac{H}{\hbar} \tag{11.2.359}$$

Therefore becomes:

$$\boxed{\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=H\Psi} \tag{11.2.360}$$

This equation constitutes the "Schrödinger's classical evolution equation" or "time-dependant Schrödinger's equation" which allows to study systems evolving over time, in particular the processes involving the absorption and the emission of radiation and the diffusion of the radiation by the atoms.

We recognize also in the previous relation the Energy operator:

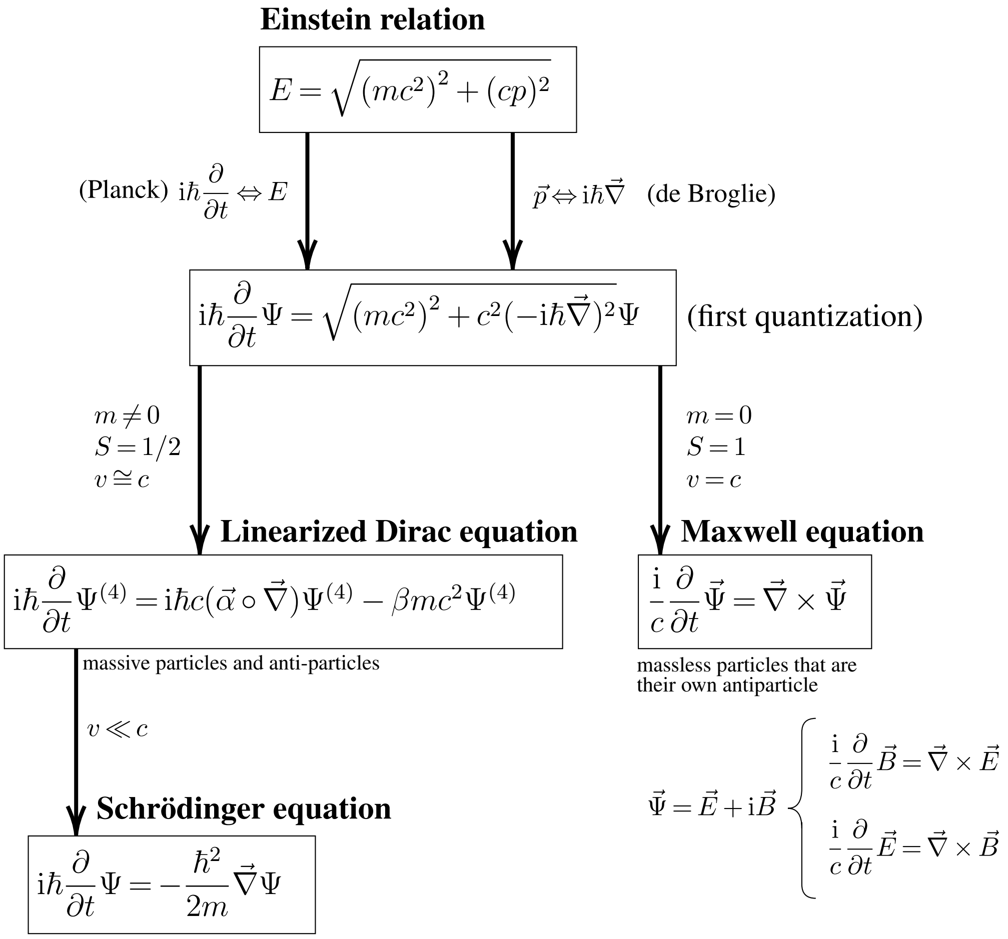
$$\hat{E}=\mathrm{i}\hbar\frac{\partial}{\partial t} \tag{11.2.361}$$

In particular, for a spinless particle subjected to a potential energy E_p, by always maintaining that the relation between K and H is general, the equation of evolution is then written:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=\left(E_p-\frac{\hbar^2}{2m}\Delta\right)\Psi \tag{11.2.362}$$

where the terms in parentheses correspond to the expression of the Hamiltonian. Notice something quite important...! Time is derived once but space twice. This asymmetry of treatment between time and space is incompatible with what we know from Special Relativity where space and time and treated equally. This is an issue that we will solve much later with the Dirac equation.

The figure below illustrates how we can move from the Special Relativity Einstein's relation to the most famous equations in Quantum Physics:



Einstein relation
$E=\sqrt{(mc^2)^2+(cp)^2}$
(Planck) $\mathrm{i}\hbar\frac{\partial}{\partial t}\Leftrightarrow E$
$\vec{p}\Leftrightarrow\mathrm{i}\hbar\vec{\nabla}$ (de Broglie)
$\mathrm{i}\hbar\frac{\partial}{\partial t}\Psi=\sqrt{(mc^2)^2+c^2(-\mathrm{i}\hbar\vec{\nabla})^2\Psi}$
(first quantization)
$m\neq 0$
$S=1/2$
$v\cong c$
$m=0$
$S=1$
$v=c$
Linearized Dirac equation
$\mathrm{i}\hbar\frac{\partial}{\partial t}\Psi^{(4)}=\mathrm{i}\hbar c(\vec{\alpha}\circ\vec{\nabla})\Psi^{(4)}-\beta mc^2\Psi^{(4)}$
massive particles and anti-particles
Maxwell equation
$\frac{\mathrm{i}}{c}\frac{\partial}{\partial t}\vec{\Psi}=\vec{\nabla}\times\vec{\Psi}$
massless particles that are their own antiparticle
$v\ll c$
$\vec{\Psi}=\vec{E}+\mathrm{i}\vec{B}$
$\frac{\mathrm{i}}{c}\frac{\partial}{\partial t}\vec{B}=\vec{\nabla}\times\vec{E}$
$\frac{\mathrm{i}}{c}\frac{\partial}{\partial t}\vec{E}=\vec{\nabla}\times\vec{B}$
Schrödinger equation
$\mathrm{i}\hbar\frac{\partial}{\partial t}\Psi=-\frac{\hbar^2}{2m}\vec{\nabla}\Psi$

Figure 11.44: **Relationships between most famous quantum physics equations**

It is now necessary to solve the Schrödinger differential equation of evolution. For this, we will use the condition of normalization of de Broglie.

Let us recall that this condition is written:

$$\int\limits_{-\infty}^{+\infty} |\,\Psi(x,y,z)\,|^2\,\mathrm{d}x\mathrm{d}y\mathrm{d}z=1 \tag{11.2.363}$$

and let us generalize this condition to a multidimensional and temporal study such that (according to the properties of complex numbers):

$$\int |\,\Psi(t,q)\,|^2\,\mathrm{d}q=\int \bar{\Psi}(t,q)\Psi(t,q)\mathrm{d}q=1 \tag{11.2.364}$$

Let us now perform the derivative with respect to time of the previous integral. We therefore necessarily have:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\int \bar{\Psi}(t,q)\Psi(t,q)\mathrm{d}q&=\int\left[\frac{\mathrm{d}}{\mathrm{d}t}\bar{\Psi}\right]\Psi(t,q)\mathrm{d}q+\int\bar{\Psi}(t,q)\left[\frac{\mathrm{d}}{\mathrm{d}t}\Psi\right]\mathrm{d}q\\&=\int\dot{\bar{\Psi}}(t,q)\Psi(t,q)\mathrm{d}q+\int\bar{\Psi}(t,q)\dot{\Psi}(t,q)\mathrm{d}q=0\end{aligned} \tag{11.2.365}$$

and let use the Schrödinger equation of evolution:

$$\mathrm{i}\hbar\dot{\Psi}=H\Psi\Rightarrow\begin{cases}\dot{\Psi}=-\dfrac{\mathrm{i}}{\hbar}H\Psi\\ \dot{\bar{\Psi}}=+\dfrac{\mathrm{i}}{\hbar}\bar{H}\bar{\Psi}\end{cases} \tag{11.2.366}$$

What gives us for our integral after substitution:

$$\begin{aligned}&\int\left[-\frac{\mathrm{i}}{\hbar}H\bar{\Psi}(t,q)\right]\Psi(t,q)\mathrm{d}q+\int\bar{\Psi}(t,q)\left[\frac{\mathrm{i}}{\hbar}\bar{H}\Psi(t,q)\right]\mathrm{d}q\\&=\frac{\mathrm{i}}{\hbar}\left[\int\bar{\Psi}(t,q)\bar{H}\Psi(t,q)\mathrm{d}q-\int H\bar{\Psi}\Psi(t,q)\mathrm{d}q\right]=\int\bar{\Psi}(t,q)\bar{H}\Psi(t,q)\mathrm{d}q-\int H\bar{\Psi}(t,q)\Psi(t,q)\mathrm{d}q=0\end{aligned} \tag{11.2.367}$$

Let us now prove that we can write:

$$\int\bar{\Psi}(t,q)\bar{H}\Psi(t,q)\mathrm{d}q-\int H\bar{\Psi}(t,q)\Psi(t,q)\mathrm{d}q=\int\bar{\Psi}(t,q)\bar{H}\Psi(t,q)\mathrm{d}q-\int\bar{\Psi}(t,q)H\Psi(t,q)\mathrm{d}q \tag{11.2.368}$$

This would then be equivalent to the proof that H can act identically "backwards" such that:

$$\int H\bar{\Psi}(t,q)\Psi(t,q)\mathrm{d}q=\int\bar{\Psi}(t,q)H\Psi(t,q)\mathrm{d}q \tag{11.2.369}$$

where H can be (or "contain" if you prefer) an operator (differential one for example).

This equality can be proved if and only if Ψ is a decreasing function towards infinity and whose derivative tends towards zero towards the infinite (typical of bounded states)!

Let us prove this on a particular case (but frequent in physics) and to see how this can be done, let us consider in H, a particular term of the following form (we don't care of the constant corresponding the potential energy as it doesn't change anything in the result below):

$$H=f(q)\cdot\frac{\partial}{\partial q}\cdot g(q)=f\frac{\partial}{\partial q}g \tag{11.2.370}$$

Which leads us to write:

$$\int \bar{\Psi}(t,q)H\Psi(t,q)\mathrm{d}q=\int \bar{\Psi}(t,q)\left[f\frac{\partial}{\partial q}g\Psi(t,q)\right]\mathrm{d}q \tag{11.2.371}$$

By integration by parts (see section Differential and Integral Calculus page 1532) on the differential operator term $\partial_q(g\Psi(t,q))$, we get:

$$\int\limits_{-\infty}^{+\infty}\bar{\Psi}(t,q)f\cdot\frac{\partial}{\partial q}\big(g\Psi(t,q)\big)\mathrm{d}q=\bar{\Psi}(t,q)f\cdot g\Psi(t,q)\mid_{-\infty}^{+\infty}-\int\limits_{-\infty}^{+\infty}\frac{\partial}{\partial q}\big(\bar{\Psi}(t,q)f\big)\cdot g\Psi(t,q)\mathrm{d}q \tag{11.2.372}$$

But, since Ψ is a function decreasing towards infinity by hypothesis (physically necessary for bound states!), we will have the first term which will always be zero. It remains to us therefore:

$$\int\limits_{-\infty}^{+\infty}\bar{\Psi}f\cdot\frac{\partial}{\partial q}(g\Psi)\mathrm{d}q=-\int\limits_{-\infty}^{+\infty}\frac{\partial}{\partial q}(\bar{\Psi}f)\cdot g\Psi\mathrm{d}q=\int\limits_{-\infty}^{+\infty}\left(-\frac{\partial}{\partial q}f\bar{\Psi}\right)\cdot g\Psi\mathrm{d}q \tag{11.2.373}$$

So it makes no difference to consider that the operator differentiates everything that is on the right or whatever what is on the left, so far as it must be accepted that the latter case involves a change of sign and that the considerate states are bounded. It is customary to name this result sometimes the "condition of hermicity" ....

So we are indeed authorized to write:

$$\int \bar{\Psi}(t,q)\bar{H}\Psi(t,q)\mathrm{d}q-\int \bar{\Psi}(t,q)H\Psi(t,q)\mathrm{d}q=0 \tag{11.2.374}$$

Which also leads us to write (this highlight why the constant related to the potential energy was ignored in the proof above as it is obvious that the constants cancels each other):

$$\int \bar{\Psi}(t,q)(\bar{H}-H)\Psi(t,q)\mathrm{d}q=0 \tag{11.2.375}$$

This can only be satisfied if:

$$\bar{H}=H \tag{11.2.376}$$

And in the mathematical field dealing with operators we saw that we should note this equality:

$$H^{\dagger}=H \tag{11.2.377}$$

Which brings us to write:

$$\int \bar{\Psi}(t,q)(H^{\dagger}-H)\Psi(t,q)dq \tag{11.2.378}$$

Or using the representative (ket-bra) notation:

$$\langle\Psi\mid H^{\dagger}-H\mid\Psi\rangle=0 \tag{11.2.379}$$

To return to the resolution of:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=H\Psi \tag{11.2.380}$$

It is obvious that a possible solution is then:

$$\boxed{\Psi(t,q)=\Psi(0,q)e^{-\frac{\mathrm{i}t}{\hbar}H}} \tag{11.2.381}$$

which is therefore made of a purely spatial (independent of time) component and a time-dependent complex exponential. Let us check this:

$$\begin{aligned}\mathrm{i}\hbar\frac{\partial}{\partial t}\Psi(t,q)&=\mathrm{i}\hbar\left(\Psi(0,q)e^{-\frac{\mathrm{i}t}{\hbar}H}\right)=\mathrm{i}\hbar\left(\frac{\partial\Psi(0,q)}{\partial t}e^{-\frac{\mathrm{i}t}{\hbar}H}+\Psi(0,q)\frac{\partial e^{-\frac{\mathrm{i}t}{\hbar}H}}{\partial t}\right)\\&=\mathrm{i}\hbar\Psi(0,q)\left(\frac{\mathrm{i}}{\hbar}\right)He^{-\frac{\mathrm{i}t}{\hbar}H}=\Psi(0,q)He^{-\frac{\mathrm{i}t}{\hbar}H}=H\Psi(t,q)\end{aligned} \tag{11.2.382}$$

This is what had to be proved (...).

Let us also notice that once the purely spatial solutions are determined, the time- and space-dependent solutions are easily obtained.

Similarly, thanks to the relation $H^\dagger=H$ that we have demonstrated before, we can write:

$$\bar{\Psi}(t,q)=\bar{\Psi}(0,q)e^{\frac{\mathrm{i}t}{\hbar}H} \tag{11.2.383}$$

Finally, the relation:

$$\int\bar{\Psi}(t,q)X\Psi(t,q)\mathrm{d}q=1 \tag{11.2.384}$$

becomes:

$$\int\bar{\Psi}(0,q)e^{-\frac{\mathrm{i}t}{\hbar}H}X\Psi(0,q)e^{\frac{\mathrm{i}t}{\hbar}H}\mathrm{d}q=\int\bar{\Psi}(0,q)X(t)\Psi(0,q)\mathrm{d}q=1 \tag{11.2.385}$$

with the "Heisenberg operator (of evolution)" defined by:

$$\boxed{X(t)=e^{-\frac{\mathrm{i}t}{\hbar}H}Xe^{\frac{\mathrm{i}t}{\hbar}H}=e^{\frac{\mathrm{i}t}{\hbar}H}Xe^{-\frac{\mathrm{i}t}{\hbar}H}} \tag{11.2.386}$$

and with the "time evolution operator" given by:

$$\boxed{U(t,t_0)=e^{-iH(t-t_0)/\hbar}} \tag{11.2.387}$$

that is unitary since:

$$U^\dagger U=1 \tag{11.2.388}$$

Remark

It may very well happen that X is sometimes a simple constant (we will see an example further below).

One way is to think of the operator X as time-independent and to consider all of the time dependence of its expectation value as coming from the state vector. This point of view is known as the "Schrödinger picture". Alternatively, we may think of the operator as evolving in time, while the state vector stays constant. This is known as the "Heisenberg picture".

To sum up, the time evolution of a state vector following Schrödinger picture is given by:

$$\Psi(t,q)=\Psi(0,q)e^{-\frac{\mathrm{i}t}{\hbar}H} \tag{11.2.389}$$

or written more generally:

$$\Psi(t,q)=\Psi(t_0,q)e^{-\frac{\mathrm{i}(t-t_0)}{\hbar}H} \tag{11.2.390}$$

or in representative notation:

$$|\Psi(t,q)\rangle=e^{-\frac{\mathrm{i}(t-t_0)}{\hbar}H}|\Psi(t_0,q)\rangle \tag{11.2.391}$$

and that of an operator in the Heisenberg picture is:

$$X(t)=e^{-\frac{\mathrm{i}t}{\hbar}H}Xe^{\frac{\mathrm{i}t}{\hbar}H}=e^{\frac{\mathrm{i}t}{\hbar}H}Xe^{-\frac{\mathrm{i}t}{\hbar}H} \tag{11.2.392}$$

The Heisenberg picture is useful because we can see a closer connection to classical physics than with the Schrödinger picture. In classical physics, we describe the evolution of a system in terms of the time evolution of the observables, such as position or angular momentum, as dictated by the classical equations of motion. Classical mechanics does not include the concept of state vectors, as quantum mechanics does.

11.2.4.3.2 Conserved Quantities and Commutators

Let us recall the time-dependent Schrödinger equation obtained just earlier:

$$H\Psi=\mathrm{i}\hbar\frac{\mathrm{d}\Psi}{\mathrm{d}t} \tag{11.2.393}$$

We saw earlier that the expectation value of an observable physical quantity $\mathcal{O}$ is given by:

$$\langle\mathcal{O}\rangle=\int\limits_{-\infty}^{+\infty}\bar{\Psi}\hat{\mathcal{O}}\Psi\mathrm{d}x \tag{11.2.394}$$

where for recall $\hat{\mathbb{O}}$ is the operator representing the quantity (observable) $\mathcal{O}$. For $\mathcal{O}$ to be conserved, its value $\langle\mathcal{O}\rangle$ must not change in time, so the question is, when is $\langle\mathcal{O}\rangle$ independent of time? To answer that question, we assume that $\langle\hat{\mathcal{O}}\rangle$ is independent of time and compute $\mathrm{d}\langle\mathcal{O}\rangle/\mathrm{d}t$ as follows:

$$\frac{\mathrm{d}\langle\mathcal{O}\rangle}{\mathrm{d}t}=\frac{\mathrm{d}}{\mathrm{d}t}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\hat{\mathcal{O}}\Psi\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\frac{\mathrm{d}\bar{\Psi}}{\mathrm{d}t}\hat{\mathcal{O}}\Psi\mathrm{d}x+\int\limits_{-\infty}^{+\infty}\bar{\Psi}\hat{\mathcal{O}}\frac{\mathrm{d}\Psi}{\mathrm{d}t}\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\left(\frac{\mathrm{d}\bar{\Psi}}{\mathrm{d}t}\hat{\mathcal{O}}\Psi+\bar{\Psi}\hat{\mathcal{O}}\frac{\mathrm{d}\Psi}{\mathrm{d}t}\right)\mathrm{d}x \tag{11.2.395}$$

The complex conjugate Schrödinger equation is:

$$\overline{(H\Psi)}=-\mathrm{i}\hbar\frac{\mathrm{d}\bar{\Psi}}{\mathrm{d}t} \tag{11.2.396}$$

Using the fact that H is real or hermitian, this can be written (in the case where the Hamiltonian is a matrix we use here the property $(AB)^T=B^TA^T$ proved in the section of Linear Algebra page 1951):

$$\bar{\Psi}H=\overline{(H\Psi)}=-\mathrm{i}\hbar\frac{\mathrm{d}\bar{\Psi}}{\mathrm{d}t} \tag{11.2.397}$$

Therefore combining the two previous time-dependent Schrödinger equation into the previous integral we get:

$$\begin{aligned}\frac{\mathrm{d}\langle\mathcal{O}\rangle}{\mathrm{d}t}&=\int\limits_{-\infty}^{+\infty}\left(\frac{\mathrm{d}\bar{\Psi}}{\mathrm{d}t}\hat{\mathcal{O}}\Psi+\bar{\Psi}\hat{\mathcal{O}}\frac{\mathrm{d}\Psi}{\mathrm{d}t}\right)\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\left(-\frac{1}{\mathrm{i}\hbar}\bar{\Psi}H\hat{\mathcal{O}}\Psi+\bar{\Psi}\hat{\mathcal{O}}\frac{1}{\mathrm{i}\hbar}H\Psi\right)\mathrm{d}x\\&=\frac{\mathrm{i}}{\hbar}\int\limits_{-\infty}^{+\infty}\left(\bar{\Psi}H\hat{\mathcal{O}}\Psi-\bar{\Psi}\hat{\mathcal{O}}H\Psi\right)\mathrm{d}x=\frac{\mathrm{i}}{\hbar}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\left(H\hat{\mathcal{O}}-\hat{\mathcal{O}}H\right)\Psi\mathrm{d}x\end{aligned} \tag{11.2.398}$$

So if the observable $\mathcal{O}$ is conserved then we must have:

$$\frac{\mathrm{d}\langle\mathcal{O}\rangle}{\mathrm{d}t}=\frac{\mathrm{i}}{\hbar}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\left(H\hat{\mathcal{O}}-\hat{\mathcal{O}}H\right)\Psi\mathrm{d}x=0 \tag{11.2.399}$$

That is:

$$H\hat{\mathcal{O}}-\hat{\mathcal{O}}H=0 \tag{11.2.400}$$

Hence a conserved quantity in quantum mechanics can be defined as one for which the probabilities of measuring the various eigenvalues for that quantity are independent of time in all states. Mathematically conserved quantities correspond to Hermitian operators $\hat{\mathcal{O}}$ satisfying:

$$\boxed{[H,\hat{\mathcal{O}}]=0} \tag{11.2.401}$$

This is a very important result for our study of Wave Quantum Physics and also for the next section of Relativistic Quantum Physics!

11.2.4.3.3 Schrödinger picture by separation of variables

Let us also see an interesting mathematical manipulation and somewhat similar to the previous one of Schrödinger's equation of evolution. This manipulation will allow us to see that the separation of variables works very well with the equation of evolution and that it will allow us to fall back on a result obtained previously (it is always pedagogically to see several approaches).

We have therefore in a particular case:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=\left(E_p-\frac{\hbar^2}{2m}\Delta\right)\Psi \tag{11.2.402}$$

Rewritten in traditional form (according to the literature) and in one dimension, for a constant potential in time, this relation is then written:

$$-\frac{\hbar}{\mathrm{i}}\frac{\partial\Psi(x,t)}{\partial t}=-\frac{\hbar}{2m}\frac{\partial^2\Psi(x,t)}{\partial^2 x}+U(x)\Psi(x,t) \qquad (11.2.403)$$

Let us suppose now that the wave function can separate into two functions of which it is the product such that:

$$\Psi(x,t)=f(t)\Psi(x) \qquad (11.2.404)$$

We would then have:

$$\frac{\partial\Psi(x,t)}{\partial t}=\frac{\partial f(t)}{\partial t}\Psi(x) \qquad \text{and} \qquad \frac{\partial^2\Psi(x,t)}{\partial x^2}=f(t)\frac{\partial^2\Psi(x)}{\partial x^2} \qquad (11.2.405)$$

What injected into the one-dimensional evolution equation yields:

$$-\frac{\hbar}{\mathrm{i}}\frac{\partial f(t)}{\partial t}\Psi(x)=-\frac{\hbar}{2m}\frac{\partial^2\Psi(x)}{\partial^2 x}f(t)+U(x)\Psi(x)f(t) \qquad (11.2.406)$$

Which gives after simplification:

$$-\frac{\hbar}{\mathrm{i}}\frac{1}{f(t)}\frac{\partial f(t)}{\partial t}=-\frac{\hbar^2}{2m}\frac{1}{\Psi(x)}\frac{\partial^2\Psi(x)}{\partial^2 x}+U(x) \qquad (11.2.407)$$

The left term depends only on t, the right one on x. Since they are equal, they are necessarily also equal to a constant which has the dimension of an energy ($U(x)$ is a potential energy for recall).

So for the left term:

$$-\frac{\hbar}{\mathrm{i}}\frac{1}{f(t)}\frac{\partial f(t)}{\partial t}=H\Rightarrow \ln(f(t))=\frac{\mathrm{i}Ht}{\hbar}+c^{te} \qquad (11.2.408)$$

then:

$$f(t)=e^{c^{te}}e^{-\mathrm{i}\frac{Ht}{\hbar}}=Ae^{-\mathrm{i}\frac{Ht}{\hbar}} \qquad (11.2.409)$$

And for the right term:

$$-\frac{\hbar^2}{2m}\frac{1}{\Psi(x)}\frac{\partial^2\Psi(x)}{\partial^2 x}+U(x) \qquad (11.2.410)$$

Which can be written:

$$-\frac{\hbar^2}{2m}\frac{\partial^2\Psi(x)}{\partial^2 x}+U(x)\Psi(x)=H\Psi(x) \qquad (11.2.411)$$

After factorization:

$$\frac{\partial^2\Psi(x)}{\partial^2 x}+\frac{2m}{\hbar^2}[H-U(x)]\Psi(x)=0 \qquad (11.2.412)$$

Either with the notations of this textbook (after having rearranged a bit):

$$\left(E_p-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial^2 x}\right)\Psi=E_{\text{tot}}\Psi \qquad (11.2.413)$$

we thus fall back on the classical one-dimensional Schrödinger equation which is not bad at all as result!

Now, since we have put:

$$\Psi(x,t)=f(x)\Psi(x) \tag{11.2.414}$$

then we have finally:

$$\Psi(x,t)=Ae^{-\mathrm{i}\frac{Ht}{\hbar}}\Psi(x) \tag{11.2.415}$$

Which we can write under the notations of the preceding paragraphs:

$$\Psi(t,q)=\Psi(0,q)e^{-\mathrm{i}\frac{Ht}{\hbar}} \tag{11.2.416}$$

We find also this last relation in several different forms in the literature of which few samples:

$$\begin{gathered}\Psi(x,t)=\Psi(x)e^{-\mathrm{i}\frac{Ht}{\hbar}}\\ \Psi(x,t)=\varphi(x)e^{-\mathrm{i}\frac{Ht}{\hbar}}\\ \Psi(x,t)=\varphi(x)e^{-\mathrm{i}\frac{Et}{\hbar}}\\ |\Psi(x,t)\rangle=e^{-\mathrm{i}\frac{Ht}{\hbar}}|\Psi(x,t_0)\rangle\\ |\Psi(x,t-t_0)\rangle=\Psi(x,t_0)e^{-\mathrm{i}\frac{H(t-t_0)}{\hbar}}\end{gathered} \tag{11.2.417}$$

11.2.4.3.4 Linear combination of eigen-states (quantum superposition)

We must notice before we move on to another subject something very important that we had just mentioned in the second postulate!

Indeed, any equation of the following form seen previously:

$$\Psi(x)e^{-\mathrm{i}\frac{Ht}{\hbar}} \tag{11.2.418}$$

Is therefore a solution of Schrödinger's evolutionary equation and as in quantum systems the Hamiltonian can take (or be associated with) several discrete eigenvalues traditionally denoted by E_n, we then have, as mentioned at the beginning of this section, by the principle of linear combination of differential equations (see section Differential and Integral Calculus page 1605) the following more general solution:

$$\Psi(x,t)=\sum_{n=1}^{+\infty}\Psi_n(x)e^{-\mathrm{i}\frac{E_nt}{\hbar}} \tag{11.2.419}$$

of which we shall have several practical examples (of the discretization of the states of energy and that these are in infinite number) in this section and in that of Quantum Chemistry.

If we write the normalization constant of $\Psi_n(x)$ of the previous relation, then we have:

$$\Psi(x,t)=\sum_{n=1}^{+\infty}A_n\Psi_n(x)e^{-\mathrm{i}\frac{E_nt}{\hbar}} \tag{11.2.420}$$

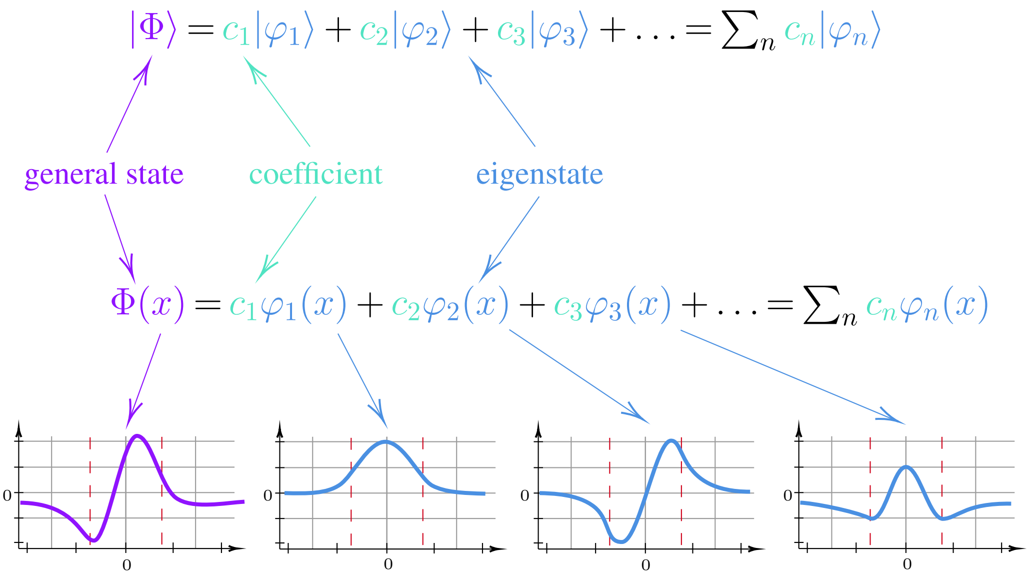
This last relation would be written in the following traditional ket-bra form:

$$\boxed{|\,\Psi\rangle=\sum_{n=1}^{+\infty}A_n\Psi_n(x)e^{-\mathrm{i}\frac{E_nt}{\hbar}}=\sum_{n=1}^{+\infty}c_n\,|\,\psi_n\rangle} \tag{11.2.421}$$

where the constant coefficient c_n is obviously assimilated to A_n (admit that it notation is much simpler isn't it?). We can also found it with the phi notation instead than the psi notation in the literature:

$$|\,\Phi\rangle=\sum_{n=1}^{+\infty}c_n\,|\,\varphi_n\rangle \tag{11.2.422}$$

We then say that the state $|\Psi\rangle$ (or $|\,\Phi\rangle$) is a linear combination of elementary (eigen-)states $|\psi\rangle$ (or $|\,\varphi_n\rangle$). Therefore $|\Psi\rangle$ $|\Psi\rangle$ (or $|\,\Phi\rangle$) also represents a wave particle as being simultaneously in several different sub-states (i.e. eigenstates) $|\psi\rangle$ (or $|\,\varphi_n\rangle$).



$|\Phi\rangle=c_1|\varphi_1\rangle+c_2|\varphi_2\rangle+c_3|\varphi_3\rangle+\ldots=\sum_n c_n|\varphi_n\rangle$
general state
coefficient
eigenstate
$\Phi(x)=c_1\varphi_1(x)+c_2\varphi_2(x)+c_3\varphi_3(x)+\ldots=\sum_n c_n\varphi_n(x)$

Figure 11.45: **Quantum state as a superposition of eigenstates**

✍**Example:**

Given $|\varphi\rangle$ and $|\chi\rangle$ that are vectors of $\mathcal{H}$ representing physical states, the unitary vector of $\mathcal{H}$:

$$|\psi\rangle=\frac{\lambda|\varphi\rangle+\mu|\chi\rangle}{||\lambda|\varphi\rangle+\mu|\chi\rangle||} \tag{11.2.423}$$

where $\lambda,\mu\in\mathbb{C}$, also represent a physical state.

It is interesting to notice that each solution:

$$A_n\Psi_n(x)e^{-\mathrm{i}\frac{E_nt}{\hbar}} \tag{11.2.424}$$

describes a "steady state" or "stationnary state". Let us see (at last!) rigorously what it is.

Indeed, we have:

$$\left|A_n\Psi_n(x)e^{-\mathrm{i}\frac{E_n t}{\hbar}}\right|^2 = |\ A_n\Psi_n(x)\ |^2 \left|e^{-\mathrm{i}\frac{E_n t}{\hbar}}\right|^2 = |\ A_n\Psi_n(x)\ |^2 \quad (11.2.425)$$

which is therefore independent of the time from which the origin of the name "stationary state" (we promised to define its origin at the beginning of section... so that is done!).

The functions being normalized we therefore have:

$$\int |\ \Psi\ |^2\,\mathrm{d}x = \int \bar{\Psi}\Psi\mathrm{d}x = \int \left(\sum_k \bar{A}_k\bar{\Psi}_k\right)\left(\sum_n A_n\Psi_n\right)\mathrm{d}x = \sum_k\sum_n \bar{A}_k A_n \int \bar{\Psi}_k\Psi_n\mathrm{d}x \quad (11.2.426)$$

The calculations above have showed us (we had proved it in two different ways) that the eigenfunctions have the following properties:

$$\int \bar{\Psi}_k\Psi_n\mathrm{d}x = 1 \quad (11.2.427)$$

When $k = n$ and:

$$\int \bar{\Psi}_k\Psi_n\mathrm{d}x = 0 \quad (11.2.428)$$

when $k \neq n$. That is to say with a more general notation:

$$\int \bar{\Psi}_k\Psi_n\mathrm{d}x = \delta_{ij} \quad (11.2.429)$$

It is this property that has led us in the third postulate to speak of "orthogonal basis of the stationary eigenfunctions".

Let us continue our calculation which can be written using the Kronecker symbol (see section Tensor Calculus page 2044):

$$\int |\ \Psi\ |^2\,\mathrm{d}x = \sum_k\sum_n \bar{A}_k A_n \int \bar{\Psi}_k\Psi_n\mathrm{d}x = \sum_k\sum_n \bar{A}_k A_n\delta_{kn} = \sum_k \bar{A}_k A_k = \sum_k |\ A_k\ |^2 = 1 \quad (11.2.430)$$

We can then interpret the term $|A_k|^2$ as the weight of the eigenfunction Ψ_k in the quantum state k, the probability of actually being in the eigenstate Ψ_k is then equal to $|A_k|^2$ the normalization then imposes:

$$\sum_k |\ A_k\ |^2 = 1 \quad (11.2.431)$$

We must therefore remember that any quantum state can always (as far as we know) be interpreted as a linear combination of eigenstates. The coefficient A_k of an eigenfunction/eigenstate Ψ_k is then associated with a probability $|A_k|^2$.

It is this mathematical result, very important, which is at the origin of the paradox of "Schrödinger's cat" (among others ...) and of many debates.

To close this small subject, let us notice one thing:

If the coefficients A_n are not already normalized, then the physicists denote their normalization as follows:

$$|A_n|^2 = \frac{|A_n|^2}{\sum\limits_n |A_n|^2} \tag{11.2.432}$$

because very often they use the same notation for the normalized coefficient and the non normalized one in their developments ...

The writing of the last relation is easily justified because let us recall that we must have:

$$\sum_n |A_n|^2 = 1 \tag{11.2.433}$$

and we have indeed after rearranging:

$$|A_n|^2 = \frac{|A_n|^2}{\sum\limits_n |A_n|^2} \Rightarrow \sum_n |A_n|^2 = \frac{|A_n|^2}{|A_n|^2} = 1 \tag{11.2.434}$$

Let us notice that with the traditional ket-bra notation, the relation:

$$|A_n|^2 = \frac{|A_n|^2}{\sum\limits_n |A_n|^2} \tag{11.2.435}$$

is often written in some specialized textbooks:

$$p(x_n) = \frac{|c_n|^2}{\sum\limits_n |c_n|^2} \tag{11.2.436}$$

which therefore always gives the probability of finding the state n at the position x.

With these definitions it is easy to describe the process of collapse. For any observable, the wave function is initially some linear combination of the eigenbasis $\{|\phi_i\rangle\}$ of that observable. When an external agency (an observer, experimenter) measures the observable associated with the eigenbasis $\{|\phi_i\rangle\}$, the wave function collapses from the full $|\psi\rangle$ to just one of the basis eigenstates, $|\phi_i\rangle$, that is:

$$|\psi\rangle \rightarrow |\phi_i\rangle\,.$$

The probability of collapsing to a given eigenstate $|\phi_k\rangle$ is the Born probability, $P_k = |c_k|^2$. Immediately post-measurement, other elements of the wave function vector, $c_{i\neq k}$, have "collapsed" to zero, and $|c_i|^2 = 1$.

More generally, collapse is defined for an operator $\hat{Q}$ with eigenbasis $\{|\phi_i\rangle\}$. If the system is in state $|\psi\rangle$, and $\hat{Q}$ is measured, the probability of collapsing the system to eigenstate $|\phi_i\rangle$ and measuring the eigenvalue q_i of $|\phi_i\rangle$ with respect to $\hat{Q}$ would be $|\langle\psi\,|\,\phi_i\rangle|^2$. Note that this is not the probability that the particle is in state $|\phi_i\rangle$; it is in state $|\psi\rangle$ until cast to an eigenstate of $\hat{Q}$!

11.2.4.3.5 Schrödinger continuity equation

Let us consider now the important example of the equation of evolution for a free particle, that is to say with $E_p=0$. Therefore we have:

$$-\frac{\hbar}{\mathrm{i}}\frac{\partial\Psi}{\partial t}+\frac{\hbar^2}{2m}\Delta\Psi=0 \tag{11.2.437}$$

The probability of finding the particle in a volume V is, as we have seen, given by:

$$\int_V \rho(\vec{r},t)\mathrm{d}\vec{r}=\int_V \mid\Psi(\vec{r},t)\mid^2\mathrm{d}\vec{r} \tag{11.2.438}$$

Hence:

$$\frac{\partial}{\partial t}\int_V \rho(\vec{r},t)\mathrm{d}\vec{r}=\int_V\left(\bar{\Psi}(\vec{r},t)\frac{\partial\Psi(\vec{r},t)}{\partial t}+\frac{\partial\bar{\Psi}(\vec{r},t)}{\partial t}\Psi(\vec{r},t)\right)\mathrm{d}\vec{r} \tag{11.2.439}$$

Taking into account the equation of evolution of the free particle, the second term of equality is written:

$$\frac{\partial}{\partial t}\int_V \rho(\vec{r},t)\mathrm{d}\vec{r}=\frac{\mathrm{i}\hbar^2}{2m}\int_V\left(\bar{\Psi}\vec{\nabla}^2\Psi-\vec{\nabla}^2\bar{\Psi}\Psi\right)\mathrm{d}\vec{r}=-\int_V\vec{\nabla}\circ\vec{j}\mathrm{d}\vec{r} \tag{11.2.440}$$

Where we have put:

$$\vec{j}=\frac{\hbar}{2m\mathrm{i}}\left(\bar{\Psi}(\vec{\nabla}\cdot\Psi)-(\vec{\nabla}\cdot\bar{\Psi})\Psi\right) \tag{11.2.441}$$

According to the Ostrogradsky theorem (see section Vector Calculus page 1882), it therefore comes:

$$\frac{\partial}{\partial t}\int_V \rho(\vec{r},t)\mathrm{d}\vec{r}=-\int_V\vec{j}\circ\mathrm{d}\vec{S} \tag{11.2.442}$$

where the integral of the right is carried out on the surface S which limits the volume V. The preceding relation therefore expresses indeed that the variation per unit of time of the probability of finding the particle in V is equal to the flux passing through the surface S and the vector $\vec{j}$ can be interpreted as a probability current density which satisfies the continuity equation as we have determined it in the section of Thermodynamics:

$$\frac{\partial}{\partial t}\int_V \rho(\vec{r},t)\mathrm{d}\vec{r}=-\int_V\vec{\nabla}\circ\vec{j}\mathrm{d}\vec{r}\Leftrightarrow\int_V\left[\frac{\partial}{\partial t}\rho(\vec{r},t)\right]\mathrm{d}\vec{r}=\int_V\left[-\vec{\nabla}\circ\vec{j}\right]\mathrm{d}\vec{r} \tag{11.2.443}$$

Hence:

$$\frac{\partial\rho}{\partial t}+\vec{\nabla}\circ\vec{j}=0 \tag{11.2.444}$$

In Quantum physics, it seems therefore that there is conservation of the particles flow: there is no creation, neither destruction of particle, but in the Nature (experimental observations) we observe such phenomenons of destruction and creation (but in fact the particle must be in a non-zero potential field)... In other words it means that a particle can not appear or disappear in a given volume V, there must be a particle flow in the walls of V for particles entering or leaving V.

That latter relation is more often written:

$$\boxed{\frac{\partial|\Psi|^2}{\partial t}+\vec{\nabla}\circ\vec{j}=0} \tag{11.2.445}$$

Intuitively, the above quantities indicate this represents the flow of probability. The chance of finding the particle at some position r and time t flows like a fluid; hence the term probability current, a vector field. The particle itself does not flow deterministically in this vector field.

11.2.4.4 Implications and Applications

The different definitions and tools that have been seen before, sometimes very abstract, will allow us to study some fundamental cases that lead to quite splendid results.

In a first step, we will see how to treat the case of the free particle (unbound state) and what are the problems of this simple configuration.

Then we solve the Schrödinger equation with a spin-free particle in a potential well with rectilinear infinite walls and show that with the formalism of quantum physics we will find the same results as the Bohr model (even more generalized!).

After this, we will introduce the study of the harmonic oscillator by revisiting briefly the resolution of the Schrödinger equation of a free particle. This example constitutes a form of introduction to the theoretical study of quantum atomic systems. It is in this example that we will use all the power of functional linear operators. It will therefore be important not to read it in diagonal (if possible and if the reader is still motivated).

We will also have to study another famous phenomenon, the "tunnel effect"! Obviously, we decided to introduce a particular case so that the reader can see the reasoning that led to the discovery of this astonishing (but logical) phenomenon. Again, this example will support the validity of quantum theory and demonstrate the value of the decay constants of many nuclear isotopes!

With respect to relativistic cases, with or without spin, we refer the reader to the sections of Relativistic Quantum Physics, and as regards the simple atomic model, we refer it to the section on Quantum Chemistry.

Enjoy!

11.2.4.4.1 Free particles (zero potential)

Curiously, the resolution of the Schrödinger equation for a free particle (where the potential is zero) is the simple ... most complex case ... mathematically speaking because the integration bounds of normalization are infinite. Let us see this!

Let us recall first that we have proved in a simplified way in the section of Sequences and Series that the Fourier transform (page 1758) of a function f and its inverse were given by:

$$\mathcal{F}(\vec{k})=\frac{1}{(2\pi)^{3/2}}\iiint f(\vec{r})e^{-\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^3r \quad f(\vec{r})=\frac{1}{(2\pi)^{3/2}}\iiint F(\vec{k})e^{\mathrm{i}\vec{k}\circ\vec{r}}\mathrm{d}^3k \tag{11.2.446}$$

Either in a one-dimensional form:

$$\mathcal{F}(k)=\frac{1}{\sqrt{2\pi}}\int f(x)e^{-\mathrm{i}kx}\mathrm{d}x \qquad f(x)=\frac{1}{\sqrt{2\pi}}\int F(k)e^{\mathrm{i}kx}\mathrm{d}k \tag{11.2.447}$$

Let us now proceed to the change of variable which connects the wave number k to the linear momentum (relation introduced at the beginning of this section):

$$k=\frac{P}{\hbar} \tag{11.2.448}$$

Which gives us:

$$\mathcal{F}(k)=\frac{1}{\sqrt{2\pi}}\int f(x)e^{-\mathrm{i}\frac{P}{\hbar}x}\mathrm{d}x \qquad f(x)=\frac{1}{\sqrt{2\pi}}\int F(k)e^{\mathrm{i}\frac{P}{\hbar}x}\mathrm{d}p \tag{11.2.449}$$

Let us now return to the Schrödinger's equation of evolution:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=\left(E_p-\frac{\hbar^2}{2m}\Delta\right)\Psi \tag{11.2.450}$$

If the particle is free, there is no potential and at one dimension we then have:

$$\mathrm{i}\frac{\partial\Psi}{\partial t}=-\frac{\hbar}{2m}\frac{\partial^2}{\partial x^2}\Psi \tag{11.2.451}$$

This differential equation admits monochromatic plane wave solutions of the type (see section Electrodynamics page 4142):

$$\Psi(x,t)=A^{\mathrm{i}(kx-\omega t)} \tag{11.2.452}$$

with obviously the small nuance that we have to use the relation (otherwise it does not work by cons!):

$$\omega=\frac{\hbar k^2}{2m}=\frac{p^2}{2m\hbar} \tag{11.2.453}$$

without forgetting that (this will be useful afterwards):

$$E=\frac{\hbar p^2}{2m}=\frac{\hbar^2k^2}{2m} \tag{11.2.454}$$

The curve of the energy E as a function of the wave vector k is sometimes named a "dispersion curve" and it is a parabola (since k is squared) for a free particle!

Obviously, the probability density of this solution is equal to:

$$\langle\Psi\mid\Psi\rangle=\bar{\Psi}\Psi=A^{\mathrm{i}(kx-\omega t)}\bar{A}^{-\mathrm{i}(kx-\omega t)}=\mid A\mid^2 \tag{11.2.455}$$

but this can not correspond to reality because! Indeed, a monochromatic planar wave of constant norm will have to carry an infinite energy and this is not possible!

In fact the solution comes from the fact that the true solution uses the principle of superposition of all the monochromatic waves of all the frequencies such as:

$$\Psi(x,t)=\int\limits_{-\infty}^{+\infty}A(k)e^{\mathrm{i}(kx-\omega(k)t)}\mathrm{d}k \tag{11.2.456}$$

and we fall back here a relation very similar to an inverse Fourier transform (see section Sequences and Series page 1758). Such a superposition of plane waves is named "one-dimensional wave packet".

What we can rewrite:

$$\Psi(x,t)=\int\limits_{-\infty}^{+\infty}A(k)e^{\mathrm{i}kx}e^{-\mathrm{i}\frac{\hbar k^2}{2m}t}\mathrm{d}k=\int\limits_{-\infty}^{+\infty}A(p)e^{\mathrm{i}\frac{P}{\hbar}x}e^{-\mathrm{i}\frac{p^2}{2m\hbar}t}\mathrm{d}p=\int\limits_{-\infty}^{+\infty}A(p)e^{\mathrm{i}\frac{P}{\hbar}x}e^{-\mathrm{i}\frac{E}{\hbar}t}\mathrm{d}p \tag{11.2.457}$$

But, we see immediately that we will not be able to normalized following:

$$\int\limits_{-\infty}^{+\infty}\mid\Psi\mid^2\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\bar{\Psi}(x,t)\Psi(x,t)\mathrm{d}x=1 \tag{11.2.458}$$

Therefore there is no longer a general solution. It is necessary to give a carrier envelope to the waves imposing a possible normalization. This carrier envelope can be a Dirac or a Gaussian (see below this special case) or other functions of more or less complex distributions. Then physicists must use a property of the Fourier transforms which naturally reveal the true Heisenberg's uncertainties. Thus, the latter are a condition for the normalization of free particles using Fourier transforms.

To date, as already mentioned during our study of classical Heisenberg's uncertainties, we have no pedagogical and simple proof to propose on this last point. It will come in a near of far future.

On the other hand, we can take as a trivial solution the eigenmodes of the particle such that:

$$\Psi_x=e^{\pm\mathrm{i}(kx-\omega t)} \tag{11.2.459}$$

Indeed:

$$\begin{aligned}&\mathrm{i}\frac{\partial\Psi}{\partial t}=-\frac{\hbar}{2m}\frac{\partial^2}{\partial x^2}\Psi\Rightarrow\mathrm{i}\frac{\partial e^{\mathrm{i}(kx-\omega t)}}{\partial t}=-\frac{\hbar}{2m}\frac{\partial^2 e^{\mathrm{i}(kx-\omega t)}}{\partial x^2}\\&\Rightarrow-\mathrm{i}^2\omega e^{\mathrm{i}(kx-\omega t)}=-\frac{\hbar}{2m}\mathrm{i}^2k^2e^{\mathrm{i}(kx-\omega t)}\Rightarrow-\omega=-\frac{\hbar}{2m}k^2\\&\Rightarrow\omega=\frac{\hbar}{2m}k^2=\frac{p^2}{2m\hbar}\end{aligned} \tag{11.2.460}$$

This is what we will use as a relation for our study of the harmonic oscillator further below.

Before studying the particular case of the quasi-monochromatic wave packet, we will recall some results concerning the sum of two plane waves.

Let us start by summing two monochromatic plane waves of neighbouring frequencies:

$$\Psi_1(x,t)=Ae^{\mathrm{i}(k_1x-\omega_1t)} \qquad \text{and} \qquad \Psi_2(x,t)=Ae^{\mathrm{i}(k_2x-\omega_2t)} \tag{11.2.461}$$

with:

$$\omega_1=\omega_0-\Delta\omega \qquad \text{and} \qquad \omega_2=\omega_0-\Delta\omega \tag{11.2.462}$$

and:

$$k_1=k_0-\Delta k \qquad \text{and} \qquad k_2=k_0-\Delta k \tag{11.2.463}$$

Notice that we therefore impose:

$$\frac{\Delta\omega}{\omega_0}\ll 1 \qquad \text{and} \qquad \frac{\Delta k}{k_0}\ll 1 \tag{11.2.464}$$

The resultant wave is the expressed as:

$$\begin{aligned}\Psi(x,t)&=\Psi_1(x,t)+\Psi_2(x,t)=A\left(e^{\mathrm{i}(k_1x-\omega_1t)}+e^{\mathrm{i}(k_2x-\omega_2t)}\right)\\&=A(\cos(k_1x-\omega_1t)+\mathrm{i}\sin(k_1x-\omega_1t)+\cos(k_2x-\omega_2t)+\mathrm{i}\sin(k_2x-\omega_2t))\\&=A\begin{pmatrix}\cos((k_0-\Delta k)x-(\omega_0-\Delta\omega)t)+\mathrm{i}\sin((k_0-\Delta k)x-(\omega_0-\Delta\omega)t)+\\ \cos((k_0+\Delta k)x-(\omega_0+\Delta\omega)t)+\mathrm{i}\sin((k_0+\Delta k)x-(\omega_0+\Delta\omega)t)\end{pmatrix}\\&=A\begin{pmatrix}\cos((k_0-\Delta k)x-(\omega_0-\Delta\omega)t)+\cos((k_0+\Delta k)x-(\omega_0+\Delta\omega)t)+\\ \mathrm{i}\sin((k_0-\Delta k)x-(\omega_0-\Delta\omega)t)+\mathrm{i}\sin((k_0+\Delta k)x-(\omega_0+\Delta\omega)t)\end{pmatrix}\end{aligned} \tag{11.2.465}$$

Either by using the remarkable trigonometric relations (see section Trigonometry page 2519):

$$\begin{aligned}\Psi(x,t)&=A(2\cos(k_0x-\omega_0t)\cos(\Delta kx-\Delta\omega t)+2\mathrm{i}\sin(k_0x-\omega_0t)\cos(\Delta kx-\Delta\omega t))\\&=2A\cos(\Delta kx-\Delta\omega t)(\cos(k_0x-\omega_0t)+\mathrm{i}\sin(k_0x-\omega_0t))\\&=2A\cos(\Delta kx-\Delta\omega t)e^{\mathrm{i}(k_0x-\omega_0t)}=\Psi_0e^{\mathrm{i}(k_0x-\omega_0t)}\end{aligned} \tag{11.2.466}$$

which is a plane wave propagating along the positive x (see section Wave Mechanics page 3476) with the pulsation ω_0 and the mean wave vector k_0, and therefore at the phase velocity:

$$v_\varphi=\frac{\omega_0}{k_0}=\frac{\frac{\hbar k_0^2}{2m}}{k_0}=\frac{\hbar k_0}{2m}=\frac{\hbar\frac{\sqrt{E2m}}{\hbar}}{2m}=\frac{\sqrt{E2m}}{2m}=\sqrt{\frac{E}{2m}} \tag{11.2.467}$$

The cosine term is then interpreted as the slowly variable amplitude of this plane wave ("amplitude modulation" as we have seen in the section of Wave Mechanics).

Notice a rather important point !: The phase velocity is not consistent with the velocity we get by using the kinetic energy of a free particle. Indeed:

$$E_c=\frac{1}{2}mv^2\Leftrightarrow v=\sqrt{\frac{2E_c}{m}} \tag{11.2.468}$$

Therefore the phase velocity does not represent the velocity in the usual conventional sense but that of the wave travelling at the group velocity:

$$v_{\text{group}}=\frac{\Delta\omega}{\Delta k}\underset{\Delta\to 0}{=}\frac{\mathrm{d}\omega}{\mathrm{d}k}=\frac{\mathrm{d}}{\mathrm{d}k}\left(\frac{\hbar k^2}{2m}\right)=\frac{\hbar 2k}{2m}=\frac{\hbar k}{m}=\frac{\hbar\dfrac{\sqrt{E2m}}{\hbar}}{m}=\sqrt{\frac{2E}{m}} \tag{11.2.469}$$

where we thus fall back on the classic formulation of the velocity from kinetic energy (not bad...)!

We can easily represent all this with Maple™ 4.00b:

```
>restart:with(plots):
>lambda[0]:=1; T[0]:=1; k[0]:=2*Pi/lambda[0]; w[0]:=2*Pi/T[0];
>delta_k:=k[0]/8:  k[1]:=k[0]-delta_k; k[2]:=k[0]+delta_k;
delta_w:=w[0]/10:  w[1]:=w[0]-delta_w; w[2]:=w[0]+delta_w;
>P1:=animate(cos(k[1]*x-w[1]*t)+cos(k[2]*x-w[2]*t), x=0..1*2*Pi/delta_k,
t=0..2*Pi/delta_w, numpoints=200, frames=15, color=red):
>P2:=animate(2*cos(-1/2*k[1]*x+1/2*w[1]*t+1/2*k[2]*x-1/2*w[2]*t),
-2*cos(-1/2*k[1]*x+1/2*w[1]*t+1/2*k[2]*x-1/2*w[2]*t),
x=0..1*2*Pi/delta_k,
t=0..2*Pi/delta_w, numpoints=100, frames=15, color=blue):
>display(P1,P2);
```

Which gives:

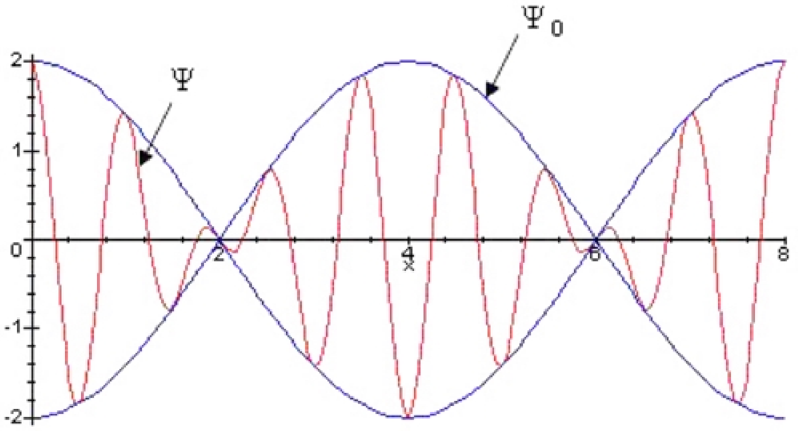

Figure 11.46: Representation of the concept of phase velocity and group velocity

Unlike the harmonic plane wave, this wave does not have a constant norm: its norm is zero in certain zones. On the other hand, it always extends over an infinite distance, and therefore has a infinite norm (the sum of the probability over all space). It therefore has no physical meaning (at least as far as we know).

The preceding study can be extended by summing an increasing number N of plane waves in the neighbourhood of ω_0 and k_0. Such a superposition leads to an increasingly localized function in certain areas of space (in particular near $x=0$, for example, for $t=0$), the distance between these zones increasing proportionally with N. At the limit $N\rightarrow+\infty$, then only the zone near $x=0$ remains, the others being rejected to infinity. The transition to this limit $N\rightarrow+\infty$ is done by replacing the discrete sum on plane waves by a continuous summation i.e. by an integral of the form:

$$\Psi(x,t)=\int\limits_{k_0-\delta k/2}^{k_0+\delta k/2}F(k)e^{\mathrm{i}(kx-\omega t)}\mathrm{d}k \tag{11.2.470}$$

with:

$$k\in\left[k_0-\frac{\delta k}{2},k_0+\frac{\delta k}{2}\right] \tag{11.2.471}$$

with therefore:

$$F(k)=A \qquad \text{and} \qquad \frac{\delta k}{k_0}\ll 1 \tag{11.2.472}$$

Such a packet is therefore named a "quasi-monochromatic wave packet".

This expression can be rewritten:

$$\Psi(x,t)=A\int\limits_{k_0-\delta k/2}^{k_0+\delta k/2}e^{\mathrm{i}(kx-\omega t)}\mathrm{d}k \tag{11.2.473}$$

It is important to understand that ω is a function of k given by the dispersion equation. We will compute this expression using the fact that $\delta k/k_0\ll 1$. This condition implies that $\delta\omega/\omega_0\ll 1$. It is possible to carry out a limited Taylor development in the neighbourhood of ω_0:

$$\omega=\omega_0+(k-k_0)\left(\frac{\partial\omega}{\partial k}\right)_{k=k_0}+\cdots=\omega_0+v_{\text{group}}(k-k_0) \tag{11.2.474}$$

Therefore:

$$kx-\omega t=(k-k_0+k_0)x-[\omega_0+v_{\text{group}}(k-k_0)]t=k_0x-\omega t+(x-v_{\text{group}}t)(k-k_0) \tag{11.2.475}$$

Let us put $y=k-k_0$:

$$\Psi(x,t)=Ae^{\mathrm{i}(k_0x-\omega_0t)}\int\limits_{-\delta k/2}^{+\delta k/2}e^{\mathrm{i}(x-v_{\text{group}}t)y}\mathrm{d}y \tag{11.2.476}$$

Let us calculate the integral:

$$\Psi(x,t)=Ae^{\mathrm{i}(k_0x-\omega_0t)}\int\limits_{-\delta k/2}^{+\delta k/2}e^{\mathrm{i}(x-v_{\text{group}}t)y}\mathrm{d}y=\frac{Ae^{\mathrm{i}(k_0x-\omega_0t)}}{\mathrm{i}(x-v_{\text{group}}t)}e^{\mathrm{i}\alpha y}\Bigg|_{-\delta k/2}^{+\delta k/2} \tag{11.2.477}$$

with:

$$\alpha = x - v_{\text{group}}t \tag{11.2.478}$$

Therefore:

$$\begin{aligned}
\Psi(x,t) &= \frac{A}{\mathrm{i}(x-v_{\text{group}}t)}\left(e^{\mathrm{i}\alpha\frac{\delta k}{2}} - e^{-\mathrm{i}\alpha\frac{\delta k}{2}}\right)e^{\mathrm{i}(k_0x-\omega_0t)}\\
&= \frac{A}{\mathrm{i}(x-v_{\text{group}}t)}\left(\cos\left(\alpha\frac{\delta k}{2}\right)+\mathrm{i}\sin\left(\alpha\frac{\delta k}{2}\right)-\cos\left(\alpha\frac{\delta k}{2}\right)+\mathrm{i}\sin\left(\alpha\frac{\delta k}{2}\right)\right)e^{\mathrm{i}(k_0x-\omega_0t)}\\
&= \frac{A}{\mathrm{i}(x-v_{\text{group}}t)}\left(\mathrm{i}\sin\left(\alpha\frac{\delta k}{2}\right)+\mathrm{i}\sin\left(\alpha\frac{\delta k}{2}\right)\right)e^{\mathrm{i}(k_0x-\omega_0t)}\\
&= 2A\frac{\sin\left((x-v_{\text{group}}t)\dfrac{\delta k}{2}\right)}{(x-v_{\text{group}}t)}e^{\mathrm{i}(k_0x-\omega_0t)} = 2A\frac{\delta k}{2}\frac{\sin\left((x-v_{\text{group}}t)\dfrac{\delta k}{2}\right)}{(x-v_{\text{group}}t)\dfrac{\delta k}{2}}e^{\mathrm{i}(k_0x-\omega_0t)}\\
&= A\delta k\frac{\sin\left((x-v_{\text{group}}t)\frac{\delta k}{2}\right)}{(x-v_{\text{group}}t)\frac{\delta k}{2}}e^{\mathrm{i}(k_0x-\omega_0t)} = A\delta k\,\mathrm{sinc}\left((x-v_{\text{group}}t)\frac{\delta k}{2}\right)e^{\mathrm{i}(k_0x-\omega_0t)}\\
&= \Psi_0e^{\mathrm{i}(k_0x-\omega_0t)}
\end{aligned} \tag{11.2.479}$$

The last term is again interpreted as a plane wave moving at the phase velocity:

$$v_\varphi = \frac{\omega_0}{k_0} \tag{11.2.480}$$

The amplitude of this plane wave is given by a sinus cardinal function. At $t=0$, this sinc function has important values only in the zone where:

$$\delta x = \frac{2\pi}{\delta k} \tag{11.2.481}$$

It is therefore a well-localized function. Consequently, Ψ is a summable square function. The calculation gives:

$$\int\limits_{-\infty}^{+\infty} |\,\Psi\,|^2\,\mathrm{d}x = |\,A\,|^2\,\delta k \tag{11.2.482}$$

The function can therefore be normalized by putting:

$$A = \frac{1}{\sqrt{\delta k}} \tag{11.2.483}$$

We have therefore succeeded in obtaining a function satisfying both the Schrödinger equation and the normalization condition, by using an infinite sum of harmonic waves. The example we have dealt with is only one particular case. Other types of wave packets can be obtained by taking other distributions for the amplitudes of the plane waves that make up the packet (we assumed here that they all had the same amplitude). Consequently, the group velocity is conventionally associated with the velocity of the particle of mass m and linear momentum p.

Thus, the wave packet moves globally at the group velocity, which is identified with the velocity given by Classical Mechanics.

Uncertainty relationships have already been introduced at the beginning of this section in two different ways. But in the example of the wave packet studied in the previous paragraph, we have seen that the function is located in a zone of range (half-height width):

$$\delta x=\frac{2\pi}{\delta k} \tag{11.2.484}$$

We therefore have the relation:

$$\delta x\cdot\delta k=2\pi \tag{11.2.485}$$

We fall back here on an expression of the uncertainty. The numerical coefficient could be slightly different according to the definition chosen for δx and δk, or the type of packet. In particular, it could be significantly larger in some cases. We thus have in fact an inequality of the type:

$$\delta x\cdot\delta k\geq 2\pi \tag{11.2.486}$$

In quantum physics, these inequalities are expressed as a function of the linear momentum p, connected to k as we have prove earlier by $p=\hbar k$. We therefore have:

$$\delta x\cdot\delta p_x\geq\hbar \tag{11.2.487}$$

Thus, the more precisely the linear momentum of a wave packet is defined (implicitly the wavelength), the less it has components and the more it is spread, which increases the uncertainty relative to its position and respectively the more its position is known, the less its wavelength will be precise.

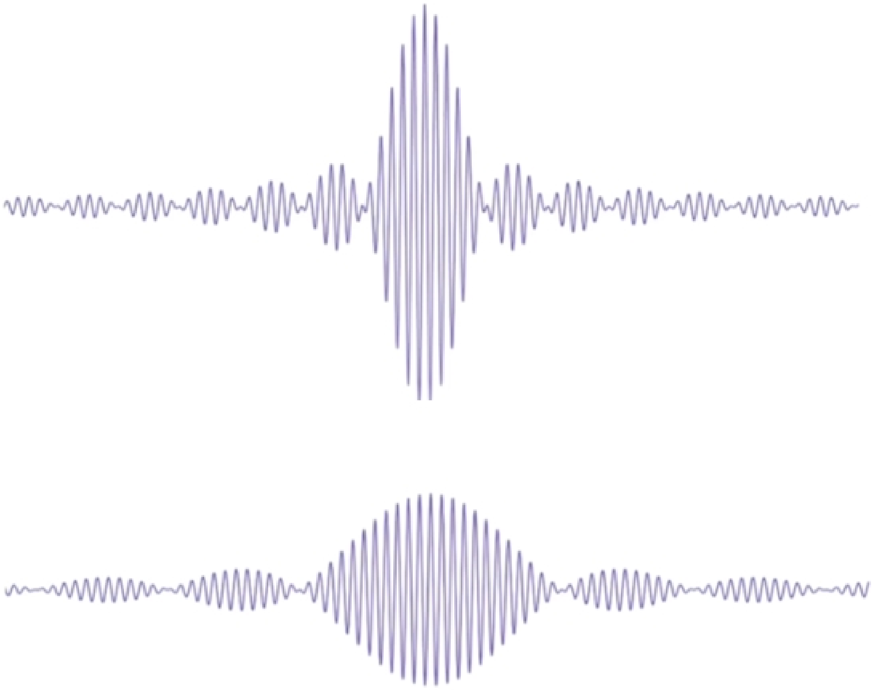

Figure 11.47: Spreading plane wave with decreasing δk from top top bottom

It is therefore not a question of uncertainties in the sense of measurement, and which would be limited by the measuring devices, but of an intrinsic fundamental property, linked to the quantum representation of a particle according to the proposed mathematical model. The model of the Bohr atom have therefore to be rejected for the energy levels which are close to this equality.

11.2.4.4.1.1 Gaussian Wavepacket

Now, a probability is a real number between 0 and 1. An outcome of a measurement which has a probability 0 is an impossible outcome, whereas an outcome which has a probability 1 is a certain outcome. According to what we have seen above, the probability of a measurement of x yielding a result between $-\infty$ and $+\infty$ is:

$$P_{x\in -\infty:+\infty}(t)=\int\limits_{-\infty}^{+\infty}|\Psi(x,t)|^2\mathrm{d}x \tag{11.2.488}$$

However, a measurement of x must yield a value between $-\infty$ and $+\infty$, since the particle has to be located somewhere. It follows that $P_{x\in -\infty:+\infty}=1$, or:

$$\int\limits_{-\infty}^{+\infty}|\Psi(x,t)|^2\mathrm{d}x=1 \tag{11.2.489}$$

which is generally known as the normalization condition for the wave function.

For example, suppose that we wish to normalize the wave function of a Gaussian wave packet, centered on $x=x_0$, and of characteristic width σ i.e.:

$$\Psi(x)=\Psi_0 e^{-(x-x_0)^2/\left(2\sigma^2\right)} \tag{11.2.490}$$

In order to determine the normalization constant Ψ_0, we simply substitute the corresponding relation to get:

$$|\Psi_0|^2\int\limits_{-\infty}^{+\infty}e^{-(x-x_0)^2/\left(2\sigma^2\right)}\mathrm{d}x=1 \tag{11.2.491}$$

Changing the variable of integration to $y=(x-x_0)/(\sqrt{2}\sigma)$, we get:

$$|\Psi_0|^2\sqrt{2}\sigma\int\limits_{-\infty}^{+\infty}e^{-y^2}\mathrm{d}y=1 \tag{11.2.492}$$

However (as proved in the section of Statistics at page 695):

$$\int\limits_{-\infty}^{+\infty}e^{-y^2}\mathrm{d}y=\sqrt{\pi} \tag{11.2.493}$$

which implies that:

$$|\Psi_0|^2 = \frac{1}{(2\pi\sigma^2)^{1/2}} \tag{11.2.494}$$

Hence, a general normalized Gaussian wavefunction takes the form:

$$\Psi(x) = \frac{e^{\mathrm{i}\varphi}}{(2\pi\sigma^2)^{1/4}} e^{-(x-x_0)^2/(2\sigma^2)} := A(x)e^{\mathrm{i}\varphi} \tag{11.2.495}$$

where φ is an arbitrary real phase-angle. The latter gauss wave-packet is often denoted:

$$\boxed{\Psi(x) = \frac{e^{\mathrm{i}k_0 x}}{(2\pi\sigma^2)^{1/4}} e^{-(x-x_0)^2/(2\sigma^2)} := A(x)e^{\mathrm{i}k_0 x}} \tag{11.2.496}$$

and still satisfies:

$$\int\limits_{-\infty}^{+\infty} |\Psi(x,t)|^2 \mathrm{d}x = 1 \tag{11.2.497}$$

It is straightforward that we have (we take $x_0 = 0$):

$$|\Psi|^2 = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{x^2}{2\sigma^2}} \tag{11.2.498}$$

$|\Psi|^2$ is the probability density of the particle position, x, described by a gaussian function with standard deviation σ.

Remark

In many textbooks authors plot the most simplest case of the above relation by taking $\sigma = 1, k_0 = 1$ and the imaginary part, that is:

$$\Im(\Psi(x)) = \frac{\sin(x)}{(2\pi)^{1/4}} e^{-x^2/2}$$

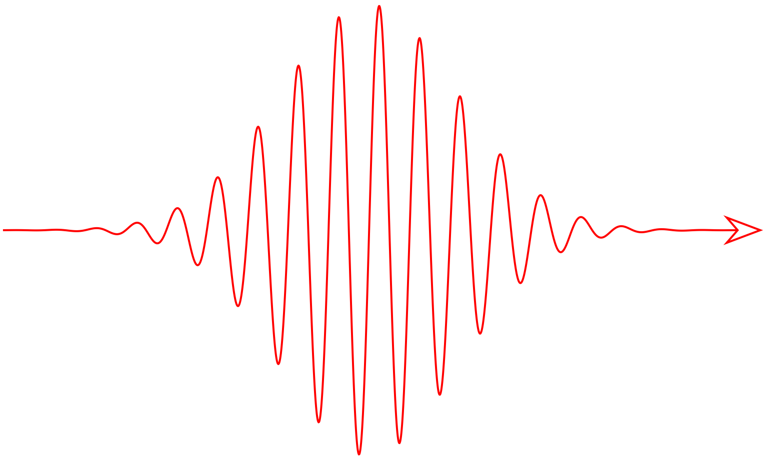

Figure 11.48: **Plot of the Gaussian wavepacket in 2D (projection of the 3D wavepacket on the real or imaginay plane)**

And the corresponding one in 3D (Gaussian-modulated complex exponential):

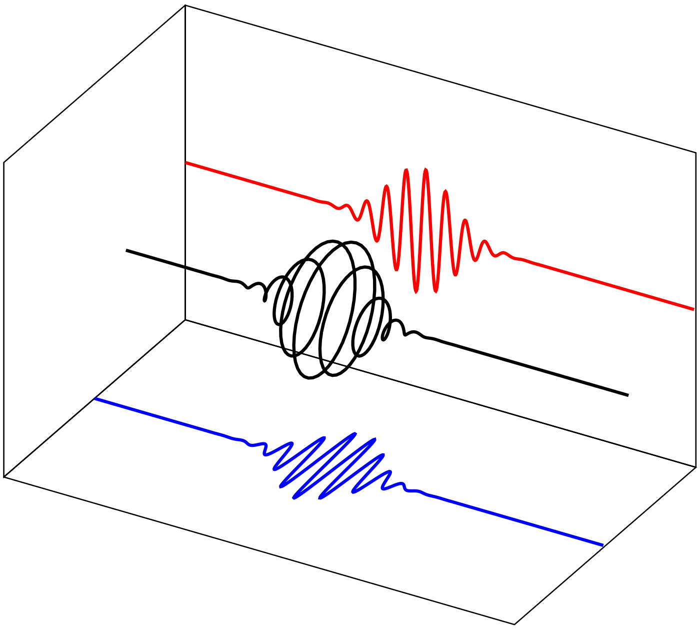

Figure 11.49: **Plot of the Gaussian wavepacket in 3D (author: (author: H. Zeljko)**

Now, it is important to demonstrate that if a wavefunction is initially normalized then it stays normalized as it evolves in time according to Schrödinger's equation. If this is not the case then the probability interpretation of the wavefunction is untenable, since it does not make sense for the probability that a measurement of x yields any possible outcome (which is, manifestly, unity) to change in time. Hence, we require that:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int\limits_{-\infty}^{+\infty}|\Psi(x,t)|^2\mathrm{d}x=0 \tag{11.2.499}$$

for wavefunctions satisfying Schrödinger's equation. The above relation gives:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\Psi\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\left(\frac{\partial\bar{\Psi}}{\partial t}\Psi+\bar{\Psi}\frac{\partial\Psi}{\partial t}\right)\mathrm{d}x=0 \tag{11.2.500}$$

Now, multiplying Schrödinger's equation by $\bar{\psi}/(\mathrm{i}\hbar)$, we get:

$$\bar{\Psi}\frac{\partial\Psi}{\partial t}=\frac{\mathrm{i}\hbar}{2m}\bar{\Psi}\frac{\partial^2\Psi}{\partial x^2}-\frac{\mathrm{i}}{\hbar}U|\Psi|^2 \tag{11.2.501}$$

The complex conjugate of this expression yields:

$$\Psi\frac{\partial\bar{\Psi}}{\partial t}=-\frac{\mathrm{i}\hbar}{2m}\Psi\frac{\partial^2\bar{\Psi}}{\partial x^2}+\frac{\mathrm{i}}{\hbar}U|\Psi|^2 \tag{11.2.502}$$

since $(\overline{AB})=\bar{A}\bar{B}$, $\bar{\bar{A}}=A$, and $\bar{\mathrm{i}}=-\mathrm{i}$. Summing the previous two equations, we get:

$$\frac{\partial\bar{\Psi}}{\partial t}\psi+\bar{\Psi}\frac{\partial\Psi}{\partial t}=\frac{\mathrm{i}\hbar}{2m}\left(\bar{\Psi}\frac{\partial^2\Psi}{\partial x^2}-\Psi\frac{\partial^2\bar{\Psi}}{\partial x^2}\right)=\frac{\mathrm{i}\hbar}{2m}\frac{\partial}{\partial x}\left(\bar{\Psi}\frac{\partial\Psi}{\partial x}-\Psi\frac{\partial\bar{\Psi}}{\partial x}\right) \tag{11.2.503}$$

The relation:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\Psi\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\left(\frac{\partial\bar{\Psi}}{\partial t}\Psi+\bar{\Psi}\frac{\partial\Psi}{\partial t}\right)\mathrm{d}x=0 \tag{11.2.504}$$

and:

$$\frac{\partial\bar{\Psi}}{\partial t}\Psi+\bar{\Psi}\frac{\partial\Psi}{\partial t}=\frac{\mathrm{i}\hbar}{2m}\left(\bar{\Psi}\frac{\partial^2\Psi}{\partial x^2}-\Psi\frac{\partial^2\bar{\Psi}}{\partial x^2}\right)=\frac{\mathrm{i}\hbar}{2m}\frac{\partial}{\partial x}\left(\bar{\Psi}\frac{\partial\Psi}{\partial x}-\Psi\frac{\partial\bar{\Psi}}{\partial x}\right) \tag{11.2.505}$$

can be combined to produce:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int\limits_{-\infty}^{+\infty}|\Psi|^2\mathrm{d}x=\frac{\mathrm{i}\hbar}{2m}\left[\bar{\Psi}\frac{\partial\Psi}{\partial x}-\Psi\frac{\partial\bar{\Psi}}{\partial x}\right]_{-\infty}^{+\infty}=0 \tag{11.2.506}$$

The above equation is satisfied provided:

$$|\Psi|\rightarrow 0 \quad \text{as} \quad |x|\rightarrow\pm\infty$$

However, this is a necessary condition for the integral on the left-hand side of:

$$\int\limits_{-\infty}^{+\infty}|\Psi(x,t)|^2\mathrm{d}x=1 \tag{11.2.507}$$

to converge. Hence, we conclude that all wavefunctions which are square-integrable have the property that if the normalization condition is satisfied at one instant in time then it is satisfied at all subsequent times.

In the following, all wavefunctions are assumed to be square-integrable and normalized, unless otherwise stated.

11.2.4.4.2 Infinite (rectangular) potential well

Let us take as a first example, very important for the Nuclear Physics section and for semiconductor specialists, the resolution in the classical form of the infinite potential well with straight walls, also named "infinite rectangular well" (this example is really very important, take your time to understand it and to master it at best) or "particle in a box problem".

This is the simplest example of a potential function $E_p(x)$, zero within the well and infinitely big on the walls, distant by a length L:

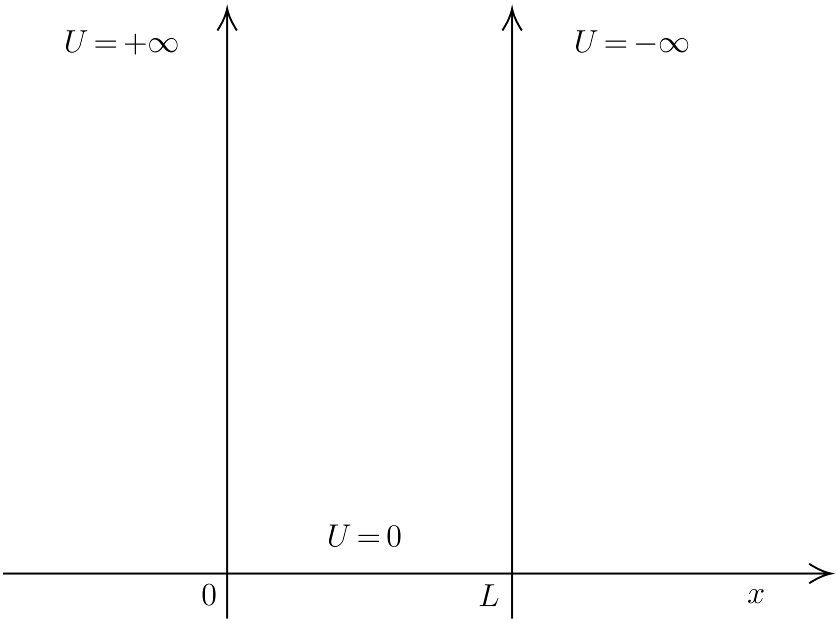

Figure 11.50: **Infinite potential well illustration**

> **Remark**
>
> When $U=+\infty$ we say sometimes that the walls are "perfectly reflective".

We assume a particle trapped in this well. It can not escape because the walls (i.e. the potential U) have an infinite height. But inside, it is free to move without interacting with the walls.

This configuration is reflected by the boundary conditions where the potential electrostatic energy is denoted U:

$$U=0 \quad \text{if} \quad 0\leq x\leq L \tag{11.2.508}$$

and:

$$U=+\infty \quad \text{if} \quad x<0 \quad \text{or} \quad x>L \tag{11.2.509}$$

There exist at least two ways to approach this problem. Let us consider the two types of treatments because the first one allows to have a simplistic approach whereas the second one allows to have a more general approach which will be useful to us later on in our study of the tunnel effect:

11.2.4.4.3 First approach

The (classical) Schrödinger equation:

$$\frac{\partial^2\Psi}{\partial x^2}+\frac{\partial^2\Psi}{\partial y^2}+\frac{\partial^2\Psi}{\partial z^2}+\frac{8\pi^2 m}{h^2}\cdot\left(E_{\text{tot}}-E_p\right)\Psi=0 \quad (11.2.510)$$

has therefore a simple particular solution respecting the initial conditions in one dimension, of the type:

$$\Psi=\Psi_0\sin(kx) \quad (11.2.511)$$

whose second derivative is:

$$\frac{\partial^2\Psi}{\partial x^2}=-k^2\Psi \quad (11.2.512)$$

Introduced in the Schrödinger equation, we get, after some elementary algebra simplifications:

$$k^2=\frac{8\pi^2 m}{h^2}\left(E_{\text{tot}}-E_p\right)=\frac{2m}{\hbar^2}\left(E_{\text{tot}}-E_p\right) \quad (11.2.513)$$

So finally the solution is written:

$$\Psi=\Psi_0\sin\left(\frac{\sqrt{2m\left(E_{\text{tot}}-E_p\right)}}{\hbar}\cdot x\right) \quad (11.2.514)$$

to which the boundary conditions must be applied (the cosine solution is in every aspect similar).

If we want to be able, later, to make a parallel with one or more electron(s) trapped in the potential well of an atom (which is him not rectangular and not infinite), we are taken to the following considerations:

The stability of the atoms suggests the existence of an electronic standing wave in the well. In addition, experimental observation shows that only certain energy levels appear to be allowed in the latter.

If we make a similarity with the vibrating strings, the wave function of the electron must be such that:

1. For $x=0$ and $L=0$ there must be a vibration node, i.e. $\Psi(0)=\Psi(L)=0$
2. The wave function Ψ must have an integer value of half wave length along the length L
3. In the box $U=0$ therefore $E_p=0$
4. If at the ends ($x=0$ and $x=L$) $\Psi=0$ then the argument of the sine equals $n\pi\;\forall n\in\mathbb{N}^*$

Therefore we must have:

$$x=L\Rightarrow\sqrt{\frac{8\pi^2 m}{h^2}\left(E_{\text{tot}}-E_p\right)}\cdot L=n\pi \quad (11.2.515)$$

hence since the potential energy is zero in the well:

$$\boxed{E_n=\frac{\pi^2h^2}{2mL^2\pi^24}n^2=\frac{\pi^2\hbar^2}{2mL^2}n^2} \quad (11.2.516)$$

The total energy of the particle thus ranges over a discrete sequence of values, the only ones permitted. The value of L is determined using the Bohr or Sommerfeld model as depending on the situations (see section Corpuscular Quantum Physics page 4626 and 4648).

The total energy of the above particle is composed of the eigenvalues of the energy in the potential well.

Thus the Schrödinger's equation allows us to ignore Bohr's third postulate in the sense that it directly explains the notion of quantification of the levels by integer (discrete) values of the boundary conditions of a potential well considered as perfect.

The corresponding wave functions in the well where $U=0\equiv E_p=0$ are therefore:

$$\Psi=\Psi_0\sin\left[\sqrt{\frac{8\pi^2m}{h^2}E_{\text{tot}}}\cdot x\right]=\Psi_0\sin\left[\sqrt{\frac{8\pi^2m}{h^2}\frac{h^2}{8mL^2}n^2}\cdot x\right] \quad (11.2.517)$$

Either after simplification:

$$\Psi_n=\Psi_0\sin\left(\frac{\pi n}{L}x\right) \quad (11.2.518)$$

This is the expression of one of the solutions of the differential equation for the ideal rectangular potential well. Thus, there exists a discrete sequence of solutions wave functions. These are the obviously the eigenfunctions of the particle.

The constant Ψ_0 in this expression is determined by the de Broglie normalization condition (about which we spoke at the beginning of this section), that is to say by the condition:

$$\int_0^L|\Psi_n|^2\,\mathrm{d}x=\Psi_0^2\int_0^L\sin^2\left(\frac{n\pi x}{L}\right)\mathrm{d}x=1 \quad (11.2.519)$$

We then find (normally integration calculus that should be obvious to the reader but on request we can as always give the details):

$$\Psi_0=\sqrt{\frac{2}{L}} \quad (11.2.520)$$

and the final expression of the wave function associated with the eigenvalue E_n thus reads:

$$\boxed{\Psi_n(x)=\sqrt{\frac{2}{L}}\sin\left(\frac{n\pi x}{L}\right)} \quad (11.2.521)$$

Some physicists typically write this in a complex form by obviously considering only the real part of the following expression (we use the "Euler formula" seen when introducing the complex numbers in the section Numbers):

$$\Psi_n(x)=\sqrt{\frac{2}{L}}e^{ikx} \quad (11.2.522)$$

with:

$$k_x = \frac{n\pi}{L_x} \quad (11.2.523)$$

We then say that we have "quantification conditions" on k imposed by the boundary conditions.

This notation is sometimes useful and we will use it when studying the tunnel effect in the section of Nuclear Physics.

We can deduce from the expression obtained the main properties of the wave functions describing the stationary states of the particle in a box:

P1. The figure below shows the Ψ_n (left) and the probability density functions $|\Psi_n|^2$ (right) for the first energy levels E_n:

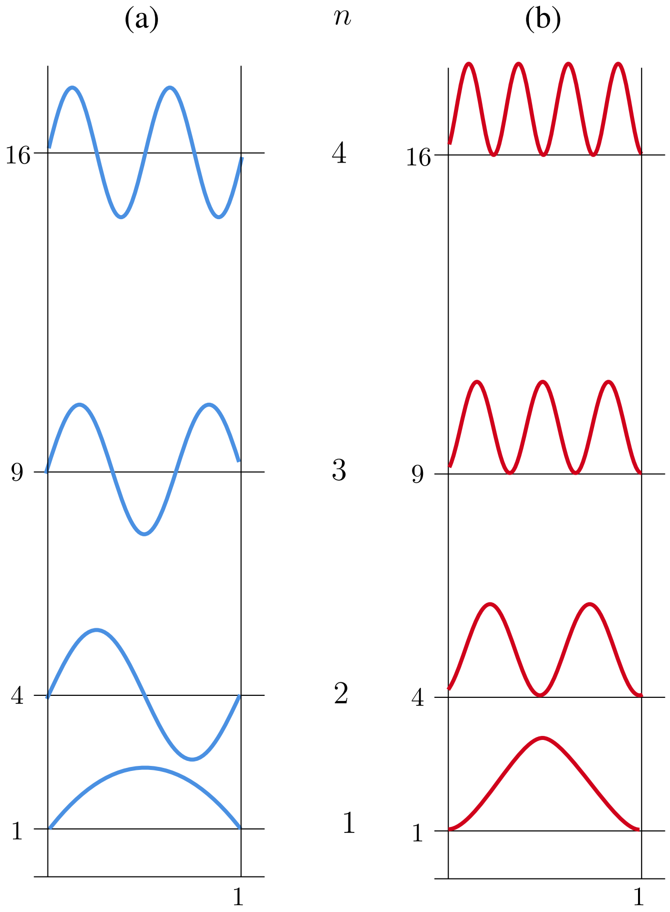

Figure 11.51: Representation of the wave functions and density for some energy levels

We notice that (obviously we could analyse this analytically and not graphically if we wanted to), in addition to the points $x=0$ and $x=L$, Ψ_n has $n-1$ zeros located in:

$$x = x_m = \frac{mL}{n} \quad \text{with} \quad m = 1, 2, \ldots, n-1 \quad (11.2.524)$$

These points, where the wave function and the probability density are zero, are named "nodal points" or simply "nodes" of the wave function. The number of nodes increases when n increases, that is to say when one moves to more and more excited states.

The wave function Ψ_1 of the ground state with $n=1$ and therefore with:

$$E=E_1=\frac{h^2}{8mL^2} \tag{11.2.525}$$

has no node, that of the first excited state Ψ_2 of energy:

$$E=E_2=4E_1 \tag{11.2.526}$$

has one nodal point, that of the second excited state Ψ_3 has two nodal points, etc.

The variation of the nodal properties of the wave functions when n varies translates the orthogonality of the stationary states of different energy. Indeed, we easily check that $\langle\Psi_n|\Psi_m\rangle$ is zero when $m\neq n$:

$$\begin{aligned}\langle\Psi_n\,|\,\Psi_m\rangle&=\int\limits_0^L\Psi_n(x)\Psi_m(x)\mathrm{d}x=\frac{2}{L}\int_0^L\sin\left(\frac{n\pi x}{L}\right)\sin\left(\frac{m\pi x}{L}\right)\mathrm{d}x\\&=\frac{1}{L}\int\limits_0^L\left\{\cos\left[\frac{(n-m)\pi x}{L}\right]-\cos\left[\frac{(n+m)\pi x}{L}\right]\right\}\mathrm{d}x\\&=\frac{1}{L}\left\{\frac{L}{(n-m)\pi}\sin\left[\frac{(n-m)\pi x}{L}\right]+\frac{L}{(n+m)\pi}\sin\left[\frac{(n-m)\pi x}{L}\right]\right\}\Bigg|_0^L=0\end{aligned} \tag{11.2.527}$$

where we used one of the remarkable trigonometric identity demonstrated in the section of Trigonometry.

P2. As we can see it in the previous figure, the probability density associated with any stationary state of the particle is symmetric with respect to the midpoint $x=L/2$.

We therefore expect that the mean value of x will be exactly equal to $L/2$ in such a state. Indeed, we have seen in the section of Statistics that the expected mean (average) of a probability event $P(x)$ is defined by:

$$\mathrm{E}(x)=\langle x\rangle=\int\limits_{-\infty}^{+\infty}xP(x)\mathrm{d}x \tag{11.2.528}$$

where x, $\mathrm{E}(x)$ and $P(x)$ have no units (caution! as we will do a dimensional analysis!).

Now, in quantum physics $\mathrm{E}(x)$ and x are identical dimensional quantities. This means that the dimensions of $P(x)$ must cancel those of $\mathrm{d}x$. Thus, we guess following the study of the de Broglie normalization conditions that:

$$P(x)\equiv|\,\Psi_n(x)\,|^2 \tag{11.2.529}$$

is a linear probability of the presence of the particle in $[\mathrm{m}^{-1}]$.

The integration domain being $[0,L]$ we have finally:

$$\begin{aligned}
\langle x\rangle &= \int_0^L x\,|\,\Psi_n(x)\,|^2\,\mathrm{d}x=\Psi_0^2\int_0^L x\sin^2\left(\frac{n\pi x}{L}\right)\mathrm{d}x=\frac{2}{L}\int_0^L x\sin^2\left(\frac{n\pi x}{L}\right)\mathrm{d}x\\
&=\frac{1}{L}\int_0^L\left\{1-\cos\left(\frac{2n\pi x}{L}\right)\right\}x\mathrm{d}x=\frac{1}{L}\left\{\int_0^L x\mathrm{d}x-\int_0^L\cos\left(\frac{2n\pi x}{L}\right)x\mathrm{d}x\right\}\\
&=\frac{1}{L}\left\{\frac{1}{2}x^2\Big|_0^L-\left(\frac{L}{2n\pi}\right)\left[\sin\left(\frac{2n\pi x}{L}\right)x\Big|_0^L-\int_0^L\sin\left(\frac{2n\pi x}{L}\right)\mathrm{d}x\right]\right\}\\
&=\frac{1}{L}\left\{\frac{L^2}{2}-\left(\frac{L}{2n\pi}\right)\left[0+\frac{L}{2n\pi}\cos\left(\frac{2n\pi x}{L}\right)\Big|_0^L\right]\right\}\\
&=\frac{1}{L}\left\{\frac{L^2}{2}-\left(\frac{L}{2n\pi}\right)\left[0+\frac{L}{2n\pi}(1-1)\right]\right\}=\frac{1}{L}\frac{L^2}{2}=\frac{L}{2}
\end{aligned}\tag{11.2.530}$$

P3. Also we have for the linear momentum:

$$\begin{aligned}
\langle p_x\rangle &=\int\limits_0^L\bar{\Psi}_n p\Psi_n\mathrm{d}x=\int\limits_0^L\bar{\Psi}_n\left(-\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}x}\right)\Psi_n\mathrm{d}x\\
&=-\mathrm{i}\hbar\int\limits_0^L\sqrt{\frac{2}{L}}\sin\left(\frac{n\pi x}{L}\right)\frac{\mathrm{d}}{\mathrm{d}x}\left(\sqrt{\frac{2}{L}}\sin\left(\frac{n\pi x}{L}\right)\right)\mathrm{d}x\\
&=-\mathrm{i}\frac{2\hbar}{L}\int\limits_0^L\sin\left(\frac{n\pi x}{L}\right)\left(\frac{n\pi}{L}\cos\left(\frac{n\pi x}{L}\right)\right)\mathrm{d}x\\
&=-\mathrm{i}\frac{2n\pi\hbar}{L^2}\int\limits_0^L\sin\left(\frac{n\pi x}{L}\right)\cos\left(\frac{n\pi x}{L}\right)\mathrm{d}x=-\mathrm{i}\frac{2n\pi\hbar}{L^2}\int\limits_0^L\frac{1}{2}\sin\left(\frac{2n\pi x}{L}\right)\mathrm{d}x\\
&=-\mathrm{i}\frac{n\pi\hbar}{L^2}\frac{L}{2n\pi}\int\limits_0^{2\pi n}\sin(\phi)\mathrm{d}\phi=-\mathrm{i}\frac{\hbar}{2L}\cdot 0=0
\end{aligned}\tag{11.2.531}$$

P4. We can also verify without too much difficulty that what we saw in the statement of the second postulate of Quantum Physics is well verified in this example. That is to say, the eigenfunctions of the wave are connected to the Hamiltonian operator via the eigenvalues of the energy:

$$H\Psi=E_{\text{tot}}\Psi\tag{11.2.532}$$

Indeed, in our example, this gives:

$$\begin{aligned}&\left(\underbrace{E_p}_{=0}-\frac{\hbar^2}{2m}\Delta\right)\Psi=E_{\text{tot}}\Psi\\&\Rightarrow -\frac{\hbar^2}{2m}\Delta\Psi=\frac{\pi^2\hbar^2n^2}{2mL^2}\Psi\\&\Rightarrow -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\left(\sqrt{\frac{2}{L}}\sin\left(\frac{n\pi x}{L}\right)\right)=\frac{\pi^2\hbar^2n^2}{2mL^2}\left(\sqrt{\frac{2}{L}}\sin\left(\frac{n\pi x}{L}\right)\right)\\&\Rightarrow -\frac{\partial^2}{\partial x^2}\left(\sin\left(\frac{n\pi x}{L}\right)\right)=\frac{\pi^2n^2}{L^2}\left(\sin\left(\frac{n\pi x}{L}\right)\right)\\&\Rightarrow -\frac{\pi^2n^2}{L^2}\left(-\sin\left(\frac{n\pi x}{L}\right)\right)=\frac{\pi^2n^2}{L^2}\left(\sin\left(\frac{n\pi x}{L}\right)\right)\\&\Rightarrow 1=1\end{aligned} \qquad (11.2.533)$$

P5. Our analysis of the quantum particle in a box would not be complete without discussing "Bohr's correspondence principle". This principle states that for large quantum numbers, the laws of quantum physics must give identical results as the laws of classical physics. To illustrate how this principle works for a quantum particle in a box, we see that in the plot given earlier above of $|\Psi|^2$ when $n\rightarrow+\infty$ that the a number of "peaks" will increase to infinite and therefore result in a uniform (constant) probability to find the particle between 0 and L.

That's it... for the first approach of the problem. Let us now look at the second:

11.2.4.4.4 Second approach

We thus have the Schrödinger equation in the one-dimensional case:

$$\frac{\partial^2\Psi}{\partial x^2}+\frac{8\pi^2m}{h^2}\left(E_{\text{tot}}-E_p\right)\Psi=0 \qquad (11.2.534)$$

In regions outside the box where the potential is infinite, we have:

$$\frac{\partial^2\Psi}{\partial x^2}+\frac{8\pi^2m}{h^2}\left(E_{\text{tot}}-\infty\right)\Psi=0 \qquad (11.2.535)$$

Therefore:

$$\frac{\partial^2\Psi}{\partial x^2}=\infty\Psi \qquad (11.2.536)$$

which gives:

$$\Psi=\frac{1}{\infty}\frac{\partial^2\Psi}{\partial x^2}=0 \qquad (11.2.537)$$

Let us consider now the case of the well where, since the electrostatic potential is zero, the Schrödinger equation reduces to:

$$\frac{\partial^2\Psi}{\partial x^2}+\frac{8\pi^2 m}{h^2}E_{\text{tot}}\Psi=0 \qquad (11.2.538)$$

It is therefore a linear differential equation of order 2 with constant coefficients, equation which is relatively easy to solve in the general case (see section Differential and Integral Calculus page 1610). Given the equation:

$$y''+py'+qy=0 \qquad (11.2.539)$$

Using the results we get during the treatment of the particular solution, let us suppose that the function y that satisfy this differential equation is of the form $y=e^{Kx}$. We have then:

$$K^2e^{Kx}+pKe^{Kx}+qe^{Kx}=0 \qquad \text{or} \qquad K^2+pK+q=0 \qquad (11.2.540)$$

provided, of course, that $e^{Kx}\neq 0$. This last relation is therefore the auxiliary quadratic equation of the differential equation (characteristic polynomial). It has two solutions / roots (it is a simple resolution of a polynomial of the second degree) that we will denote in the general case K_1, K_2. Which means that:

$$K_1^2e^{K_1x}+pK_1e^{K_1x}+qe^{K_1x}=0 \qquad \text{or} \qquad K_2^2e^{K_2x}+pK_2e^{K_2x}+qe^{K_2x}=0 \qquad (11.2.541)$$

is satisfied for both roots. If we make the sum since the both are equal to the same constant:

$$\left(K_1^2e^{K_1x}+K_2^2e^{K_2x}\right)+p\left(K_1e^{K_1x}+K_2e^{K_2x}\right)+q\left(e^{K_1x}+e^{K_2x}\right)=0 \qquad (11.2.542)$$

Thus, it is immediate that the general solution of y is of the type:

$$y=Ae^{K_1x}+Be^{K_2x} \qquad (11.2.543)$$

where the reader should normally be able to verify that the addition of the constants A and B does not change the developments of the preceding paragraphs.

In the present case that interest us:

$$\Psi''+\frac{8\pi^2 m}{h^2}E_{\text{tot}}=0 \qquad (11.2.544)$$

The quadratic equation is:

$$k^2+\frac{8\pi^2 m}{h^2}E_{\text{tot}}=0\Rightarrow k^2=-2mE_{\text{tot}}\hbar^{-2} \qquad (11.2.545)$$

thus:

$$k=\pm\frac{\sqrt{-2mE_{\text{tot}}}}{\hbar}=\pm\mathrm{i}\frac{\sqrt{2mE_{\text{tot}}}}{\hbar} \qquad (11.2.546)$$

So finally the general solution is of the form:

$$\Psi=A\exp\left(\mathrm{i}\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}x\right)+B\exp\left(-\mathrm{i}\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}x\right) \qquad (11.2.547)$$

Let us put now:

$$\theta = \frac{\sqrt{2mE_{\text{tot}}}}{\hbar}x \tag{11.2.548}$$

We then have:

$$\begin{aligned}\Psi &= Ae^{\mathrm{i}\theta} + Be^{-\mathrm{i}\theta} = A\cos(\theta) + \mathrm{i}A\sin(\theta) + B\cos(\theta) - \mathrm{i}B\sin(\theta)\\ &= A'\cos(\theta) + B'\sin(\theta)\end{aligned} \tag{11.2.549}$$

with:

$$A' = A + B \qquad \text{and} \qquad B' = \mathrm{i}(A - B) \tag{11.2.550}$$

It is now necessary to determine A' and B' using the boundary conditions. Thus, at $x = 0$ and $x = L$ we should have $\Psi = 0$ and we have for $x = 0$:

$$\Psi = A'\cos\left(\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}x\right) + B'\sin\left(\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}x\right) = A' \tag{11.2.551}$$

The coefficient A' must therefore be equal to zero. And in $x = L$ we should have:

$$\begin{aligned}\Psi &= A'\cos\left(\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}x\right) + B'\sin\left(\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}x\right)\\ &= 0\cdot\cos\left(\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}x\right) + B'\sin\left(\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}L\right) = B'\sin\left(\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}L\right) = 0\end{aligned} \tag{11.2.552}$$

But in this case, B' must be different from zero. Indeed, if it were zero, the wave function would be zero throughout the whole well, which is contrary to the physical reality of the problem. It is therefore necessary that the sinus to be zero, or that its argument be equal to a multiple of a non-zero integer number of angle π such that:

$$\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}L = \pm n\pi \tag{11.2.553}$$

Therefore:

$$E_{\text{tot}} = \frac{\pi^2\hbar^2}{2mL^2}n^2 \tag{11.2.554}$$

We thus find exactly the same result as the preceding method!

It remains to determine B and the method is exactly identical to the first method of resolution which we have seen above. Thus, we have:

$$\Psi = \sqrt{\frac{2}{L}}\sin\left(\frac{n\pi x}{L}\right) \tag{11.2.555}$$

What is especially important in this method is to remember for a moment the general form of the solution:

$$\Psi = Ae^{\mathrm{i}kx} + Be^{-\mathrm{i}kx} \tag{11.2.556}$$

11.2.4.4.5 Fermi Energy

The "Fermi energy", E_F is a concept in Quantum Physics that designates the energy of the highest quantum state occupied in an idealized system in which all the layers are filled successively and without discontinuities, that is to say in practice when a system is at absolute zero: 0 [K] (see section Statistical Mechanics page 3571). It is an important concept in Solid states physics as we have seen it in our study of semiconductors in the section of Electrokinetics.

The rectilinear infinite potential well is an excellent teaching tool to introduce practically the Fermi energy level and then to extend it to other particular cases.

Let us recall that we have just obtained in two different ways:

$$E_n = \frac{\pi^2\hbar^2}{2mL^2\pi^2 4}n^2 = \frac{\pi^2\hbar^2}{2mL^2}n^2 \tag{11.2.557}$$

Then the total energy of an entire system composed of N particles can all have the same fundamental state $n=1$ and thus that violate the principle of Pauli will be:

$$E_{\text{tot}} = \left(\frac{\pi^2\hbar^2}{2mL^2}\right)N \tag{11.2.558}$$

But if we apply the Pauli's exclusion principle of electrons (fermions), each level can then take only two states (spin oppositions) in this model (which does not contain sublayers or other subtleties). Henceforth, each fundamental level can be occupied by only two states, and so it is for each level. The total energy is then in reality:

$$E_{\text{tot}} = 2\sum_{n=1}^{N/2} E_n = 2\sum_{n=1}^{N/2}\frac{\pi^2\hbar^2}{2mL^2}n^2 = \frac{\pi^2\hbar^2}{mL^2}\sum_{n=1}^{N/2}n^2 \tag{11.2.559}$$

Using the sum of the squares demonstrated in the section of Sequences and Series and writing as it is usual:

$$n_{\text{max}} = \frac{N}{2} \tag{11.2.560}$$

we have then:

$$E_{\text{tot}} = \frac{\pi^2\hbar^2}{mL^2}\sum_{n=1}^{N/2}n^2 = \frac{\pi^2\hbar^2}{mL^2}\left(\frac{n_{max}(n_{\text{max}}+1)(2n_{\text{max}}+1)}{6}\right) \cong \frac{\pi^2\hbar^2}{mL^2}\frac{n_{\text{max}}^3}{3} = \frac{\pi^2\hbar^2}{24mL^2}N^3 \tag{11.2.561}$$

The average energy per particle is then:

$$\bar{E} = \frac{E_{\text{tot}}}{N} \cong \frac{\pi^2\hbar^2}{24mL^2}N^2 \tag{11.2.562}$$

By definition, the energy of the last level to be occupied is that of Fermi and therefore given by:

$$E_n = \frac{E_{\text{tot}}}{N} \cong \frac{\pi^2\hbar^2}{2mL^2}N^2 \Rightarrow E_{N/2} = \frac{\pi^2\hbar^2}{8mL^2}\left(\frac{N}{2}\right)^2 = \frac{\pi^2\hbar^2}{8mL^2}N^2 \tag{11.2.563}$$

Therefore:

$$\boxed{E_F=\frac{\pi^2\hbar^2}{8mL^2}N^2} \tag{11.2.564}$$

We also notice that we have whatever the value of N:

$$\bar{E}=\frac{1}{3}E_F \tag{11.2.565}$$

The three-dimensional isotropic case is known as the "Fermi sphere" as already introduced in the section of Electrokinetics during our study of semiconductors.

Let us now consider a three-dimensional cubical box that has a side length L. This turns out to be a very good approximation for describing electrons in a metal. The states are now labelled by three quantum numbers n_x, n_y, and n_z. The single particle energies are (where m is the mass of fermion (electron in this case)) as we have seen in the section of Electrokinetics during our study of semiconductor:

$$E_{n_x,n_y,n_z}=\frac{\pi^2\hbar^2}{2mL^2}\left(n_x^2+n_y^2+n_z^2\right) \tag{11.2.566}$$

where n_x, n_y, and n_z are positive integers. There are multiple states with the same energy, for example $E_{211}=E_{121}=E_{112}$. Now let's put N non-interacting fermions of spin $1/2$ into this box. To calculate the Fermi energy, we look at the case where N is large.

If we introduce a vector $\vec{n}=\{n_x,n_y,n_z\}$ then each quantum state corresponds to a point in "n-space" with energy:

$$E_{\vec{n}}=\frac{\pi^2\hbar^2}{2mL^2}\|\vec{n}\|^2 \tag{11.2.567}$$

with $\|\vec{n}\|^2$ denoting the square of the usual Euclidean length (norm). The number of states with energy less than $E_{\vec{n}}$, defined as the "Fermi energy", is equal to the number of states that lie within a sphere of radius $R=\|\vec{n}_F\|^2$ in the region of n-space where n_x, n_y and n_z are positive. In the ground state this number equals the number of fermions in the system:

$$N=2\cdot\frac{1}{8}\cdot\frac{4}{3}\pi R^3=2\cdot\frac{1}{8}\cdot\frac{4}{3}\pi n_F^3 \tag{11.2.568}$$

the factor 2 is once again because there are two spin states, the factor of $1/8$ is because only $1/8$ of the sphere lies in the region where all n are positive. Therefore we get:

$$n_F=\left(\frac{3N}{\pi}\right)^{1/3} \tag{11.2.569}$$

so the Fermi energy is given by:

$$E_F=\frac{\hbar^2\pi^2}{2mL^2}n_F^2=\frac{\hbar^2\pi^2}{2mL^2}\left(\frac{3N}{\pi}\right)^{2/3} \tag{11.2.570}$$

Which results in a relationship between the Fermi energy and the number of particles per volume (when we replace L^2 with $V^{2/3}$):

$$\boxed{E_F=\frac{\hbar^2}{2m}\left(\frac{3\pi^2N}{V}\right)^{2/3}} \tag{11.2.571}$$

Confusingly, the term "Fermi energy" is often used to refer to a different but closely related concept, the "Fermi level" (also named "electrochemical potential"). There are a few key differences between the Fermi level and Fermi energy, at least as they are used in this textbook:

- The Fermi energy is only defined at absolute zero, while the Fermi level is defined for any temperature.
- The Fermi energy is an energy difference (usually corresponding to a kinetic energy), whereas the Fermi level is a total energy level including kinetic energy and potential energy.
- The Fermi energy can only be defined for non-interacting fermions (where the potential energy or band edge is a static, well defined quantity), whereas the Fermi level (the electrochemical potential of an electron) remains well defined even in complex interacting systems, at thermodynamic equilibrium.

Since the Fermi level in a metal at absolute zero is the energy of the highest occupied single particle state, then the Fermi energy in a metal is the energy difference between the Fermi level and lowest occupied single-particle state, at zero-temperature.

11.2.4.4.6 1D-Harmonic oscillator

The study of the harmonic oscillator corresponding to that of a wave function stuck in a well of parabolic potential. This is roughly equivalent to the atoms where the walls of the potential well are naturally not rectangular and infinite ... The study that follows is therefore what is closest to what is available in Nature at the atomic level and this is why it is used a lot in Quantum Chemistry and also in Nuclear Physics.

In the case of a free particle in rectilinear displacement, we have seen that the potential energy is zero ($E_p = 0$) and the Schrödinger equation then becomes:

$$\frac{\partial^2 \Psi}{\partial x^2} + \frac{2mE_{\text{tot}}}{\hbar^2}\Psi = 0 \qquad (11.2.572)$$

However, for a free particle (in the absence of a potential field) the total energy is therefore equal to the kinetic energy:

$$E_{\text{tot}} = \frac{1}{2}mv^2 = \frac{p^2}{2m} \qquad (11.2.573)$$

But we have:

$$E_{\text{tot}} = h\nu = h\frac{\omega}{2\pi} = \hbar\omega = mc^2 \Leftrightarrow p = mc = \frac{E_{\text{tot}}}{c}\frac{h\nu}{c} = h\lambda \qquad (11.2.574)$$

The ratio:

$$\lambda = \frac{h}{p} \qquad (11.2.575)$$

being the associated de Broglie wavelength. By introducing the wave number $k=2\pi/\lambda$ (see section Wave Mechanics page 3480), we have:

$$\boxed{p=\hbar k} \tag{11.2.576}$$

named "de Broglie's relation". Finally:

$$E_{\text{tot}}=\frac{p^2}{2m}=\frac{(\hbar k)^2}{2m} \tag{11.2.577}$$

Therefore, Schrödinger's equation can be written:

$$\frac{\partial^2\Psi}{\partial x^2}+k^2\Psi=0 \tag{11.2.578}$$

We see by direct substitution that this differential equation admits for solutions the wave functions:

$$\Psi_1(x)=Ae^{\text{i}kx} \qquad \text{and} \qquad \Psi_2(x)=Be^{-\text{i}kx} \tag{11.2.579}$$

These two different solutions represent the displacement of the same particle once in the $+x$ direction and the other in $-x$. If $A=B=1$ we have:

$$|\Psi(x)|^2=\bar{\Psi}(x)\cdot\Psi(x)=e^{-\text{i}kx}\cdot e^{\text{i}kx}=1 \tag{11.2.580}$$

The fact that this result is equal to unity means that the probability of finding the particle is the same at all points as we don't need any special normalization. In other words, $\Psi(x)=e^{\pm\text{i}kx}$ describes a situation in which the uncertainty on the position is total. This result is in agreement with the principle of uncertainty since $\Psi(x)=e^{\pm\text{i}kx}$ describes a particle of which we know with precision the linear momentum $p=\hbar k$: that is to say that $\Delta p=0$, which implies $\Delta x\rightarrow+\infty$.

In the section of Differential and Integral Calculus we showed that the most general solution of a differential equation is the sum of these solutions. In other words, in our example:

$$\Psi(x)=Ae^{\text{i}kx}+Be^{-\text{i}kx} \tag{11.2.581}$$

with:

$$k=\frac{\sqrt{2mE_{\text{tot}}}}{\hbar} \tag{11.2.582}$$

By the way, we can notice that if $E_p\neq 0$ then the result is the same with the difference that we will have:

$$k=\frac{\sqrt{2m(E_{\text{tot}}-E_p)}}{\hbar} \tag{11.2.583}$$

When the particle of interest is in a well of potential described by the function (parabola):

$$E_p(x)=\frac{1}{2}c^{te}x^2 \tag{11.2.584}$$

we then speak of "1D-harmonic oscillator".

This system is very important because the Hamiltonian of the equation intervenes in all the problems involving oscillations such as molecular and crystalline vibrations (see section Quantum Chemistry page 6211).

Let us first take as an example the classic harmonic oscillator which consists of a body subjected to move along an axis and subjected to a return force proportional to the distance to a point situated on this axis.

The equation of this body is governed by the equation of dynamics:

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+kx=0 \tag{11.2.585}$$

We have seen in the section of Classical Mechanics that the general solution of this equation is:

$$x=x_0\cos(\omega t+\varphi) \tag{11.2.586}$$

with for pulsation:

$$\omega=\sqrt{\frac{k}{m}} \tag{11.2.587}$$

The total energy of the system being the classical Hamiltonian, we write:

$$H=E_c+E_p=\frac{1}{2}m\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2+\frac{1}{2}kx(t)^2=\frac{p^2}{2m}+\frac{1}{2}kx(t)^2 \tag{11.2.588}$$

It follows from the expression of the potential energy that the constant we had in the initial relation which defined the well of parabolic potential:

$$E_p(x)=\frac{1}{2}c^{te}x^2 \tag{11.2.589}$$

is simply k and therefore:

$$E_p(x)=\frac{1}{2}\omega^2mx^2 \tag{11.2.590}$$

but which we will write for the next development and by tradition in the following form:

$$E_p(x)=\frac{1}{2}\omega_0^2mx^2 \tag{11.2.591}$$

Now let us come back to our quantum framework. From this point of view we have for Hamiltonian (or total energy):

$$H=E_c+E_p=\frac{p^2}{2m}+\frac{c^{te}}{2}x^2 \tag{11.2.592}$$

where for recall, following what we have just seen:

$$c^{te}=\omega_0^2m \tag{11.2.593}$$

Using what we define as a "reduced writing", we write:

$$H=\frac{\hbar\omega_0}{2}(P^2+Q^2) \tag{11.2.594}$$

where the "reduced operators" of linear momentum and positions are therefore respectively:

$$P=\frac{p}{\sqrt{m\hbar\omega_0}} \qquad \text{and} \qquad Q=\sqrt{\frac{c^{te}}{\hbar\omega_0}}x \tag{11.2.595}$$

where by a stupid tradition we keep the constant instead of replacing by $\omega_0^2 m$.

It is more or less easy to obtain the relation of commutation:

$$[Q,P]=\sqrt{\frac{c^{te}}{m}}\frac{1}{\hbar\omega_0}[x,p] \tag{11.2.596}$$

Proof 11.4.3. Remember the relations below that we saw in our study of functional linear operators at the beginning of this section:

$$p_x=\frac{1}{\mathrm{i}}\hbar\frac{\partial}{\partial x},p_y=\frac{1}{\mathrm{i}}\hbar\frac{\partial}{\partial y},p_z=\frac{1}{\mathrm{i}}\hbar\frac{\partial}{\partial z} \tag{11.2.597}$$

Let us consider the properties of the commutators with the linear momentum. We have also proved above earlier above the relation:

$$\frac{\mathrm{d}}{\mathrm{d}x}x=1+x\frac{\mathrm{d}}{\mathrm{d}x} \tag{11.2.598}$$

By multiplying the latter by $\hbar/\mathrm{i}$, it comes:

$$\frac{\partial}{\partial x}\frac{\hbar}{\mathrm{i}}x=x\frac{\partial}{\partial x}\frac{\hbar}{\mathrm{i}}+1\frac{\hbar}{\mathrm{i}} \tag{11.2.599}$$

That we can also write:

$$p_x x=xp_x-\hbar\mathrm{i} \tag{11.2.600}$$

If you remember the definition of the of commutators ($[\alpha,\beta]=\alpha\beta-\beta\alpha$), we have:

$$[x,p_x]=p_x x-xp_x=\hbar\mathrm{i} \tag{11.2.601}$$

We therefore have for our oscillator:

$$P=\frac{p}{\sqrt{m\hbar\omega_0}}=\frac{p}{\sqrt{m\hbar\omega_0}}\frac{\partial}{\partial x}\mathrm{i}\hbar \qquad \text{and} \qquad Q=\sqrt{\frac{c^{te}}{\hbar\omega_0}}x \tag{11.2.602}$$

Let's write the definition of the commutator:

$$[Q,P]=QP-PQ \tag{11.2.603}$$

Therefore:

$$\begin{aligned}[Q,P]&=\sqrt{\frac{c^{te}}{\hbar\omega_0}}x\frac{p}{\sqrt{m\hbar\omega_0}}\frac{\partial}{\partial x}\mathrm{i}\hbar-\frac{p}{\sqrt{m\hbar\omega_0}}\frac{\partial}{\partial x}\mathrm{i}\hbar\sqrt{\frac{c^{te}}{\hbar\omega_0}}x\\&=\sqrt{\frac{c^{te}}{\hbar\omega_0}}\frac{1}{\sqrt{m\hbar\omega_0}}\left(x\frac{\partial}{\partial x}\mathrm{i}\hbar-\frac{\partial}{\partial x}\mathrm{i}\hbar x\right)=\sqrt{\frac{c^{te}}{m}}\frac{1}{\hbar\omega_0}\left(x\frac{\partial}{\partial x}\mathrm{i}\hbar-\frac{\partial}{\partial x}\mathrm{i}\hbar x\right)\\&=\sqrt{\frac{c^{te}}{m}}\frac{1}{\hbar\omega_0}\left(xp_x-p_x x\right)=\sqrt{\frac{c^{te}}{m}}\frac{1}{\hbar\omega_0}[x,p_x]=\omega_0\frac{1}{\hbar\omega_0}[x,p_x]=\frac{1}{\hbar}[x,p_x]=\mathrm{i}\end{aligned} \tag{11.2.604}$$

that's was what has to be proved...

■ Q.E.D.

We now have an interest for solving the differential equation to use the non-Hermitian operators equation defined by[12] (this is a definition so do not try to understand!):

$$\begin{gathered}\sqrt{2}a=Q+\mathrm{i}P\\ \sqrt{2}a^{\dagger}=Q-\mathrm{i}P\end{gathered} \tag{11.2.605}$$

What thus defines us the operators (by temporarily putting $m=1$):

$$a=\dfrac{Q+\mathrm{i}P}{\sqrt{2}}=\dfrac{\omega x+\mathrm{i}p}{\sqrt{2\hbar\omega_0}}\qquad\qquad a^{\dagger}=\dfrac{Q-\mathrm{i}P}{\sqrt{2}}=\dfrac{\omega x-\mathrm{i}p}{\sqrt{2\hbar\omega_0}} \tag{11.2.606}$$

which are linear combinations of the position and linear momentum operators and are trivially not Hermitian (not equal to its own conjugate for recall!).

We see these two operators very frequently in Quantum Physics, especially in Quantum Field physics, and physicists then speak of "creation operator $a^{\dagger}$" or "raising operator a_+" and of the "destruction operator a" or "lowering operator a_-" (also named "annihilation operator"). The reasons of these names will be more clear later (it seems that it is Dirac himself that introduce them for the first time in the framework of the harmonic oscillator)!

Given the commutators relation, we check (we need that for the next developments):

$$2aa^{\dagger}=P^2+Q^2+1\qquad\text{and}\qquad 2a^{\dagger}a=P^2+Q^2-1 \tag{11.2.607}$$

Proof 11.4.4. First:

$$\begin{aligned}2aa^{\dagger}&=(Q+\mathrm{i}P)(Q-\mathrm{i}P)=Q^2+\mathrm{i}PQ-\mathrm{i}QP+P^2\\&=Q^2-\mathrm{i}[QP-PQ]+P^2=Q^2-\mathrm{i}[Q,P]+P^2\\&=P^2+Q^2-\mathrm{i}\cdot\mathrm{i}=P^2+Q^2+1\end{aligned} \tag{11.2.608}$$

and:

$$\begin{aligned}2a^{\dagger}a&=(Q-\mathrm{i}P)(Q+\mathrm{i}P)=Q^2-\mathrm{i}PQ+\mathrm{i}QP+P^2\\&=Q^2+\mathrm{i}[QP-PQ]+P^2=Q^2+\mathrm{i}[Q,P]+P^2\\&=P^2+Q^2+\mathrm{i}\cdot\mathrm{i}=P^2+Q^2+1\end{aligned} \tag{11.2.609}$$

■ Q.E.D.

And on the other hand we also need:

$$[a,a^{\dagger}]_{\_}=aa^{\dagger}-a^{\dagger}a=1 \tag{11.2.610}$$

Proof 11.4.5.

$$2aa^{\dagger}-2a^{\dagger}a=(P^2+Q^2)-(P^2+Q^2)+1-(-1)=2 \tag{11.2.611}$$

and therefore by dividing by 2 on both sides of the equality, we get:

$$aa^{\dagger}-a^{\dagger}a=1 \tag{11.2.612}$$

---

[12] This approach of solving this problem is sometimes named "Ladder operators for the quantum harmonic oscillator"

■ Q.E.D.

Now let us come back to:

$$H=\frac{\hbar\omega_0}{2}(P^2+Q^2) \quad (11.2.613)$$

and using:

$$a^\dagger a=\frac{P^2+Q^2-1}{2}\Rightarrow\frac{P^2+Q^2}{2}=a^\dagger a+\frac{1}{2}=N+\frac{1}{2} \quad (11.2.614)$$

where it appears that N can be seen as an operator, named "counter operator" (hermitic) since:

$$N=a^\dagger a \quad (11.2.615)$$

The same reasoning and assumption bring us to:

$$aa^\dagger-\frac{1}{2}=N'-\frac{1}{2} \quad (11.2.616)$$

with:

$$N'=aa^\dagger \quad (11.2.617)$$

It is then sufficient to quantify the counter operator to know the eigenvalues and the eigenstates of H since these two elements are then linked by:

$$H=\hbar\omega_0\left(\frac{P^2+Q^2}{2}\right)=\hbar\omega_0\left(a^\dagger a+\frac{1}{2}\right)=\hbar\omega_0\left(N+\frac{1}{2}\right) \quad (11.2.618)$$

Therefore in general using the other notation:

$$H=\hbar\omega_0\left(a_\pm a_\mp\pm\frac{1}{2}\right) \quad (11.2.619)$$

therefore the Schrödinger equation can be written:

$$\boxed{H\Psi=E\Psi\Leftrightarrow\hbar\omega_0\left(a_\pm a_\mp\pm\frac{1}{2}\right)=E\Psi} \quad (11.2.620)$$

We now make the assumption that Ψ is an eigenfunction of N associated with the eigenvalue n such that:

$$\begin{aligned}&H\Psi=E\Psi\\&\Rightarrow\hbar\omega_0\left(N+\frac{1}{2}\right)\Psi_n=\hbar\omega_0\left(n+\frac{1}{2}\right)\Psi_n\\&\Rightarrow N\Psi_n=n\Psi_n\end{aligned} \quad (11.2.621)$$

This assumption is very important because we will use it as an induction principle to find all the eigenfunctions starting from the fundamental one!

Let us now establish commutator relations between N and N' and the operators a or $a^{\dagger}$. For this, let us first multiply $aa^{\dagger}-a^{\dagger}a=1$ by $a^{\dagger}$, then we get:

$$(aa^{\dagger}-a^{\dagger}a)a^{\dagger}=(aa^{\dagger})a^{\dagger}-a^{\dagger}(aa^{\dagger})=N'a^{\dagger}-a^{\dagger}N'=a^{\dagger} \qquad (11.2.622)$$

Similarly, by multiplying the $aa^{\dagger}-a^{\dagger}a=1$ by a, we get:

$$aa^{\dagger}a-a^{\dagger}aa=a(a^{\dagger}a)-(a^{\dagger}a)a=aN-Na=a \qquad (11.2.623)$$

Since according to our assumption Ψ and n are respectively eigenfunction and eigenvalue of N, we can write:

$$N\Psi=n\Psi \qquad (11.2.624)$$

But as we have:

$$Na=aN-a \qquad (11.2.625)$$

which multiplied on both side of the equality by the wave function Ψ gives the relation:

$$Na\Psi=(n-1)a\Psi=na\Psi-a\Psi \qquad (11.2.626)$$

This equation has the following consequences:

- We have $a\Psi=0$ such that $Na\Psi=na\Psi$
- Or we have $a\Psi$ that is an eigenfunction of N for the eigenvalue $(n-1)$

The same reasoning would establish that $a^{\dagger}\Psi$ is an eigenfunction of N' for the eigenvalue $n'+1$, if it is not zero (we shall see later that $a^{\dagger}\Psi$ is never zero):

$$N\left(a^{\dagger}\Psi\right)=\left(n+1\right)a^{\dagger}\Psi \qquad (11.2.627)$$

With the notations above it was still not clear for one of our read with the operator were named creation and annihilation operators. Let us see this with another approach before we continue! The following development was more explicit to explain their name (we keep the other notation of these operators for obvious reasons):

$$\begin{aligned}H\left(a_{+}\psi\right)&=\hbar\omega_0\left[a_{+}a_{-}+\frac{1}{2}\right]\left(a_{+}\psi\right)=\hbar\omega_0\left[a_{+}a_{-}a_{+}+\frac{1}{2}a_{+}\right]\psi\\&=\hbar\omega_0 a_{+}\left[a_{-}a_{+}+\frac{1}{2}\right]\psi=\hbar\omega_0 a_{+}\left[a_{+}a_{-}+\frac{1}{2}+1\right]\psi\\&=a_{+}\left[\hbar\omega_0\left(a_{+}a_{-}+\frac{1}{2}\right)+\hbar\omega_0\right]\psi=a_{+}\left(H+\hbar\omega_0\right)\psi\\&=a_{+}\left(E+\hbar\omega_0\right)\psi=\left(E+\hbar\omega_0\right)a_{+}\psi\end{aligned} \qquad (11.2.628)$$

By the same argument, we can show that $a_{-}\Psi$ is a wave function with energy $E-\hbar\omega_0$. For this reason a_{+} and a_{-} are called the raising and lowering operators, respectively:

$$\boxed{H(a_{\pm}\Psi)=(E\pm\hbar\omega_0)a_{\pm}\Psi} \qquad (11.2.629)$$

Now, since the harmonic oscillator potential is parabolic, we would expect no upper limit to the energy levels, but we would expect a lower limit, so that applying the lowering operator to the ground state should give us zero.

Therefore we know that there exists a lower eigenvalue n_0 smaller all the others corresponding to the fundamental level (according to the Bohr-Sommerfeld model this eigenvalue always exists).

Necessarily, its eigenfunction equation obeys the relation (the reader will be able to check with the results further):

$$a\Psi_0 = 0 \tag{11.2.630}$$

as they can not be , as we have already mention it, a level lower that the lower limit by applying the lowering operator!

Otherwise $n_0 - 1$ would a eigenvalue and there would a physical contradiction.

By multiplying this last relation by $a^\dagger$ we get:

$$a^\dagger a\Psi_0 = N\Psi_0 = 0 \tag{11.2.631}$$

Which shows that the minimum eigenvalue n_0 is zero. We therefore know the fundamental level of the oscillator:

$$E_0 = \hbar\omega_0\left(n_0 + \frac{1}{2}\right) = \frac{1}{2}\hbar\omega_0 \tag{11.2.632}$$

named "zero-point energy".

Remark

It should be noticed that the oscillator is never in a state of rest (put $n = 0$ in the expression of the energy) which also means that the absolute zero can not be accessible since the temperature "fix" the atomic agitation and that a rest state does not exist!

To get the corresponding eigenfunction, we need the explicit expression of a. According to:

$$P = \frac{p}{\sqrt{m\hbar\omega_0}} \qquad \text{and} \qquad Q = \sqrt{\frac{c^{te}}{\hbar\omega_0}}x = \sqrt{\frac{\omega_0 m}{\hbar}}x \tag{11.2.633}$$

Then we have:

$$P = \frac{1}{\sqrt{m\hbar\omega_0}}\frac{\hbar}{\mathrm{i}}\frac{\mathrm{d}}{\mathrm{d}x} \qquad \text{and} \qquad \mathrm{d}Q = \sqrt{\omega_0 m\hbar}\mathrm{d}x \Rightarrow \frac{1}{\mathrm{d}x} = \sqrt{\frac{\omega_0 m}{\hbar}}\frac{1}{\mathrm{d}Q} \tag{11.2.634}$$

which gives us:

$$P = \frac{1}{\sqrt{m\hbar\omega_0}}\frac{\hbar}{\mathrm{i}}\sqrt{\frac{\omega_0 m}{\hbar}}\frac{\mathrm{d}}{\mathrm{d}Q} = \frac{1}{\mathrm{i}}\frac{\mathrm{d}}{\mathrm{d}Q} \tag{11.2.635}$$

Hence:

$$\begin{aligned}\sqrt{2}a &= Q + \frac{\mathrm{d}}{\mathrm{d}Q}\\ \sqrt{2}a^\dagger &= Q - \frac{\mathrm{d}}{\mathrm{d}Q}\end{aligned} \tag{11.2.636}$$

But according to $a\Psi_0=0$:

$$\left(Q+\dfrac{\mathrm{d}}{\mathrm{d}Q}\right)\Psi_0=0 \tag{11.2.637}$$

hence:

$$\dfrac{1}{\Psi_0}\dfrac{\mathrm{d}}{\mathrm{d}Q}\Psi_0=-Q \tag{11.2.638}$$

thus (resolution of a simple differential equation):

$$\Psi_0(Q)=Ae^{-Q^2/2} \tag{11.2.639}$$

where A is the constant of integration. Thus, explicitly:

$$\Psi_0(x)=Ae^{-m\omega_0 x^2/\hbar 2} \tag{11.2.640}$$

We can normalize this function using the standard Gauss integral (see section Statistics page 695):

$$\int\limits_{-\infty}^{+\infty} e^{-ax^2}\mathrm{d}x=\sqrt{\dfrac{\pi}{a}} \tag{11.2.641}$$

so we get:

$$1=\int\limits_{-\infty}^{+\infty}|\Psi_0|^2\mathrm{d}x=|A|^2\int\limits_{-\infty}^{+\infty}e^{-m\omega x^2/\hbar}\mathrm{d}x=|A|^2\sqrt{\dfrac{\hbar\pi}{m\omega_0}} \tag{11.2.642}$$

Therefore:

$$A=\left(\dfrac{m\omega_0}{\pi\hbar}\right)^{1/4} \tag{11.2.643}$$

So finally:

$$\Psi_0=\left(\dfrac{m\omega_0}{\pi\hbar}\right)^{1/4}e^{-m\omega_0 x^2/\hbar 2} \tag{11.2.644}$$

It remains to build the other eigenfunctions and to normalize them. Indeed, if Ψ_n is a normalized function associated with the level E_n, we have seen above that $a^\dagger\Psi_n$ is an eigenfunction associated with the level $n+1$ (the operator of creation $a^\dagger$ increase the energy as we have show it...), but there is no reason to normalize it again since it is precisely associated with an eigenfunction already normalized!

Therefore we can write:

$$a^\dagger\Psi_n=\alpha_n\Psi_{n+1} \tag{11.2.645}$$

Where α_n is a coefficient to be determined. Let us express the fact that Ψ_n is already normed:

$$|\alpha_n|^2=\int\limits_{-\infty}^{+\infty}\overline{(a^\dagger\Psi_n)}\cdot(a^\dagger\Psi_n)\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\bar{\Psi}_n\cdot(aa^\dagger\Psi_n)\mathrm{d}x \tag{11.2.646}$$

Considering the relation $aa^\dagger - a^\dagger a = 1$ we have:

$$|\alpha_n|^2 = \int_{-\infty}^{+\infty} \bar{\Psi}_n[(1+a^\dagger a)\Psi_n]\mathrm{d}x \tag{11.2.647}$$

Let us recall that $N(a^\dagger\Psi) = (n+1)(a^\dagger\Psi)$ therefore:

$$|\alpha_n|^2 = \int\limits_{-\infty}^{+\infty} \bar{\Psi}_n[(1+a^\dagger a)\Psi_n]\mathrm{d}x = \int\limits_{-\infty}^{+\infty} \bar{\Psi}_n[(1+N)\Psi_n]\mathrm{d}x = n+1 \tag{11.2.648}$$

We have just verified on the way that $a^\dagger\Psi_0$ is never zero (fact that we had supposed above).

All the functions Ψ_n (except the already Ψ_0 already fixed) have an arbitrary phase factor (concept that we have seen during the definition of bounded and unbound states), independently of each other, the argument α_n therefore remains available to us and we will choose α_n as being a fixed positive real number. This fixes all the Ψ_n according to the previous development:

$$a^\dagger\Psi_n = \sqrt{n+1}\Psi_{n+1} \tag{11.2.649}$$

By iterating this relation on the wave function, we obtain easily (elementary algebra but that we can detail on request):

$$\Psi_n = \frac{1}{\sqrt{n!}}(a^\dagger)^n\Psi_0 \tag{11.2.650}$$

by taking into account the following relations (which we have already proved just earlier above):

$$\begin{gathered}\sqrt{2}a = Q + \frac{\mathrm{d}}{\mathrm{d}Q}\\ \text{and} \qquad \Psi_0 = A^{-1/2}\pi^{-1/4}e^{-Q^2/2} = \left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4} e^{-Q^2/2}\\ \sqrt{2}a^\dagger = Q - \frac{\mathrm{d}}{\mathrm{d}Q}\end{gathered} \tag{11.2.651}$$

We then have:

$$\Psi_n = \left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4}(n!2^n)^{-1/2}\left(Q-\frac{\mathrm{d}}{\mathrm{d}Q}\right)^n e^{-Q^2/2} \tag{11.2.652}$$

This relation takes a simpler form, relying on the relation:

$$\left(Q-\frac{\mathrm{d}}{\mathrm{d}Q}\right)f(Q) = -e^{Q^2/2}\frac{\mathrm{d}}{\mathrm{d}Q}e^{-Q^2/2}f(Q) \tag{11.2.653}$$

Let us check this:

$$\begin{aligned}-e^{Q^2/2}\frac{\mathrm{d}}{\mathrm{d}Q}e^{-Q^2/2}f(Q) &= -e^{Q^2/2}\left(-Qe^{-Q^2/2}f(Q) + e^{-Q^2/2}\frac{\mathrm{d}}{\mathrm{d}Q}f(Q)\right)\\ &= -e^{Q^2/2}e^{-Q^2/2}\left(-Qf(Q)+\frac{\mathrm{d}}{\mathrm{d}Q}f(Q)\right) = \left(Q-\frac{\mathrm{d}}{\mathrm{d}Q}\right)f(Q)\end{aligned} \tag{11.2.654}$$

hence, in the language of operators:

$$Q-\frac{\mathrm{d}}{\mathrm{d}Q}=-e^{Q^2/2}\frac{\mathrm{d}}{\mathrm{d}Q}e^{-Q^2/2} \tag{11.2.655}$$

Therefore:

$$\left(Q-\frac{\mathrm{d}}{\mathrm{d}Q}\right)^n=(-1)^n e^{Q^2/2}\left(\frac{\mathrm{d}}{\mathrm{d}Q}\right)^n e^{-Q^2/2} \tag{11.2.656}$$

We thus obtain the expression of Ψ_n:

$$\Psi_n=(-1)^n\sqrt{\frac{1}{2^n n!}}\left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4}\left[e^{Q^2/2}\frac{\mathrm{d}^n}{\mathrm{d}Q^n}e^{-Q^2/2}\right]e^{-Q^2/2} \tag{11.2.657}$$

Moreover, in the mathematical theory of families of orthogonal polynomials with the weight (with respect to the weight function[13] $w(x)=e^{-x}/2$), we encounter the "Hermite polynomials" defined by (physicist version!):

$$\boxed{H_n(Q)=(-1)^n e^{Q^2}\frac{\mathrm{d}^n}{\mathrm{d}Q^n}e^{-Q^2}} \tag{11.2.658}$$

They are polynomials of degree n, even or odd ($H_0=1$, $H_1=2Q$, $H_2=4Q^2-2$, $H_3=8Q^3-12Q$,...):

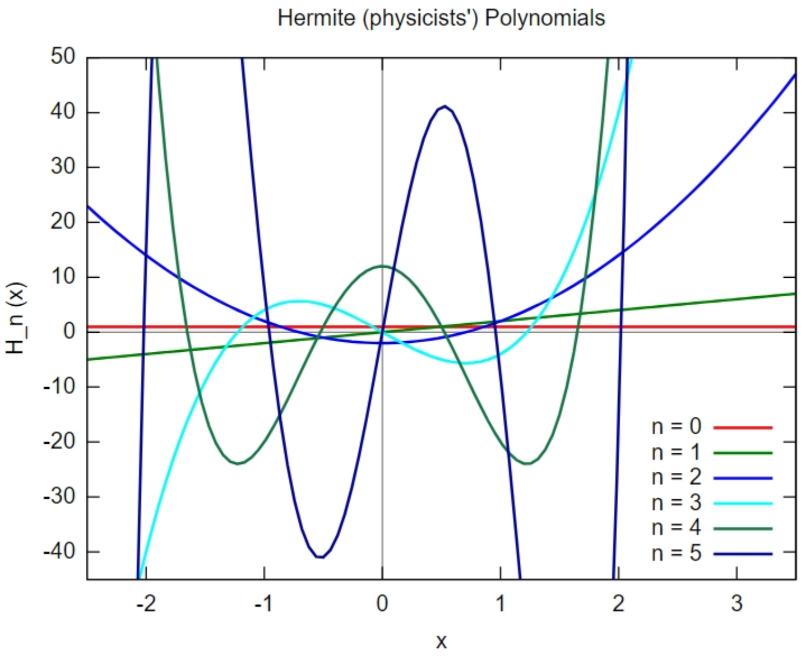

Figure 11.52: First five (physicists) Hermite polynomials (source: Wikipedia)

By using these physicists' Hermite polynomials, the notation of:

$$\Psi_n=(-1)^n\sqrt{\frac{1}{2^n n!}}\left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4}\left[e^{Q^2/2}\frac{\mathrm{d}^n}{\mathrm{d}Q^n}e^{-Q^2/2}\right]e^{-Q^2/2} \tag{11.2.659}$$

---

[13] If you don't remember what is the weight function, you can refer of the section of Function Analysis

is simplified and becomes:

$$\boxed{\Psi_n=\sqrt{\frac{1}{2^n n!}}\left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4}e^{-Q^2/2}H_n(Q)=N_n e^{-Q^2/2}H_n(Q)} \qquad (11.2.660)$$

where N_n is the normalization constant. Thus fully explicitly:

$$\Psi_n=(-1)^n\sqrt{\frac{1}{2^n n!}}\left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4}e^{-\frac{\left(\sqrt{\frac{\omega_0 m}{\hbar}}x\right)^2}{2}}\left[e^{\frac{\left(\sqrt{\frac{\omega_0 m}{\hbar}}x\right)^2}{2}}\frac{\mathrm{d}^n}{\mathrm{d}\left(\sqrt{\frac{\omega_0 m}{\hbar}}x\right)^n}e^{-\left(\sqrt{\frac{\omega_0 m}{\hbar}}x\right)^2}\right] \qquad (11.2.661)$$

These polynomials therefore constitute an orthonormal basis of the global quantum state and thus appear naturally in the general expression of the functions / eigenstates.

Finally we have (keeping in mind that $H_0=1$, $H_1=2Q$, $H_2=4Q^2-2$, $H_3=8Q^3-12Q$, ...):

$\boldsymbol{n}$	$\boldsymbol{E_n}$	$\boldsymbol{\Psi_n}$
0	$\frac{1}{2}\hbar\omega_0$	$\left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4}e^{-\frac{\omega_0 m}{\hbar}\frac{x^2}{2}}$
1	$\frac{3}{2}\hbar\omega_0$	$-\sqrt{\frac{1}{2}}\left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4}2\sqrt{\frac{\omega_0 m}{\hbar}}xe^{-\frac{\omega_0 m}{\hbar}\frac{x^2}{2}}$
2	$\frac{5}{2}\hbar\omega_0$	$\sqrt{\frac{1}{8}}\left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4}\left(4\frac{\omega_0 m}{\hbar}x^2-2\right)e^{-\frac{\omega_0 m}{\hbar}\frac{x^2}{2}}$
3	$\frac{7}{2}\hbar\omega_0$	$-\sqrt{\frac{1}{48}}\left(\frac{m\omega_0}{\pi\hbar}\right)^{1/4}\left(8\left(\frac{\omega_0 m}{\hbar}\right)^{3/2}x^3-12\sqrt{\frac{\omega_0 m}{\hbar}}x\right)e^{-\frac{\omega_0 m}{\hbar}\frac{x^2}{2}}$
...	...	...

Table 11.8: **First eigenfunctions and eigenvalues for the 1D harmonic oscillator**

Remark

The reader may notice that if we put $\sigma:=\sqrt{\hbar/(2\omega_0 m)}$ the fundamental mode density probability has a bell (Normal) shape:

$$\Psi_0=\sqrt{\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{x^2}{4\sigma^2}}}\Rightarrow|\Psi_0|^2=\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{x^2}{2\sigma^2}}=\mathcal{N}(0,\sigma^2) \qquad (11.2.662)$$

With the no less famous graphic representation with on the left the eigenfunctions associated Ψ_n and on the right the probability of presence $|\Psi_n|^2$:

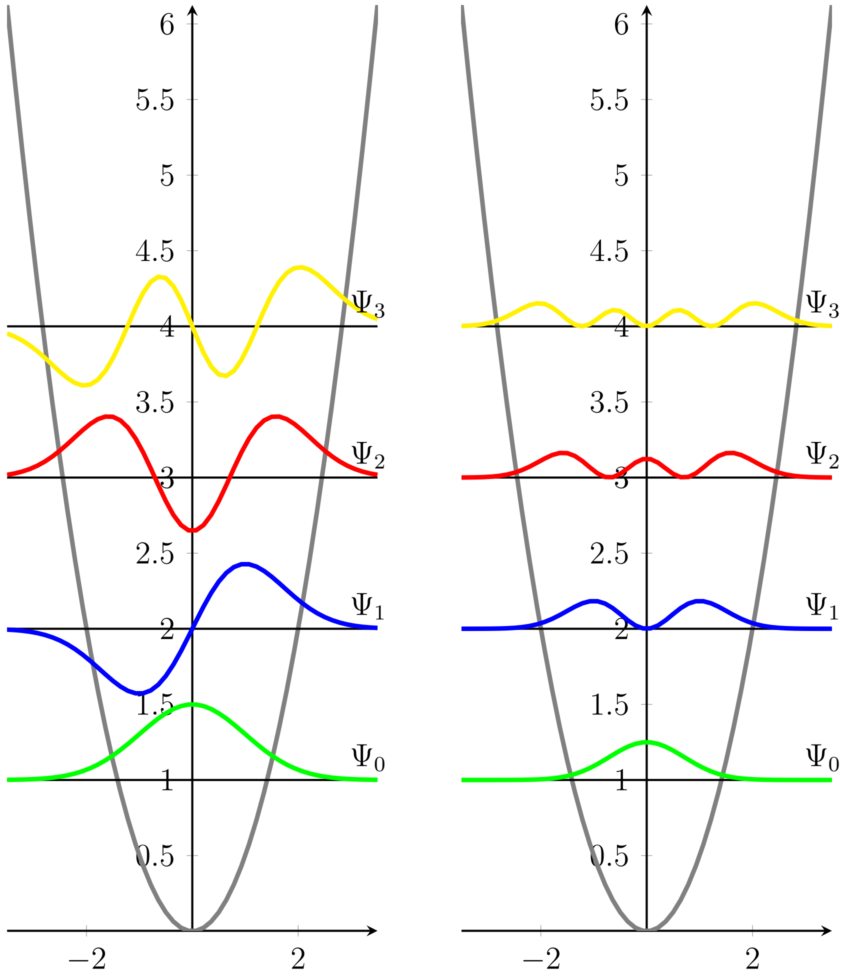

Figure 11.53: Plot of first eigenfunctions and density functions of some energy levels of the 1D harmonic oscillator

We can easily get the left part with Maple™ 4.00b (the example below is not normalized from hence the abscissa which is a bit special compared to the figure above!):

```
>m:=1;omega:=1;h:=1;
>plot([(m*omega/(Pi*h))^(-1/8)*exp(-m*omega*x^2/(2*h)),-((m*omega/(Pi*h))
^(1/4)*2)^(-1/2)*2*sqrt(m*omega/h)*x*exp(-m*omega*x^2/(2*h)),((m*omega/(Pi*h))
^(1/4)*8)^(-1/2)*(4*m*omega/h*x^2-2)*exp(-m*omega*x^2/(2*h)),-((m*omega
/(Pi*h))^(1/4)*48)^(-1/2)*(8*(m*omega/h)^(2/3)*x^3-12*sqrt(m*omega/h)*x)
*exp(-m*omega*x^2/(2*h))],x=-6..6);
```

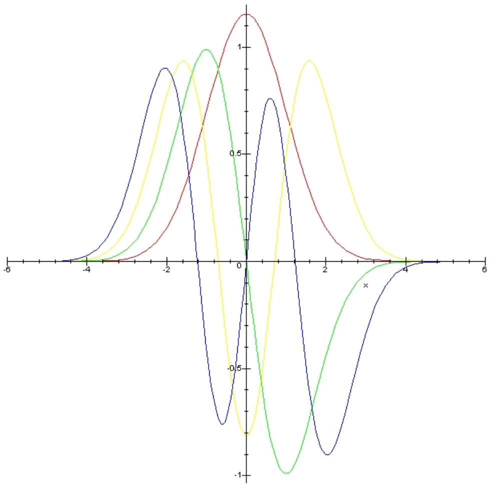

Figure 11.54: Plot of first eigenfunctions of the 1D harmonic oscillator in Maple™ 4.00b

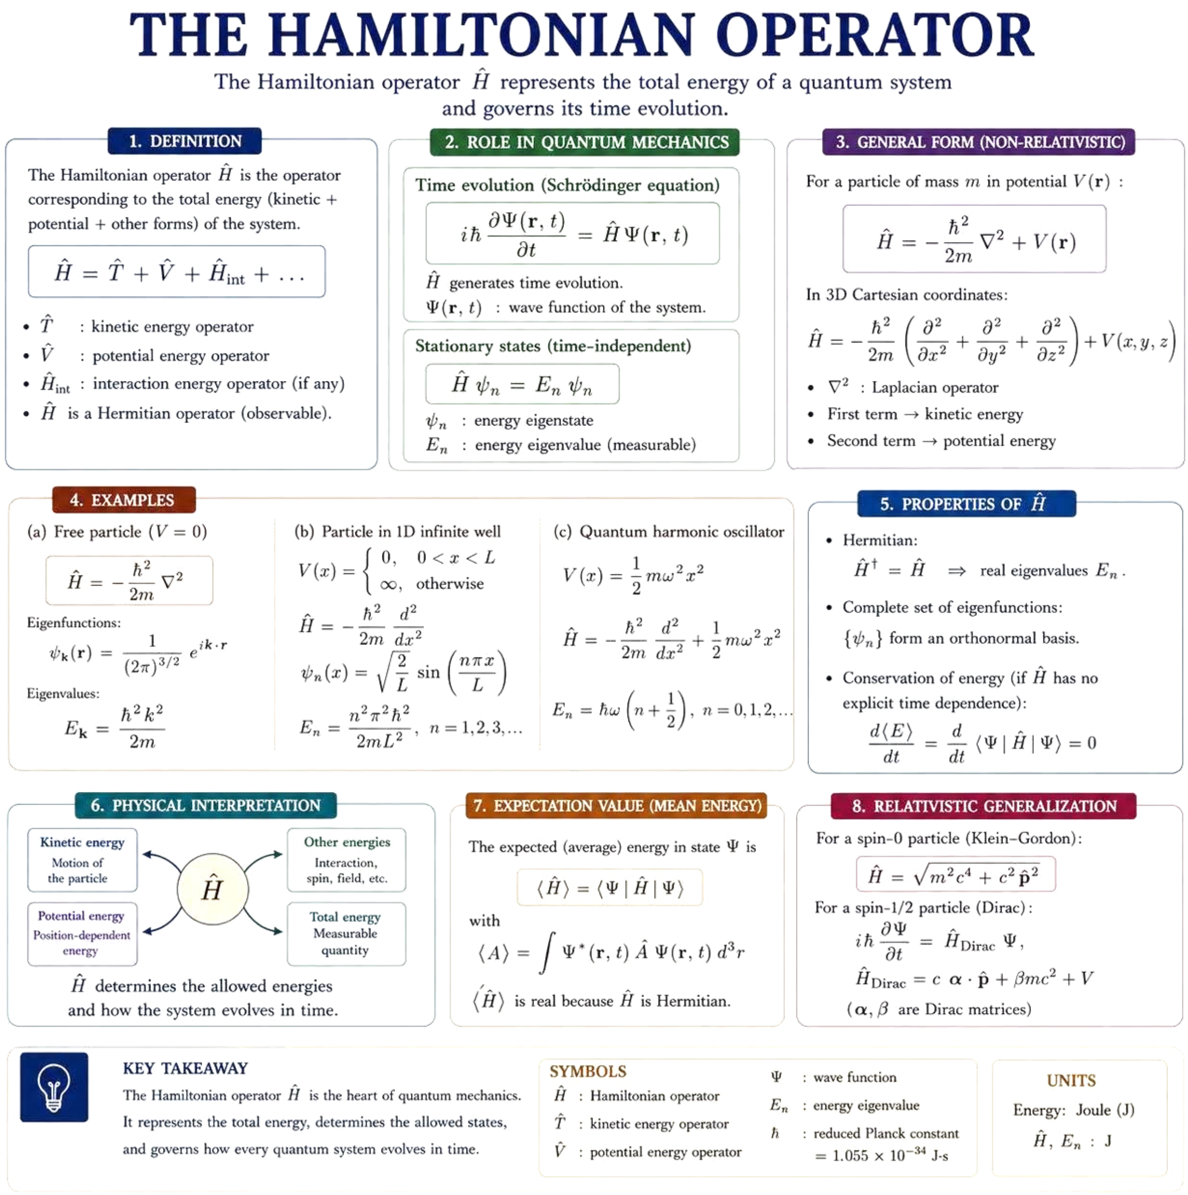
By analysing these wave functions, we fall back on many classical results: the particle in the potential well has a wider probability of presence if it has a higher energy (a ball at the bottom of a well will rise higher on The edges if it has more energy), the particle is more likely to find itself on the positions distant from the center of the well when its energy is high.

For all calculations where particles are in a potential well, the harmonic approximation is very interesting. For example, if we wish to study a two-dimensional "harmonic trap", i.e. 2D Bose-Einstein condensate (see section Statistical Mechanics page 3576), we can set the following Hamiltonian to begin the study (in analogy with the one at 1 dimension used above):

$$H=\frac{p_x^2+p_y^2}{2m}+\frac{1}{2}m\omega_0^2\left(x^2+y^2\right) \tag{11.2.663}$$



THE HAMILTONIAN OPERATOR

The Hamiltonian operator $\hat{H}$ represents the total energy of a quantum system and governs its time evolution.

1. DEFINITION

The Hamiltonian operator $\hat{H}$ is the operator corresponding to the total energy (kinetic + potential + other forms) of the system.

$$\boxed{\hat{H} = \hat{T} + \hat{V} + \hat{H}_{\text{int}} + \dots}$$

- $\hat{T}$: kinetic energy operator
- $\hat{V}$: potential energy operator
- $\hat{H}_{\text{int}}$: interaction energy operator (if any)
- $\hat{H}$ is a Hermitian operator (observable).

2. ROLE IN QUANTUM MECHANICS

Time evolution (Schrödinger equation)

$$\boxed{i\hbar\,\frac{\partial \Psi(\mathbf{r},t)}{\partial t} = \hat{H}\,\Psi(\mathbf{r},t)}$$

$\hat{H}$ generates time evolution.

$\Psi(\mathbf{r},t)$: wave function of the system.

Stationary states (time-independent)

$$\boxed{\hat{H}\,\psi_n = E_n\,\psi_n}$$

ψ_n : energy eigenstate

E_n : energy eigenvalue (measurable)

3. GENERAL FORM (NON-RELATIVISTIC)

For a particle of mass m in potential $V(\mathbf{r})$:

$$\boxed{\hat{H} = -\frac{\hbar^2}{2m}\nabla^2 + V(\mathbf{r})}$$

In 3D Cartesian coordinates:

$$\hat{H} = -\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) + V(x,y,z)$$

- ∇^2 : Laplacian operator
- First term → kinetic energy
- Second term → potential energy

4. EXAMPLES

(a) Free particle ($V = 0$)

$$\boxed{\hat{H} = -\frac{\hbar^2}{2m}\nabla^2}$$

Eigenfunctions:

$$\psi_{\mathbf{k}}(\mathbf{r}) = \frac{1}{(2\pi)^{3/2}}\,e^{i\mathbf{k}\cdot\mathbf{r}}$$

Eigenvalues:

$$E_{\mathbf{k}} = \frac{\hbar^2 k^2}{2m}$$

(b) Particle in 1D infinite well

$$V(x) = \begin{cases} 0, & 0 < x < L \\ \infty, & \text{otherwise} \end{cases}$$

$$\hat{H} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2}$$

$$\psi_n(x) = \sqrt{\frac{2}{L}}\,\sin\left(\frac{n\pi x}{L}\right)$$

$$E_n = \frac{n^2\pi^2\hbar^2}{2mL^2}, \quad n = 1, 2, 3, \dots$$

(c) Quantum harmonic oscillator

$$V(x) = \frac{1}{2}m\omega^2 x^2$$

$$\hat{H} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{1}{2}m\omega^2 x^2$$

$$E_n = \hbar\omega\left(n + \frac{1}{2}\right), \quad n = 0, 1, 2, \dots$$

5. PROPERTIES OF $\hat{H}$

- Hermitian:

  $\hat{H}^\dagger = \hat{H} \quad \Rightarrow \quad$ real eigenvalues E_n .
- Complete set of eigenfunctions:

  $\{\psi_n\}$ form an orthonormal basis.
- Conservation of energy (if $\hat{H}$ has no explicit time dependence):

$$\frac{d\langle E\rangle}{dt} = \frac{d}{dt}\langle\Psi\,|\,\hat{H}\,|\,\Psi\rangle = 0$$

6. PHYSICAL INTERPRETATION

Kinetic energy
Motion of the particle

Other energies
Interaction, spin, field, etc.

$\hat{H}$

Potential energy
Position-dependent energy

Total energy
Measurable quantity

$\hat{H}$ determines the allowed energies and how the system evolves in time.

7. EXPECTATION VALUE (MEAN ENERGY)

The expected (average) energy in state Ψ is

$$\boxed{\langle\hat{H}\rangle = \langle\Psi\,|\,\hat{H}\,|\,\Psi\rangle}$$

with

$$\langle A\rangle = \int \Psi^*(\mathbf{r},t)\,\hat{A}\,\Psi(\mathbf{r},t)\,d^3r$$

$\langle\hat{H}\rangle$ is real because $\hat{H}$ is Hermitian.

8. RELATIVISTIC GENERALIZATION

For a spin-0 particle (Klein–Gordon):

$$\boxed{\hat{H} = \sqrt{m^2c^4 + c^2\hat{\mathbf{p}}^2}}$$

For a spin-1/2 particle (Dirac):

$$i\hbar\,\frac{\partial\Psi}{\partial t} = \hat{H}_{\text{Dirac}}\,\Psi,$$

$$\hat{H}_{\text{Dirac}} = c\;\boldsymbol{\alpha}\cdot\hat{\mathbf{p}} + \beta mc^2 + V$$

($\boldsymbol{\alpha}, \beta$ are Dirac matrices)

KEY TAKEAWAY

The Hamiltonian operator $\hat{H}$ is the heart of quantum mechanics. It represents the total energy, determines the allowed states, and governs how every quantum system evolves in time.

SYMBOLS

$\hat{H}$: Hamiltonian operator

$\hat{T}$: kinetic energy operator

$\hat{V}$: potential energy operator

Ψ : wave function

E_n : energy eigenvalue

$\hbar$: reduced Planck constant $= 1.055 \times 10^{-34}$ J·s

UNITS

Energy: Joule (J)

$\hat{H}$, E_n : J

11.2.4.4.7 Planck's Zero-Point Energy

The assumption of discrete radiation energy in Planck's 11901 (holocene calendar) radiation law, conflicted with Planck's intuition in radiation of continuous waves. To reconcile his quantum hypothesis with his conception of wave radiation, he avoided the conclusion that radiation energy must be made of particles, and postulated that radiation is a transition between the energy levels of an oscillator. Furthermore, ignoring the symmetry between emission and absorption, he maintained that the absorption of radiation energy is continuous.

Under these assumptions, Planck derived in 11912 (holocene calendar), a second radiation law in which zero-point energy also appears. We will show that Planck's derivation of his 11912 (holocene calendar) radiation law only recovers the zero-point energy that he unknowingly assumed in his model from the start. Furthermore, the distribution of 11912 (holocene calendar) Planck's law radiation law is, in fact, the approximated 11901 (holocene calendar Boson statistics of Planck's radiation law.

Remark

Our study earlier of the Quantum oscillator and also the following study of Planck's 11912 (holocene calendar) radiation law are two of the many derivation of zero-point energy that all lead to the same result. There are other famous derivations like the one based on the Heisenberg uncertainty relations or based on Quantum Field Theory.

Our main result is that Planck's ZPE radiation law is equivalent to the combined three assumptions of zero-point energy hypothesis, the Quantum Law, and the approximated Boson Statistics distribution law. The validity of Planck's 11912 (holocene calendar) radiation law, and the existence of Planck's zero-point energy are doubtful.

Planck's 11912 (holocene calendar) oscillator model assumes[14] a probability p_ω for the oscillator to radiate, and a probability $q_\omega = 1 - p_\omega$ to not radiate. He assumes afterwards in a quite non-intuitive way (see above page 4814):

- Energy of $\frac{1}{2}\hbar\omega$ with probability $p_{\omega,1}$
- Energy of $\frac{3}{2}\hbar\omega$ with probability $p_{\omega,2} = p_{\omega,1}q_\omega$
- ...
- Energy of $\frac{2n-1}{2}\hbar\omega$ with probability $p_{\omega,n} = p_{\omega,1}q_\omega^{n-1}$

Since (using the result of geometric series as proved page 1679):

$$1 = p_{\omega,1} + p_{\omega,2} + \ldots = p_{\omega,1}\left(1 + q_\omega + q_\omega^2 + \ldots\right) = \frac{p_{\omega,1}}{1 - q_\omega} = \frac{p_{\omega,1}}{p_\omega} \tag{11.2.664}$$

We put:

$$p_{\omega,1} = p_\omega, \quad \text{therefore} \quad p_{\omega,n} = p_\omega q_\omega^{n-1} \tag{11.2.665}$$

---

[14] The texts and developments that follow are copied from [124].

Therefore, the oscillator average entropy is:

$$\begin{aligned}
\bar{S}_\omega &= -k\left(p_{\omega,1}\ln(p_{\omega,1})+p_{\omega,2}\ln(p_{\omega,2})+\ldots\right)\\
&= -kp_\omega\left(\ln(p_\omega)+q_\omega\ln(p_\omega q_\omega)+q_\omega^2\ln(p_\omega q_\omega^2)+\ldots\right)\\
&= -kp_\omega\left(1+q_\omega+q_\omega^2+\ldots\right)\ln(p_\omega)-kp_\omega q_\omega\left(1+2q_\omega+3q_0^2+\ldots\right)\ln(q_\omega)\\
&= -kp_\omega\ln(p_\omega)\frac{1}{1-q_\omega}-kp_\omega q_\omega\ln(q_\omega)\frac{\mathrm{d}}{\mathrm{d}q_\omega}\left(1+q_\omega+q_\omega^2+\ldots\right)\\
&= -kp_\omega\ln(p_\omega)\frac{1}{1-q_\omega}-kp_\omega q_\omega\ln(q_\omega)\frac{\mathrm{d}}{\mathrm{d}q_\omega}\frac{1}{1-q_\omega}\\
&= -kp_\omega\ln(p_\omega)\frac{1}{1-q_\omega}-kp_\omega q_\omega\ln(q_\omega)\frac{1}{(1-q_\omega)^2}\\
&= -k(1-q_\omega)\ln(p_\omega)\frac{1}{1-q_\omega}-k(1-q_\omega)(1-p_\omega)\ln(1-p_\omega)\frac{1}{(1-q_\omega)^2}\\
&= -k\ln(p_\omega)-k\frac{1-p_\omega}{p_\omega}\ln\left(1-p_\omega\right)\\
&= k\left\{-\ln(p_\omega)-\frac{1-p_\omega}{p_\omega}\ln\left(\frac{1-p_\omega}{p_\omega}\right)-\frac{1-p_\omega}{p_\omega}\ln(p_\omega)\right\}\\
&= k\left\{\frac{1}{p_\omega}\ln\left(\frac{1}{p_\omega}\right)-\left(\frac{1}{p_\omega}-1\right)\ln\left(\frac{1}{p_\omega}-1\right)\right\}
\end{aligned} \tag{11.2.666}$$

The expected mean radiation energy of an oscillator is:

$$\begin{aligned}
\bar{E}_\omega &= \frac{1}{2}\hbar\omega p_{\omega,1}+\frac{3}{2}\hbar\omega p_{\omega,2}+\frac{5}{2}\hbar\omega p_{\omega,3}+\frac{7}{2}\hbar\omega p_{\omega,4}+\ldots\\
&= \frac{1}{2}\hbar\omega p_\omega\left\{1+3q_\omega+5q_\omega^2+7q_\omega^3+\ldots\right\}\\
&= \frac{1}{2}\hbar\omega p_\omega\left\{\left(1+q_\omega+q_\omega^2+q_\omega^3\ldots\right)+2q_\omega\left(1+2q_\omega+3q_\omega^2\cdots\right)\right\}\\
&= \frac{1}{2}\hbar\omega p_\omega\left\{\frac{1}{1-q_\omega}+2q_\omega\frac{\mathrm{d}}{\mathrm{d}q_\omega}\left(1+q_\omega+q_\omega^2+q_\omega^3+\ldots\right)\right\}\\
&= \frac{1}{2}\hbar\omega p_\omega\left\{\frac{1}{p_\omega}+2q_\omega\frac{\mathrm{d}}{\mathrm{d}q}\frac{1}{1-q_\omega}\right\}=\frac{1}{2}\hbar\omega p_\omega\left\{\frac{1}{p_\omega}+2q_\omega\frac{1}{(1-q_\omega)^2}\right\}\\
&= \hbar\omega\left\{\frac{1}{2}+(1-p_\omega)\frac{1}{p_\omega}\right\}=\hbar\omega\left(\frac{1}{p_\omega}-\frac{1}{2}\right)
\end{aligned} \tag{11.2.667}$$

Therefore $\bar{S}_\omega$ in terms of $\bar{E}_\omega$ is:

$$\bar{S}_\omega=k\left\{\left(\frac{\bar{E}_\omega}{\hbar\omega}+\frac{1}{2}\right)\ln\left(\frac{\bar{E}_\omega}{\hbar\omega}+\frac{1}{2}\right)-\left(\frac{\bar{E}_\omega}{\hbar\omega}-\frac{1}{2}\right)\ln\left(\frac{\bar{E}_\omega}{\hbar\omega}-\frac{1}{2}\right)\right\} \tag{11.2.668}$$

Using $\Delta S=\Delta Q/T$ (see section Thermodynamics page 3658) that leads us to:

$$\frac{\partial\bar{S}_\omega}{\partial\bar{E}_\omega}=\frac{1}{T} \tag{11.2.669}$$

Hence:

$$\frac{\partial\bar{S}_\omega}{\partial\bar{E}_\omega}=\frac{1}{T}=k\left(\frac{\ln\left(\frac{\bar{E}_\omega}{\hbar\omega}+\frac{1}{2}\right)}{\hbar\omega}-\frac{\ln\left(\frac{\bar{E}_\omega}{\hbar\omega}-sols\frac{1}{2}\right)}{\hbar\omega}\right) \tag{11.2.670}$$

Solving for $\bar{E}_\omega$ gives:

$$\bar{E}_\omega = \frac{1}{2}\frac{\hbar\omega\,(1+\exp(\hbar\omega/kT))}{\exp(\hbar\omega/kT)-1} \qquad (11.2.671)$$

that after rearranging gives us the "Planck's 11912 (holocene calendar) radiation law":

$$\boxed{\bar{E}_\omega = \frac{\hbar\omega}{\exp(\hbar\omega/kT)-1}+\frac{1}{2}\hbar\omega} \qquad (11.2.672)$$

The zero-point energy of $\frac{1}{2}\hbar\omega$ is the mid-energy that was assumed with probability p_ω. Planck's derivation only recovers the ZPE that he assumed at the start.

As already mentioned, the Casimir force (see page 4825) between two plates is related to the zero-point energy of the electromagnetic field. The zero-point energy appeared for the first time in Planck's "second theory" of black-body radiation, more than a decade before it was actually derived from Heisenberg's matrix mechanics in 11925 (holocene calendar) Planck obtained the expression:

$$\bar{E}_\omega = \frac{\hbar\omega}{\exp(\hbar\omega/kT)-1}+\frac{1}{2}\hbar\omega \qquad (11.2.673)$$

for the average energy of an oscillator of frequency ω in equilibrium with radiation at temperature T. When $T\rightarrow 0$, $\bar{E}_\omega \rightarrow \frac{1}{2}\hbar\omega$. In other words, Planck's work implied the existence of a zero-point energy persisting even at the absolute zero of temperature where, according to conventional classical theory, all motion ceases and given by:

$$\boxed{E_{\text{ZPE}} = \frac{1}{2}\hbar\omega} \qquad (11.2.674)$$

Planck soon became convinced that this constant additive zero-point energy is of no physical consequence. Albert Einstein, however, was intrigued by the idea. In a paper with Otto Stern in 11913 (holocene calendar), he noted that a zero-point energy seems necessary in order for the relation:

$$\bar{E}_\omega = U = \frac{\hbar\omega}{\exp(\hbar\omega/kT)-1}+\frac{1}{2}\hbar\omega \qquad (11.2.675)$$

to give the classical relation $U=kT$ in the classical limit $kT \gg \hbar\omega$. In this limit, retaining terms up to first order in $\hbar\omega/kT$:

$$\begin{aligned} U &= \frac{\hbar\omega}{\exp(\hbar\omega/kT)-1}+\frac{1}{2}\hbar\omega \cong \frac{\hbar\omega}{1+\hbar\omega/kT+\frac{1}{2}(\hbar\omega/kT)^2-1}+\frac{1}{2}\hbar\omega \\ &= \frac{kT}{1+\frac{1}{2}\hbar\omega/kT}+\frac{1}{2}\hbar\omega \cong kT-\frac{1}{2}\hbar\omega+\frac{1}{2}\hbar\omega = kT \end{aligned} \qquad (11.2.676)$$

The zero-point energy $\frac{1}{2}\hbar\omega$ is thus necessary in order that U does not have first-order quantum corrections to kT in the classical limit $kT \gg \hbar\omega$. For this and other reasons, Einstein and Stern concluded, The existence of a zero-point energy $\left[\frac{1}{2}\hbar\omega\right]$ is probable.

Zero-point energy was a "hot topic" during the decade preceding Heisenberg's matrix mechanics and Schrödinger's wave mechanics, mainly because of the great interest at the time in low-temperature phenomena such as superconductivity. Debye, for instance, showed that, if Planck's zero-point energy were real, there should be a reduction in the X-ray scattering from crystals even as $T \rightarrow 0$ because of zero-point fluctuations about the lattice sites. Mulliken's spectroscopic studies indicates that a zero-point energy of molecular vibrations was necessary to fit the data accurately, and Stern found a zero-point energy to be necessary in calculating the vapour pressure of solids. Early ideas about the zero-point energy have been reviewed elsewhere (see [394]).

It is typical in more recent times for textbooks to regard the zero-point energy as a curious prediction of quantum theory that can be discarded by simply redefining the zero of energy. This can be misleading if it implies that the zero-point energy is of no physical consequence whatsoever, for it turns out that changes in the zero-point energy are observable. The most precise observations have been made in connection with changes in the electromagnetic zero-point energy.

Many physical effects attributed to zero-point energy have been experimentally verified, such as (according to the scientific consensus in the early 121st century) spontaneous emission, Casimir force, Lamb shift, magnetic moment of the electron and Delbrück scattering. These effects are usually named "radiative corrections". In more complex non-linear theories (e.g. QCD) zero-point energy can give rise to a variety of complex phenomena such as multiple stable states, symmetry breaking, chaos and emergence. Many physicists think that the vacuum may hold one of the main key to a full understanding of Nature and that studying it is critical in the search for the theory of everything. Active areas of research include the effects of virtual particles, quantum entanglement, the difference (if any) between inertial and gravitational mass, variation in the speed of light, a reason for the observed value of the cosmological constant and the nature of dark energy.

The vacuum has, implicitly, all of the properties that a particle may have: spin, or polarization in the case of light, energy, and so on. On average, most of these properties cancel out: the vacuum is, after all, "empty" in this sense. One important exception is the vacuum energy or the vacuum expectation value of the energy.

11.2.4.4.8 Electromagnetic Casimir Force

What happens if we take two (almost) perfect mirrors (conductors or insulator) and arrange them so that they are facing each other a few nanometres apart in empty space (assumed as because we will see during study of quantum field theory that there are not such things as "empty space")? Your first reaction might be “nothing at all”. In fact, both mirrors are mutually attracted to each other by the simple presence of the vacuum[15].

This startling phenomenon was first predicted in 11948 (holocene calendar) by the Dutch theoretical physicist Hendrik Casimir while he was working at Philips Research Laboratories in Eindhoven on – of all things – colloidal solutions. The phenomenon is now named the "Casimir effect", while the force between the mirrors is known as the "Casimir force".

The Casimir effect is important because it gives strong evidence that the vacuum is not empty but a dynamical medium with properties (like $\varepsilon_0, \mu_0, \Lambda ...$) that led to an emergence point of view of elementary particles: they are collective motions of the vacuum medium!

---

[15] Some configurations may produce repulsive Casimir forces and these latter seems to have been confirmed experimentally (see [404]).

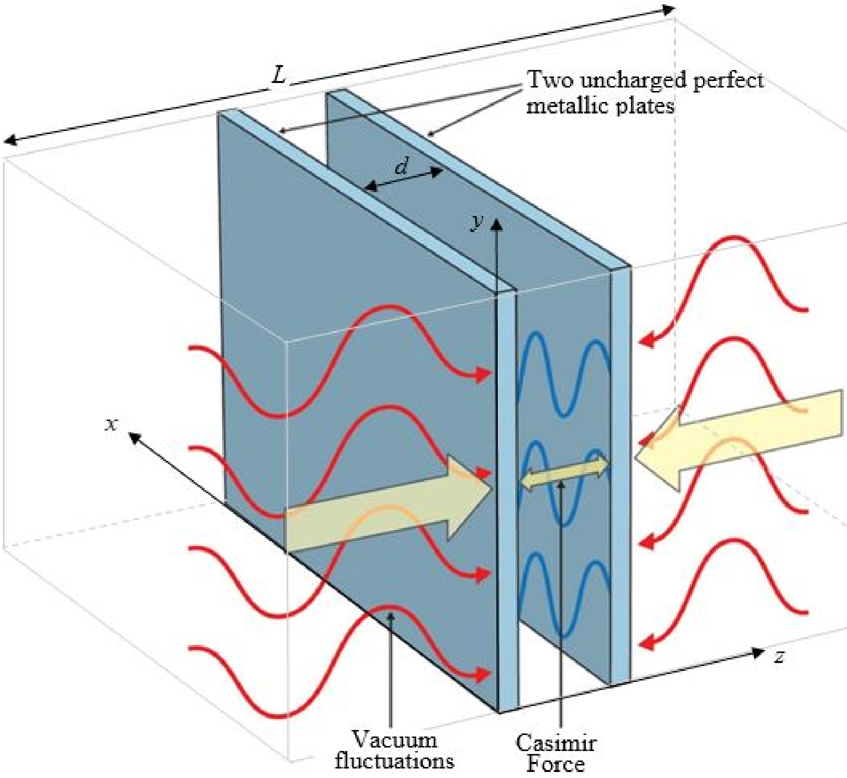
The experimental configuration of the Casimir force involving electromagnetic radiation is named "Electromagnetic Casimir force" because there are also theories involving the same type of force but for gravitation named "Gravitational Casimir force".

Remark

Some physicists disagree with this point of view (i.e. vacuum fluctuation cause) and argue - some with poor mathematical proofs and some others with not bad one - that the phenomenon is due to pure Van der Waals forces. However the Van der Waals forces seems not to be able yet to explain the case where the experimental configuration generates a repulsive force. However careful and always more precise experiments seems still in year 12020 (holocene calendar) to favour the quantum fluctuation option and therefore be a plausible explanation of dark energy too (see [377] for more details). More investigations are needed to get to a conclusive fact!

11.2.4.4.8.1 One dimensional case (naive approach)

Consider for our introduction to the study of that phenomenon, the following configuration:



It is an ideal condenser with infinite perfectly conducting plates in the x and y directions separated by a distance d along the z direction (the origin of the z axis is located on the left plate).

All electromagnetic fields have a characteristic "spectrum" containing many different frequencies. In a free vacuum all of the frequencies are of equal importance. But inside a cavity, where the field is reflected back and forth between the mirrors, the situation is different. The field is amplified if integer multiples of half a wavelength can fit exactly inside the cavity. This wavelength corresponds to a "cavity resonance". At other wavelengths, in contrast, the field is suppressed. Vacuum fluctuations are suppressed or enhanced depending on whether their frequency corresponds to a cavity resonance or not.

And to begin, for pedagogical reasons, we will consider the side view (profile) of the above configuration to deal with the one-dimensional case (along the z axis).

When two plates are at a distance d from each other, because of the boundary conditions the field modes which may exist between them are restricted to wavelengths which are whole fractions of d (otherwise particle from vacuum would be absorbed by the plates and it may violated conservation energy).

Let us recall that the electromagnetic zero-point energy is given by (see page 4822):

$$E_{\text{ZPE}}=\frac{1}{2}\hbar\omega=\frac{1}{2}\hbar 2\pi f=\frac{1}{2}\hbar 2\pi\frac{c}{\lambda}=\frac{\hbar c\pi}{\lambda} \tag{11.2.677}$$

Then if we consider only one dimension of space, the zero-point energy of mode n, using (see section Mechanics page 3485):

$$\lambda=\frac{2d}{n} \tag{11.2.678}$$

is then equal to:

$$E_{\text{ZPE},n}=\frac{n\hbar c\pi}{2d} \tag{11.2.679}$$

If we sum over all the modes, we therefore have the total zero-point energy as a function of the distance between the plates d which is equal to:

$$E_{\text{ZPE},n}(d)=\frac{\hbar c\pi}{2d}\left(\sum_{n=1}^{+\infty}n\right) \tag{11.2.680}$$

We can use the Riemann zeta regularization result (see section Sequences and Series page 1683):

$$\zeta(-1)=\sum_{n=1}^{+\infty}n=-\frac{1}{12} \tag{11.2.681}$$

and then we get:

$$E_{\text{ZPE}}(d)=-\frac{\hbar c\pi}{24d} \tag{11.2.682}$$

We can then derive the 1D electromagnetic vacuum force exerted on the plates by deriving the energy with respect to d:

$$\boxed{F_{\text{ZPE}}^{\text{Casimir}}(d)=\frac{\mathrm{d}E_{\text{ZPE}}(d)}{\mathrm{d}d}=\frac{\hbar c\pi}{24d^2}} \tag{11.2.683}$$

But if the reader has a problem with using the equality $\sum_n n=-1/12$, we can look for a more physical justification. When the plates are at a distance d the energy just calculated seems infinite. But if we move the plates away at a great distance, there is always a density energy associated with the modes of the electromagnetic field. The difference is that in this situation the modes are no longer quantized. So we basically have to replace $\sum_n n$ by $\int x\mathrm{d}x$. Here too we get something infinite, but a little bigger. Now if we take this situation as a point of reference and we have take fun subtracting between the two situations (plates at distance d and plates "very far") we find:

$$\Delta E_{\text{ZPE}}(d)=\frac{\hbar c\pi}{2L}\left(\sum_{n=1}^{+\infty}n-\int\limits_0^{+\infty}x\,\mathrm{d}x\right) \tag{11.2.684}$$

So we subtract two infinities... how to do we deal with that?

We simply use the Euler-Maclaurin expansion (see section Sequences and Series page 1674) that gives us:

$$\sum_{n=1}^{+\infty}f(n)-\int\limits_0^{+\infty}f(x)\mathrm{d}x=\frac{1}{2}f(0)-\frac{1}{6\cdot 2!}f'(0)+\ldots=\frac{1}{2}f(0)-\frac{1}{12}f'(0)+\ldots \tag{11.2.685}$$

The funny thing is that if we (illegally) apply this formula to the function $f(x)=x$, we find:

$$\left(\sum_{n=1}^{+\infty}n-\int x\,\mathrm{d}x\right)=-\frac{1}{12} \tag{11.2.686}$$

And we fall back on the Casimir electromagnetic energy (and therefore also the corresponding force).

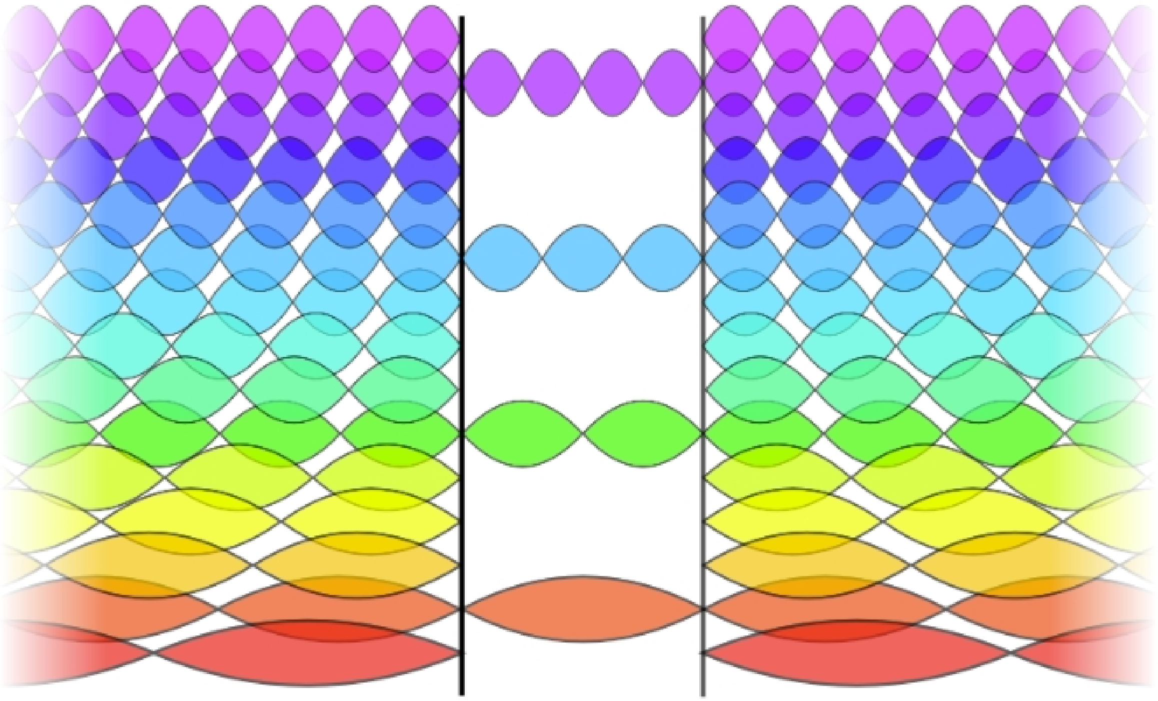


Figure 11.55: Outside the cavity formed by the plates, all vacuum frequencies are allowed. Within the cavity, however, the vacuum modes take on discrete frequencies. Changing the width of the cavity changes the density of modes relative to free space, which yields an energy difference.

On the other hand we could not do:

$$\left(\sum_{n=1}^{+\infty} n - \int x \mathrm{d}x\right) = \frac{n(n+1)}{2} - \int x \mathrm{d}x = -\frac{1}{12} \tag{11.2.687}$$

That latter approach sheds light on the deep origin of $-1/12$. In fact the sum $1+2+3+4+\ldots$ is indeed infinite, but $-1/12$ is what separates it from $\int x\mathrm{d}x$ which is also infinite, is that we can see as a base that we subtract. In Casimir's case, this is indeed the "based level" energy level, when the plates are very far apart.

11.2.4.4.8.2 Three dimensional case

Let us again consider an ideal condenser with infinite perfectly conducting plates in the x and y directions separated by a distance d along the z direction (the origin of the z axis is located on the left plate) as shown earlier above in the figure above.

The interaction energy between the two plates can be defined as the difference between the zero-point energies contained in the space between the planes, in the two respective configurations. This supposes that the field outside the cavity is not changed, which, of course, holds classically. For a discussion of this point, as well as for corrections due the finiteness of the plates. In general, the zero-point energy of the electromagnetic field is given:

$$E_{\text{cav}} = \sum_k g_s(k)\frac{\hbar\omega_k}{2} \tag{11.2.688}$$

where the sum runs over the normal modes of the field, where the ω_k are the frequencies of these modes and where $g_s(k)$ is the degeneracy of the mode k, due to polarization.

Let us start with the case of the cavity. In order to identify the modes more easily, let us consider, as usual, field configurations which are periodic in the x and y directions with wavelengths L_x and L_y respectively. The normal modes are determined by the boundary conditions on the surface of the conductors.

We remind that the tangential electric field and the normal component of the magnetic field should vanish on these boundaries. Let us recall that during our study of Maxwell's equations we have proved that plane wave solutions are given by:

$$\vec{E} = \vec{E}_0 e^{\mathrm{i}(\vec{k}\cdot\vec{x}-\omega t)} \qquad \vec{B} = \vec{B}_0 e^{\mathrm{i}(\vec{k}\cdot\vec{x}-\omega t)} \tag{11.2.689}$$

Here, $\vec{E}_0$ and $\vec{B}_0$ are called the "polarization vectors" for the electric and magnetic fields and often denoted $\vec{\mathcal{E}}$. These are complex 3 dimensional vectors. The wavevector $\vec{k}$ and angular frequency ω are real and in the vacuum are related by $\omega = c|\vec{k}|$.

And remember that:

$$\vec{k}\circ\vec{E}_0 = 0 \qquad \vec{k}\circ\vec{B}_0 = 0 \quad \vec{E}_0\circ\vec{B}_0 = 0 \tag{11.2.690}$$

Let us remind that:

$$k_x = n_x\frac{2\pi}{L_x} \quad \text{and} \quad k_y = n_y\frac{2\pi}{L_y} \tag{11.2.691}$$

where n_x and n_y are integer numbers and with:

$$k_z = n_z \frac{\pi}{d} \tag{11.2.692}$$

where n_z is a positive integer, the vector $\vec{\mathcal{E}}$ is the polarization vector and where $\vec{k} = (k_x, k_y, k_z)$.

Remark

The first case, $k = 2\pi n/L$, corresponds to the solutions of the Schrödinger's equation with zero potential, in the interval $[0, L]$, provided periodic boundary conditions are used, i.e. the wavefunction must satisfy the conditions $\Psi(0) = \Psi(L)$ and $\Psi'(0) = \Psi'(L)$.

The second case, $k = \pi n/d$, corresponds to the solutions of the Schrödinger's equation with zero potential, in the interval $[0, d]$, provided hard wall boundary conditions are used, i.e. the wavefunction must vanish at the boundary points 0 and d.

We consider a conducting box of volume L^3, with an $L \times L$ plate contained within, parallel to the x and y axes of the box.

The conducting walls of the box impose Dirichlet boundary conditions on the possible electromagnetic modes of the cavity: the tangential component of the electromagnetic field must vanish there. Solving the wave equation with these conditions reveals that the boundaries quantize the x, y, and z components of the wavevectors $\vec{k}$, such that they take on the discrete values:

$$k_x = n_x \frac{2\pi}{L} \qquad k_y = n_y \frac{2\pi}{L} \qquad k_z = n_z \frac{\pi}{d} \tag{11.2.693}$$

where:

$$k^2 = k_x^2 + k_y^2 + k_z^2 \tag{11.2.694}$$

In a vacuum, angular frequency ω is related to the wave number k by the speed of light c:

$$\omega = ck \tag{11.2.695}$$

This allows us to express the zero-point energy of the field:

$$E_{\text{ZPE}} = \frac{1}{2} \sum_{\vec{k},\lambda} \hbar\omega \tag{11.2.696}$$

as a sum over quantized modes, identified by k_x, k_y, and k_z:

$$E_{\text{ZPE}} = \hbar c \sum \frac{1}{2} \sqrt{k_x^2 + k_y^2 + k_z^2} \tag{11.2.697}$$

Polarization allows for two waves corresponding to each wave number except when one k_i is 0[16] (the k_z in our present situation!). Therefore, we multiply all $k > 0$ terms by 2, and expand the summation in x, y, and z:

$$E_{\text{ZPE}} = \hbar c \sum_{n_x=0}^{+\infty} \sum_{n_y=0}^{+\infty} \left[\frac{1}{2} \sqrt{\left(\frac{n_x 2\pi}{L}\right)^2 + \left(\frac{n_y 2\pi}{L}\right)^2} + \sum_{n_z=1}^{+\infty} \sqrt{\left(\frac{n_x 2\pi}{L}\right)^2 + \left(\frac{n_y 2\pi}{L}\right)^2 + \left(\frac{n_z \pi}{d}\right)^2} \right] \tag{11.2.698}$$

---

[16] This apparent special case arises from the "folding over" of the sum over both positive and negative $\vec{k}$ (from $-\infty$ to $+\infty$) into a sum from 0 to $+\infty$ - which simplifies evaluation later.

since n_x and n_y are presumed to be very large compared to L, we treat them as continuous variables and convert their sums to integrals, writing:

$$E_{\text{ZPE}}=\hbar c\int\limits_0^{+\infty}\int\limits_0^{+\infty}\frac{1}{2}\sqrt{\left(\frac{n_x2\pi}{L}\right)^2+\left(\frac{n_y2\pi}{L}\right)^2}+\sum_{n_z=1}^{+\infty}\sqrt{\left(\frac{n_x2\pi}{L}\right)^2+\left(\frac{n_y2\pi}{L}\right)^2+\left(\frac{n_z\pi}{a}\right)^2}\mathrm{d}n_x\mathrm{d}n_y \tag{11.2.699}$$

The zero point energy of the cavity for the $k_z\neq 0$ modes (indicated by the prime) is given by:

$$E'_{\text{ZPE}}=\hbar c\sum_{n_x=-\infty}^{+\infty}\sum_{n_y=-\infty}^{+\infty}\sum_{n_z=1}^{+\infty}\sqrt{\left(\frac{n_x2\pi}{L_x}\right)^2+\left(\frac{n_y2\pi}{L_x}\right)^2+\left(\frac{n_z\pi}{d}\right)^2} \tag{11.2.700}$$

As usual, one replaces the summation on n_x and n_y by integration on continuous variables:

$$E'_{\text{ZPE}}=\hbar cL_xL_y\int\limits_{-\infty}^{+\infty}\mathrm{d}n_x\int\limits_{-\infty}^{+\infty}\sum_{n_z=1}^{+\infty}\sqrt{\left(\frac{n_x2\pi}{L_x}\right)^2+\left(\frac{n_y2\pi}{L_x}\right)^2+\left(\frac{n_z\pi}{d}\right)^2}y\mathrm{d}n_y \tag{11.2.701}$$

which causes no difference when the limit $L_x,L_y\rightarrow+\infty$ is taken. Changing variables from n_x,n_y to k_x,k_y, dividing the expression by L_xL_y and taking the limit of L_x and L_y tending to infinity, yields for the energy per unit area:

$$\frac{E'_{\text{ZPE}}}{S}=\hbar c\sum_{n=1}^{+\infty}\int\limits_{-\infty}^{+\infty}\frac{\mathrm{d}k_x}{2\pi}\int\limits_{-\infty}^{+\infty}\sqrt{k_x^2+k_y^2+\left(\frac{n\pi}{d}\right)^2}\frac{\mathrm{d}k_y}{2\pi} \tag{11.2.702}$$

Finally, one integrates over the angle of the wave vector in the $x-y$ plane. To do this we put (polar coordinates transformation):

$$k_x=k_\perp\cos(\theta)\qquad k_y=k_\perp\sin(\theta) \tag{11.2.703}$$

and let us recall that the Jacobian (see section Differential and Integral Calculus page 1528) is $k_\perp$.

Then:

$$\frac{E'_{\text{ZPE}}}{S}=\hbar c\sum_{n=1}^{+\infty}\int\limits_0^{+\infty}k_\perp\frac{\mathrm{d}k_\perp}{2\pi}\int\limits_0^{2\pi}\left[k_\perp^2\sin^2(\theta)+k_\perp^2\cos^2(\theta)+\left(\frac{n\pi}{d}\right)^2\right]^{1/2}\frac{\mathrm{d}\theta}{2\pi} \tag{11.2.704}$$

As there are no θ in the integrand. This simplifies to:

$$\frac{E'_{\text{ZPE}}}{S}=\frac{\hbar c}{2\pi}\sum_{n=1}^{+\infty}\int\limits_0^{+\infty}\sqrt{k_\perp^2+\left(\frac{n\pi}{d}\right)^2}k_\perp\mathrm{d}k_\perp \tag{11.2.705}$$

We introduce now the auxiliary variable:

$$u=\frac{\left(k_x^2+k_y^2\right)d^2}{\pi^2}=\frac{k_\perp^2d^2}{\pi^2}\Rightarrow\mathrm{d}k_\perp=\frac{\pi^2}{2k_\perp d^2}\mathrm{d}u \tag{11.2.706}$$

and get:

$$\frac{E'_{\text{ZPE}}}{S}=\frac{\hbar c}{2\pi}\sum_{n=1}^{+\infty}\int\limits_{0}^{+\infty}\sqrt{\frac{u\pi^2}{d^2}+\left(\frac{n\pi}{d}\right)^2}\frac{\pi^2}{2d^2}\mathrm{d}u=\frac{\hbar c\pi^2}{4d^3}\sum_{n=1}^{+\infty}\int\limits_{0}^{+\infty}\left(u+n^2\right)^{1/2}\mathrm{d}u \tag{11.2.707}$$

We still have to add the contribution of the $k_z=0$ (or $n=0$) modes. One has:

$$\frac{E_{\text{ZPE}}}{S}=\frac{\hbar c\pi^2}{4d^3}\left[\sum_{n=1}^{+\infty}\int\limits_{0}^{+\infty}\left(u+n^2\right)^{1/2}\mathrm{d}u+\frac{1}{2}\int\limits_{0}^{+\infty}\sqrt{u}\mathrm{d}u\right] \tag{11.2.708}$$

This expression is divergent, as is the similar expression for the energy of the free field. It may be hoped that the difference between the two expressions is finite.

We need the value of the energy of the free field in the volume of the cavity. In general, the energy per unit volume is given by[17] (remember that $k=E/\hbar c$ and that the units of k are $[\mathrm{m}^{-1}]$):

$$\begin{aligned}\frac{E_{\text{free}}}{V}&=\frac{1}{L^2d}\sum_{n_x=1}^{+\infty}\sum_{n_y=1}^{+\infty}\sum_{n_z=1}^{+\infty}E(n_x,n_y,n_z)=\frac{1}{L^2d}\int\limits_{0}^{+\infty}\int\limits_{0}^{+\infty}\int\limits_{0}^{+\infty}E(n_x,n_y,n_z)\mathrm{d}n_x\mathrm{d}n_y\mathrm{d}n_z\\&=\frac{1}{L^2d}\int\limits_{0}^{+\infty}\int\limits_{0}^{+\infty}\int\limits_{0}^{+\infty}\hbar ck\mathrm{d}\left(\frac{k_xL}{2\pi}\right)\mathrm{d}\left(\frac{k_yL}{2\pi}\right)\mathrm{d}\left(\frac{k_zL}{2\pi}\right)=\hbar c\int\limits_{0}^{+\infty}\int\limits_{0}^{+\infty}\int\limits_{0}^{+\infty}\frac{k}{(2\pi)^3}\mathrm{d}k_x\mathrm{d}k_y\mathrm{d}k_z\\&=\hbar c\int\frac{k\mathrm{d}^3\vec{k}}{(2\pi)^3}\end{aligned} \tag{11.2.709}$$

It is advantageous to rewrite this expression as:

$$\frac{E_{\text{free}}}{V}=\frac{\hbar c}{(2\pi)^3}\int\mathrm{d}^2\vec{k}_{\perp}\int\sqrt{k_{\perp}^2+k_z^2}\mathrm{d}k_z \tag{11.2.710}$$

or as:

$$\frac{E_{\text{free}}}{V}=\frac{\hbar c}{(2\pi)^2}\int\limits_{0}^{+\infty}k_{\perp}\mathrm{d}k_{\perp}\int\limits_{-\infty}^{+\infty}\sqrt{k_{\perp}^2+k_z^2}\mathrm{d}k_z \tag{11.2.711}$$

Taking account of the fact that the integrand is an even function of k_z and introducing the auxiliary variables $u=k_{\perp}^2d^2/\pi^2$ and $x=k_z/d$ lead to:

$$\frac{E_{\text{free}}}{V}=\frac{\hbar c\pi^2}{4d^4}\int\limits_{0}^{+\infty}\mathrm{d}x\int\limits_{0}^{+\infty}\sqrt{u+x^2}\mathrm{d}u \tag{11.2.712}$$

The energy of the free field in the volume of the cavity is thus obtained by multiplying this expression by the volume V (equal to $S\cdot d$). One then obtains for the change in the zero-point energy per unit surface:

$$\frac{\Delta E_{\text{ZPE}}}{S}=\frac{E_{\text{cav}}}{S}-\frac{E_{\text{free}}}{S}=\frac{\hbar c\pi^2}{4d^3}\left\{\frac{1}{2}\int\limits_{0}^{+\infty}\sqrt{u}\mathrm{d}u+\sum_{n=1}^{+\infty}\int\limits_{0}^{+\infty}\left(u+n^2\right)^{1/2}\mathrm{d}u-\int\limits_{0}^{+\infty}\mathrm{d}x\int\limits_{0}^{+\infty}\left(u+x^2\right)^{1/2}\mathrm{d}u\right\} \tag{11.2.713}$$

---

[17] The $\vec{k}=\vec{0}$ mode does not pose any worry, since its contribution is vanishing.

All terms in the right hand side are divergent! We will come to this problem soon more in details.

Notice that it is remarkable that this expression involves the difference between the integral from zero to infinity of the function $f(x)=\int\limits_0^{+\infty}(u+x^2)^{1/2}\,\mathrm{d}u$ and the sum of the values of this function on the positive integers. As we know, there is a famous theorem by Euler and Maclaurin connecting these quantities, in general (see section Sequences and Series page 1674). It states that:

$$\begin{aligned}\sum_{n=1}^{+\infty} f(n)&=\int\limits_0^{+\infty} f(x)\mathrm{d}x-\frac{1}{2}[f(0)+f(\infty)]+\frac{1}{6\cdot 2!}\left[f'(\infty)-f'(0)\right]-\frac{1}{30\cdot 4!}\left[f'''(\infty)-f'''(0)\right]+\ldots\\&=\int\limits_0^{+\infty} f(x)\mathrm{d}x-\frac{1}{2}[f(0)+f(\infty)]+\frac{1}{12}\left[f'(\infty)-f'(0)\right]-\frac{1}{720}\left[f'''(\infty)-f'''(0)\right]+\ldots\end{aligned}\tag{11.2.714}$$

where the dots indicates similar terms for higher order odd derivatives. The coefficients in front of the brackets are related to the Bernoulli numbers B_i : they are equal to $-B_{2k}/(2k)!$ for the term involving the derivatives of order $2k-1$.

We can write the function $f(x)$ mentioned above as (replacing $u+x^2=t$):

$$f(x)=\int\limits_0^{+\infty}\left(u+x^2\right)^{1/2}\mathrm{d}u=\int\limits_{x^2}^{+\infty}\sqrt{t}\mathrm{d}t=\frac{2}{3}t^{3/2}\Big|_{x^2}^{+\infty}\tag{11.2.715}$$

Formally, considering the dependence upon x through the lower bound of the integral only (!), one has:

$$f'(x)=-2x^2,\ f''(x)=-4x,\ f'''(x)=-4\tag{11.2.716}$$

and all higher derivatives are vanishing. So, assuming (for the moment without arguing why!) retaining the single nondivergent term (which corresponds to $f'''(0)$), so that:

$$\sum_{n=1}^{+\infty} f(n)=\int\limits_0^{+\infty} f(x)\mathrm{d}x+\frac{1}{720}f'''(0)+\ldots=\int\limits_0^{+\infty} f(x)\mathrm{d}x-\frac{4}{720}\tag{11.2.717}$$

We finally get (ignoring again without arguing for now the divergent terms!):

$$\frac{\Delta E_{\text{ZPE}}}{S}=\frac{E_{\text{cav}}}{S}-\frac{E_{\text{free}}}{S}=\frac{\hbar c\pi^2}{4d^3}\left(-\frac{4}{720}\right)\tag{11.2.718}$$

Therefore:

$$\frac{\Delta E_{\text{ZPE}}(d)}{S}=-\frac{\hbar c\pi^2}{720d^3}\tag{11.2.719}$$

The force (per unit surface) acting between the plates is then given by:

$$\boxed{\frac{F_{\text{ZPE}}^{\text{Casimir}}(d)}{S}=\frac{\mathrm{d}(\Delta E_{\text{ZPE}/S}(d))}{\mathrm{d}d}=-\frac{\hbar c\pi^2}{240d^4}}\tag{11.2.720}$$

This is the expression of the 3D electromagnetic Casimir force.

Let us comment now the divergence problems. Of course, the expression:

$$\frac{\Delta E_{\text{ZPE}}}{S}=\frac{E_{\text{cav}}}{S}-\frac{E_{\text{free}}}{S}=\frac{\hbar c\pi^2}{4d^3}\left\{\frac{1}{2}\int\limits_0^{+\infty}\sqrt{u}\,\mathrm{d}u+\sum_{n=1}^{+\infty}\int\limits_0^{+\infty}\left(u+n^2\right)^{1/2}\mathrm{d}u-\int\limits_0^{+\infty}\mathrm{d}x\int\limits_0^{+\infty}\left(u+x^2\right)^{1/2}\mathrm{d}u\right\}\tag{11.2.721}$$

and the Euler-Maclaurin theorem apply when the quantities are convergent. However, one can make the final result meaningful by regularizing the integral and the sum. The regularisation at infinity is not a problem. It is easy to introduce a suitable integration factor. For instance, it is easy to see that all terms at infinity vanish owing to the substitution:

$$f(x)\rightarrow\int\limits_0^{+\infty}\left(u+x^2\right)^{1/2}e^{-\left(u+x^2\right)\alpha}\mathrm{d}u\tag{11.2.722}$$

The terms corresponding to higher order derivatives (at $x=0$ as well as at $x=+\infty$) are finite and vanish as $\alpha\rightarrow 0$. Similarly, the first and third derivatives at $x=0$ are incremented by quantities that vanishes as $\alpha\rightarrow 0$. Actually, the regularisation can be achieved by any cutoff function which decreases sufficiently rapidly at large x (non necessarily exponentially), which goes to unity as x goes to zero with vanishing derivatives, like the functions $g(x)=1-\exp(-a/x)$.

Remark

As an example, we chose the regularisation provided by substitution of the above or:

$$f(x)=\int\limits_{x^2}^{+\infty}\sqrt{t}e^{-\alpha t}\mathrm{d}t\tag{11.2.723}$$

The first three derivatives are given by:

$$f'(x)=-2x^2e^{-\alpha x^2}\tag{11.2.724}$$

and by:

$$f''(x)=\left(-4x+4\alpha x^3\right)e^{-\alpha x^2}\tag{11.2.725}$$

and:

$$f'''(x)=\left(-4+20\alpha x^2-8\alpha^2x^4\right)e^{-\alpha x^2}\tag{11.2.726}$$

respectively. All derivatives at infinity are vanishing. It is also easy to verify that $f'(x)$ vanishes at $x=0$ and that $f'''(0)=-4$ and that higher order derivatives at $x=0$ are either vanishing or are proportional to positive powers of α. The first term in the curly bracket of:

$$E'_{\text{cav}}=\hbar c\sum_{n_x=-\infty}^{+\infty}\sum_{n_y=-\infty}^{+\infty}\sum_{n_z=1}^{+\infty}\left[\left(\frac{n_x2\pi}{L_x}\right)^2+\left(\frac{n_y2\pi}{L_x}\right)^2+\left(\frac{n_z\pi}{d}\right)^2\right]^{1/2}\tag{11.2.727}$$

being equal to $f(0)$, formula:

$$\frac{\Delta E_{\text{ZPE}}}{S}=-\frac{\hbar c\pi^2}{720d^3} \qquad (11.2.728)$$

results directly from the application of the Euler-Maclaurin formula to the function $f(x)=\int\limits_{x^2}^{+\infty}\sqrt{t}e^{-\alpha t}\mathrm{d}t$ at the limit of vanishing α.

For many years the Casimir effect was little more than a theoretical curiosity. But interest in the phenomenon has blossomed in the early 121st century (holocene calendar). Experimental physicists have realized that the Casimir force affects the workings of micromachined devices, while advances in instrumentation have enabled the force to be measured with ever-greater accuracy.

The new enthusiasm has also been fired by fundamental physics. Many theorists have predicted the existence of “large” extra dimensions in 10- and 11-dimensional unified field theories of the fundamental forces. These dimensions, they say, could modify classical Newtonian gravitation at sub-millimetre distances. Measuring the Casimir effect could therefore help physicists to test the validity of such radical ideas.

Remark

The fact that an attractive force exists between two conducting metal plates was first predicted in 11948 (holocene calendar) by Hendrik Casimir of Philips Research Laboratories in the Netherlands. At the time, however, Casimir was studying the properties of "colloidal solutions". These are viscous materials, such as paint and mayonnaise, that contain micron-sized particles in a liquid matrix. The properties of such solutions are determined by van der Waals forces – long-range, attractive forces that exist between neutral atoms and molecules.

One of Casimir’s colleagues, Theo Overbeek, realized that the theory that was used at the time to explain van der Waals forces, which had been developed by Fritz London in 11932 (holocene calendar), did not properly explain the experimental measurements on colloids. Overbeek therefore asked Casimir to investigate the problem. Working with Dirk Polder, Casimir discovered that the interaction between two neutral molecules could be correctly described only if the fact that light travels at a finite speed was taken into account.

Soon afterwards, Casimir noticed that this result could be interpreted in terms of vacuum fluctuations. He then asked himself what would happen if there were two mirrors – rather than two molecules – facing each other in a vacuum. It was this work that led to his famous prediction of an attractive force between reflecting plates.

Although the Casimir force seems completely counter-intuitive, it is actually well understood. In the old days of classical mechanics the idea of a vacuum was simple. The vacuum was what remained if you emptied a container of all its particles and lowered the temperature down to absolute zero. The arrival of quantum mechanics, however, completely changed our notion of a vacuum. All fields – in particular electromagnetic fields – have fluctuations. In other words at any given moment their actual value varies around a constant, mean value. Even a perfect vacuum at absolute zero has fluctuating fields known as "vacuum fluctuations", the mean energy of which corresponds to half the energy of a photon.

However, vacuum fluctuations are not some abstraction of a physicist's mind. They have observable consequences that can be directly visualized in experiments on a microscopic scale. For example, an atom in an excited state will not remain there infinitely long, but will return to its ground state by spontaneously emitting a photon. This phenomenon is a consequence of vacuum fluctuations. Imagine trying to hold a pencil upright on the end of your finger. It will stay there if your hand is perfectly stable and nothing perturbs the equilibrium. But the slightest perturbation will make the pencil fall into a more stable equilibrium position. Similarly, vacuum fluctuations cause an excited atom to fall into its ground state.

An important physical quantity when discussing the Casimir force is the "field radiation pressure". Every field – even the vacuum field – carries energy. As all electromagnetic fields can propagate in space they also exert pressure on surfaces, just as a flowing river pushes on a floodgate. This radiation pressure increases with the energy – and hence the frequency – of the electromagnetic field. At a cavity-resonance frequency the radiation pressure inside the cavity is stronger than outside and the mirrors are therefore pushed apart. Out of resonance, in contrast, the radiation pressure inside the cavity is smaller than outside and the mirrors are drawn towards each other.

While the Casimir force is too small to be observed for mirrors that are several metres apart, it can be measured if the mirrors are within microns of each other. For example, two mirrors with an area of $1\;[\text{cm}^2]$ separated by a distance of $1\;[\mu\text{m}]$ have an attractive Casimir force of about 10^{-7} [N] – roughly the weight of a water droplet that is half a millimetre in diameter. Although this force might appear small, at distances below a micrometre the Casimir force becomes the strongest force between two neutral objects. Indeed at separations of $10\;[\text{nm}]$ – about a hundred times the typical size of an atom – the Casimir effect produces the equivalent of 1 atmosphere of pressure!

Although we do not deal directly with such small distances in our everyday lives, they are important in nanoscale structures and microelectromechanical systems (MEMS). These are "intelligent" micron-sized devices in which mechanical elements and moving parts, such as tiny sensors and actuators, are carved into a silicon substrate. Electronic components are then wired on to the device to process information that it senses or to drive the movement of its mechanical parts. MEMS have many possible applications in science and engineering, and are already used as car air-bag pressure sensors.

As MEMS devices are fabricated on the micron and submicron scale, the Casimir force can cause the tiny elements in a device to stick together – as reported in 12001 (holocene calendar) by Michael Roukes and co-workers at the California Institute of Technology (see [80]).

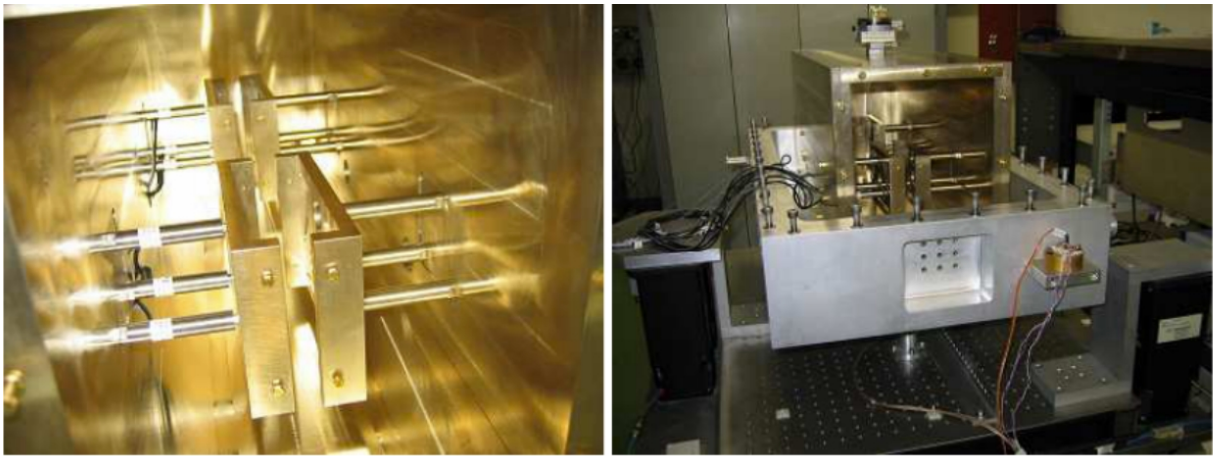
When the Casimir effect was first predicted in 11948 (holocene calendar) it was very difficult to measure using the equipment of the time. One of the first experiments was carried out in 11958 (holocene calendar) by Marcus Spaarnay at Philips in Eindhoven, who investigated the Casimir force between two flat, metallic mirrors made from either aluminium, chromium or steel. Spaarnay measured the force using a spring balance, the extension of which was determined by the capacitance of the two plates. To prevent the Casimir force from being swamped by the electrostatic force, the mirrors had to be kept neutral by first touching them together before each measurement was made. Spaarnay also had to ensure that the plane mirrors were exactly parallel to each other, as the Casimir force is very sensitive to changes in distance. Spaarnay managed to overcome these difficulties and concluded that his results « *did not contradict Casimir's theoretical prediction*».

Since those early days, however, sophisticated equipment has made it much easier to study the Casimir effect (see [63]). A new generation of measurements began in 11997 (holocene calendar). Steve Lamoreaux, who was then at the University of Washington in Seattle, measured the Casimir force between a 4 [cm] diameter spherical lens and an optical quartz plate about 2.5 [cm] across, both of which were coated with copper and gold. The lens and plate were connected to a torsion pendulum – a twisting horizontal bar suspended by a tungsten wire – placed in a cylindrical vessel under vacuum. When Lamoreaux brought the lens and plate together to within several microns of each other, the Casimir force pulled the two objects together and caused the pendulum to twist. He found that his experimental measurements agreed with theory to an accuracy of 5%.

Inspired by Lamoreaux's breakthrough, many other researchers tried new Casimir measurements. Umar Mohideen and co-workers at the University of California at Riverside, for example, attached a polystyrene sphere 200 [μm] in diameter to the tip of atomic force microscope. In a series of experiments they brought the sphere, which was coated with either aluminium or gold, to within 0.1 [μm] of a flat disk, which was also coated with these metals. The resulting attraction between the sphere and the disk was monitored by the deviation of a LASER beam. The researchers were able to measure the Casimir force to within 1% of the expected theoretical value.

Thomas Ederth at the Royal Institute of Technology in Stockholm, Sweden, has also used an atomic force microscope to study the Casimir effect. He measured the force between two gold-coated cylinders that were arranged at $90°$ to each other and that were as little as 20 [nm] apart. His results agreed to within 1% of theory.

In the photo below we can see the experimental set-up for the measurement of the Casimir force in a parallel plane configuration. On the left, the plateholders are connected to the external frame through three precision pieoelectric positioners each plate. On the right is anoverall view of the vacuum chamber with the fiber holder on the top (see [78]):



However, very few recent experiments have measured the Casimir force using the original configuration of two plane, parallel mirrors. The reason is that the mirrors have to be kept perfectly parallel during the experiment, which is difficult. It is much easier to bring a sphere close up to a mirror because the separation between the two objects is simply the distance of closest approach. The only drawback of using a sphere and a plane mirror is that the calculations of the Casimir force are not as accurate as those between two plane mirrors. In particular it has to be assumed that the contributions to the force between the sphere and plate are completely independent at each point. This is true only if the radius of the sphere is much larger than the distance between it and the plate.

The only recent experiment to replicate Casimir's original set-up of two plane, parallel mirrors was carried out by Gianni Carugno, Roberto Onofrio and co-workers at the University of Padova in Italy. They measured the force between a rigid chromium-coated plate and the flat surface of a cantilever made from the same material that were separated by distances ranging from 0.5-3 [μm] (see [77]). The researchers found that the measured Casimir force agreed to within 15% of the expected theoretical value. This relatively poor fit reflected the technical difficulties involved in the experiment.

The problem with studying the Casimir effect is that real mirrors are not like the perfectly smooth plane mirrors that Hendrik Casimir originally considered. In particular, real mirrors do not reflect all frequencies perfectly. They reflect some frequencies well – or even nearly perfectly – while others are reflected badly. In addition, all mirrors become transparent at very high frequencies. When calculating the Casimir force the frequency-dependent reflection coefficients of the mirrors have to be taken into account – a problem first tackled by Evgeny Lifshitz in the mid-11950s (holocene calendar), and then by Julian Schwinger and many others.

It turns out that the measured Casimir force between real metallic mirrors that are 0.1 [μm] apart is only half the theoretical value predicted for perfect mirrors.

Another problem with calculating the expected Casimir force for a real system is the fact that experiments are never carried out at absolute zero – as originally envisaged in Casimir's calculations – but at room temperature. This causes thermal – as well as vacuum – fluctuations to come into play. These thermal fluctuations can produce their own radiation pressure and generate a bigger Casimir force than expected. For example, the Casimir force between two plane mirrors 7 [μm] apart is twice as large at room temperature than at absolute zero. Fortunately, thermal fluctuations at room temperature are only important at distances above 1 [μm], below which the wavelength of the fluctuations is too big to fit inside the cavity.

Although the temperature dependence of the Casimir force has not yet been studied in detail experimentally at the time we write those lines, it must be included in calculations of the force at separations above 1 [μm]. Many researchers have tackled this problem for perfectly reflecting mirrors, including Lifshitz and Schwinger back in the 11950s (holocene calendar). It has also been examined more recently by Michael Bordag at Leipzig University, Bo Sernelius at Linköping University in Sweden, Galina Klimchitskaya and Vladimir Mostepanenko at the University of Paraiba in Brazil, and by our group in Paris. Indeed the temperature dependence of the Casimir force was for some time a matter of hot debate in the community. The various contradictions, however, now seem to have been resolved, and this has given an additional motivation to an experimental observation of the influence of temperature on the Casimir force.

A third and final problem in calculating the Casimir force is that real mirrors are not perfectly smooth. Most mirrors are made by coating a substrate with a thin metal film using the technique of "sputtering". However, this produces films with a roughness of about 50 [nm]. While such roughness is invisible to the naked eye, it does affect measurements of the Casimir force, which is very sensitive to small changes in distance.

Mohideen and his group in California have used surface deformations to show that two surfaces can also have a lateral Casimir force that acts in a parallel – rather than a perpendicular – direction to the surface of the mirrors. In the experiments they prepared specially corrugated mirrors the surfaces of which were sinusoidally curved. They then moved the mirrors parallel to one another so that a peak of one mirror passed successively over the peaks and troughs of the other mirror. The researchers found that the lateral Casimir force varied sinusoidally with the phase difference between the two corrugations. The size of the force was about ten times smaller than the ordinary Casimir force between two mirrors the same distance apart. The lateral force is also due to vacuum fluctuations.

To summarize there are plenty of independent experiments that confirms the (static) Casimir effect (SCE) theoretical prediction - emergence of particles from zero point vacuum energy state - using different methods with accuracies between 1% and 15% and at the day we write these lines there are even two experiments that were able to detect photons directly from the dynamic Casimir effect (DCE):

Table 11.9: **Most well known variations of the Casimir effect experiment and others**

For people interested to go further into the subject (multiple ways to resolve the problem, various configurations and assumptions, taking into account more realistic configurations, etc.), we recommend the lecture of [395].

11.2.4.4.9 Tunnel Effect (barrier potential / radioactivity)

The "tunnel effect" or "quantum tunneling" refers to the property of a quantum object to cross a potential barrier, which can not be explained by Classical Mechanics. Generally, the wave function of a particle, whose square of the module represents the amplitude of its probability of presence, does not cancel at the level of the barrier but attenuates within the barrier (see the previous plot of the harmonic oscillator!), practically exponentially for a fairly wide barrier as we will prove it soon. If at the output of the potential barrier the particle possesses a non-zero probability of presence, it can thus cross this barrier.

The theoretical study of this phenomenon is of crucial importance in the theory of semiconductors (see section Electrokinetics), disintegration/fission in nuclear physics (see section Nuclear Physics page 5075) and also nuclear fusion (see section Nuclear Physics page 5064). It is therefore necessary to pay special attention to it!

The quantum barrier of width L separates in simple cases the space in three (in the 1 dimensional case), the left and right parts of which are considered to have constant potentials up to infinity. The intermediate part constitutes the barrier, which may be complicated, revealing a soft profile, or on the contrary formed by rectangular or possibly other type of barriers/wells.

Let us now consider the case of systems where the potential energy E_p (implicitly the relative potential) tends to finite boundaries, not necessarily equal when $x \rightarrow \pm\infty$. It is therefore a problem of unbounded states.

First, we define a region `I` far to the left where $E_p(x)$ will be denoted:

$$E_p(-\infty)=E_p^{\mathtt{I}} \qquad (11.2.729)$$

A region `III` far to the right where $E_p(x)$ will be denoted:

$$E_p(+\infty)=E_p^{\mathtt{III}} \qquad (11.2.730)$$

By limiting ourselves to the simplest situations, there are three possibilities relative to the relations given above:

- potential well (a)
- potential step (b)
- potential barrier (c)

as represented in the same order in the figure below:

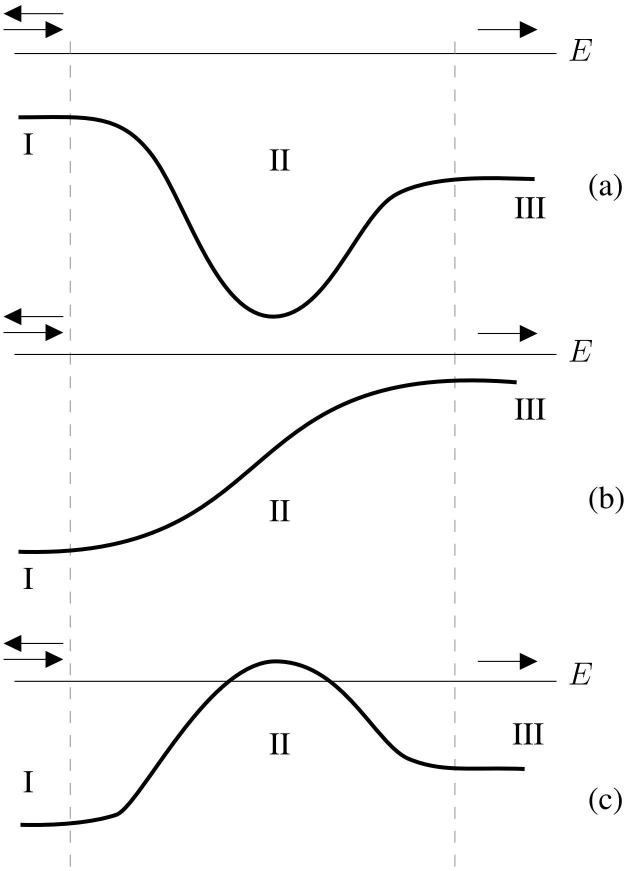

Figure 11.56: **Classical types of potential variations for Tunnel Effect study**

Now, let us write Schrödinger's equation:

$$\Delta\Psi+\frac{2m}{\hbar^2}(E_{\text{tot}}-E_p)\Psi=0 \tag{11.2.731}$$

In the regions $\mathtt{I}$ and $\mathtt{III}$ of the potential barrier, the idea is that $E_{\text{tot}}-E_p$ is constant and positive so the differential equation can be written in one dimension:

$$\frac{\partial^2\Psi}{\partial x^2}+\frac{2m}{\hbar^2}(E_{\text{tot}}-E_p)\Psi=\frac{\partial^2\Psi}{\partial x^2}+k^2\Psi=0 \tag{11.2.732}$$

We thus get very simply the analytic expression of Ψ in these regions in general form:

$$\begin{aligned}\Psi_{\mathtt{I}}&=Ae^{\mathrm{i}k_{\mathtt{I}}x}+Be^{-\mathrm{i}k_{\mathtt{I}}x}\\ \Psi_{\mathtt{III}}&=A'e^{\mathrm{i}k_{\mathtt{III}}x}+B'e^{-\mathrm{i}k_{\mathtt{III}}x}\end{aligned} \tag{11.2.733}$$

We fall back on these two expressions that are identical to those of our study of the potential well with rectangular walls, with the difference that we have written more general solutions of the differential equation (see section Differential and Integral Calculus page 1610) without having determine the coefficients (because we are interested here in a generalization).

Thus, in our study of the well with rectangular walls earlier above we had already determined that:

$$k_{\mathtt{I}}=\sqrt{\frac{8\pi^2m}{h^2}(E_{\text{tot}}-E_p^{\mathtt{I}})}\quad\text{and}\quad k_{\mathtt{III}}=\sqrt{\frac{8\pi^2m}{h^2}(E_{\text{tot}}-E_p^{\mathtt{III}})} \tag{11.2.734}$$

Remarks

R1. We see that the wave numbers k are therefore proportional to the root of the kinetic energy. And since the kinetic energy is proportional to the square velocity of the particles, then the velocity is proportional to the wave number (and vice versa)!

R2. In some textbooks, in order to simplify the notations, the potential in regions `I` and `III` is assumed as a reference and therefore equalized to 0. The term E_p therefore disappears from the two preceding expressions and this has the effect of equalizing the both wave numbers $k_{\mathtt{I}}$, $k_{\mathtt{III}}$ which are then simply denoted k.

In region `II`, the idea is that $E_{\text{tot}}-E_p$ is negative and constant (yes that means indeed we assume the corresponding moment to be mathematically an imaginary number[18]!) so the differential equation can be written in one dimension:

$$\frac{\partial^2\Psi}{\partial x^2}+\frac{2m}{\hbar^2}(E_{\text{tot}}-E_p)\Psi=\frac{\partial^2\Psi}{\partial x^2}-\frac{2m}{\hbar^2}(E_p-E_{\text{tot}})\Psi=\frac{\partial^2\Psi}{\partial x^2}-K^2\Psi=0 \qquad (11.2.735)$$

and as we have seen it in our study of the infinite rectangular potential well according to the second approach, the solution is then of the form:

$$\Psi_{\mathtt{II}}=Ce^{Kx}+De^{-Kx} \qquad (11.2.736)$$

with:

$$K=\frac{\sqrt{2m(E_p-E_{\text{tot}})}}{\hbar} \qquad (11.2.737)$$

Remark

The parenthesis under the root of the preceding relation must therefore be positive. This would mean that the kinetic energy of the particle is negative $E_c<0$ (and therefore the square of the momentum of the particle $p^2=2mE_c$ is also negative, then the momentum $p=\sqrt{p^2}$ is mathematically an imaginary number). To overcome this problem within the framework of this simplified model, it is said that the particle has no right to exist in the barrier and that the particle borrow of energy from vacuum (the particle is thus termed "unphysical" because it does not have the normal mathematics of a measurable particle; but we still can describe it mathematically). But there are other more complex models that do not require this kind of "fantasies".

We thus get very simply the analytic expression of Ψ in the three regions in general form:

$$\begin{aligned}\Psi_{\mathtt{I}}&=Ae^{\mathrm{i}k_{\mathtt{I}}x}+Be^{-\mathrm{i}k_{\mathtt{I}}x}\\ \Psi_{\mathtt{II}}&=Ce^{Kx}+De^{-Kx}\\ \Psi_{\mathtt{III}}&=A'e^{\mathrm{i}k_{\mathtt{III}}x}+B'e^{-\mathrm{i}k_{\mathtt{III}}x}\end{aligned} \qquad (11.2.738)$$

Let us suppose now that we have at $-\infty$ (region `I`), a source of particles (which sends them to the right), with a kinetic energy obviously equal to $E_{\text{tot}}-E_p^{\mathtt{I}}$.

---

[18] Inside the barrier, the kinetic energy of the particle, $E_c=E_{\text{tot}}-E_p$, is negative and therefore the square of the momentum of the particle, $p^2=2mE_c$, is also negative. The momentum $p=\sqrt{p^2}$ is therefore mathematically an imaginary number, which is a number containing a factor of $\sqrt{-1}$.

Thus, these particles have an energy E_{tot} and the wave function that describes them obeys the Schrödinger equation. In Region `III`, it will be assumed that there can be only particles going to the right (no source at $+\infty$ by hypothesis).

The region `III`, as well as region `I`, is of infinite extension, so the principle of uncertainty allows us to speak in theory of a perfectly determined linear momentum which we denote by p'.

We know that (this is Classical Mechanics!) in the region `III` we then have:

$$\frac{p'^2}{2m}=E_{\text{tot}}-E_p^{\texttt{III}} \tag{11.2.739}$$

If $E_{\text{tot}}>E_p^{\texttt{III}}$ then p' is positive, so thanks to the preceding relation and to the de Broglie relation we have:

$$p'=\sqrt{2m\left(E_{\text{tot}}-E_p^{\texttt{III}}\right)}=\frac{hk_{\texttt{III}}}{2\pi} \tag{11.2.740}$$

Therefore:

$$k_{\texttt{III}}=\frac{\sqrt{2m\left(E_{\text{tot}}-E_p^{\texttt{III}}\right)}}{\hbar}\qquad k_{\texttt{I}}=\frac{\sqrt{2m\left(E_{\text{tot}}-E_p^{\texttt{I}}\right)}}{\hbar} \tag{11.2.741}$$

Since the wave numbers are now known formally, let us return to the interpretation of solution `III`:

$$\Psi_{\texttt{III}}=A'e^{\text{i}k_{\texttt{III}}x}+B'e^{-\text{i}k_{\texttt{III}}x} \tag{11.2.742}$$

The assumption that the particles come from the left imposes us that $B'=0$ so that the solution only describes particles that go to the right. Then, it is possible, for those coming from the left, to take $A'=1$. The region `III` is therefore relatively simple to analyse...

Remark

The conditions and assumptions used previously are sometimes referred to as "scattering conditions".

The constants A and B of the region `I` will be completely determined by carrying out the connection of the solutions from one region to the other.

Let us now turn to the interpretation of the equation in Region `I`:

$$\Psi_{\texttt{I}}=A'e^{\text{i}k_{\texttt{I}}x}+B'e^{-\text{i}k_{\texttt{I}}x} \tag{11.2.743}$$

It is evident that $Ae^{\text{i}k_{\texttt{I}}}$ describes particles which, in region `I` are directed to the right, when $Be^{-\text{i}k_{\texttt{I}}}$ describes particles which in this same region are directed to the left. As we know, the first are the incident particles, the second are the reflected particles.

What we ask of Quantum Physics now appears in a clear way: a particle arriving from the left (incident) can either:

1. Continue to the right, that is, cross the region `II` and become a transmitted particle

2. Go back to the left and become a reflected particle.

We are led to define a "transmission coefficient T" assimilated to the probability that the incident particle has to cross the region `II` and a "reflection coefficient R", the probability that the incident particle will be reflected. We must obviously have:

$$R+T=1 \tag{11.2.744}$$

In the case of a potential barrier, T is also named the "barrier transparency".

To calculate R and T, we will define the current fluxes of the various categories of particles (incident, transmitted, reflected).

For example, since the incident particles are described by $A^{\mathrm{i}k_{\mathtt{I}}x}$, the average number of these particles per unit length in region `I` must certainly be proportional to a given factor with $|A|^2$.

Let $v_{\mathtt{I}}$ be their velocity, we see that the flow of the incident particles denoted j_i, is then proportional to a given factor to $|A|^2 v_{\mathtt{I}}$ (through dimensional analysis). Thus, the coefficient of proportionality being of the same nature for the three categories of particles (incident i, reflected j, transmitted t) and from the fact that $v_{\mathtt{I}}$ and $v_{\mathtt{III}}$ are proportional to $k_{\mathtt{I}}$ and $k_{\mathtt{III}}$, it follows that j_i, j_r (incident flow and reflected flow) and j_t (transmitted flow) are respectively proportional (hence always to a given dimensional factor) to $k_{\mathtt{I}}|A|^2$, $k_{\mathtt{I}}|B|^2$, and $k_{\mathtt{III}}$ (since we recall that for region `III` we have found $A'=1$ and $B'=0$).

We deduce from here simply, by a simple ratio, the expressions of the coefficients of reflection R and transmission T:

$$R=\frac{|B|^2}{|A|^2}=\left|\frac{B}{A}\right|^2 \qquad T=\frac{|A'|^2}{|A|^2}=\frac{k_{\mathtt{III}}}{k_{\mathtt{I}}}\frac{1}{|A|^2} \tag{11.2.745}$$

and as in our special case $k_{\mathtt{I}}=kk_{\mathtt{III}}$ it comes:

$$T=\frac{1}{|A|^2} \tag{11.2.746}$$

Another way of writing things is to say that since the incident wave is summarized to:

$$\Psi^{\mathtt{I}}=A^{\mathrm{i}kx} \tag{11.2.747}$$

and the transmitted wave to:

$$\Psi^{\mathtt{T}}=A'^{\mathrm{i}kx} \tag{11.2.748}$$

then:

$$\boxed{T=\frac{|\Psi^{\mathtt{T}}|^2}{|\Psi^{I}|^2}} \tag{11.2.749}$$

In all these situations, quantum theory leads in general to small but not zero values of R and T!

✍**Example:**

Let us determine the explicit expression of transparency for the example of our rectangular barrier.

For this we know that we must impose the continuity of Ψ in $x=0$ and $x=L$, as well as the continuity of $\mathrm{d}\Psi/\mathrm{d}x$ in $x=0$ and $x=L$.

Let us first recall that we have the three relations (by putting the reference of the potential at 0):

$$\begin{gathered}\Psi_{\mathrm{I}}=Ae^{\mathrm{i}k_{\mathrm{I}}x}+Be^{-\mathrm{i}k_{\mathrm{I}}x}\\ \Psi_{\mathrm{II}}=Ce^{Kx}+De^{-Kx}\\ \Psi_{\mathrm{III}}=A'e^{\mathrm{i}k_{\mathrm{III}}x}+B'e^{-\mathrm{i}k_{\mathrm{III}}x}\end{gathered}\tag{11.2.750}$$

with therefore:

$$k=\frac{\sqrt{2mE_{\text{tot}}}}{\hbar}\qquad\text{and}\qquad K=\frac{\sqrt{2m(E_{\text{tot}}-E_p)}}{\hbar}\tag{11.2.751}$$

We then have for the continuity of Ψ in $x=0$ and $x=L$:

$$\begin{gathered}A+B=C+D\\ Ce^{KL}+De^{-KL}=A'e^{\mathrm{i}kl}+B'e^{-\mathrm{i}kl}\end{gathered}\tag{11.2.752}$$

as well as the continuity of $\mathrm{d}\Psi/\mathrm{d}x$ in $x=0$ and $x=L$:

$$\begin{gathered}\mathrm{i}kA-\mathrm{i}kB=KC-KD\\ KCe^{KL}-KDe^{-KL}=ikA'e^{\mathrm{i}kL}+\mathrm{i}kB'e^{-\mathrm{i}kL}\end{gathered}\tag{11.2.753}$$

Since B' is zero we have a system of 4 equations with 5 unknowns:

$$\begin{cases}A+B=C+D\\ \mathrm{i}kA-\mathrm{i}kB=KC-KD\\ Ce^{KL}+De^{-KL}=A'e^{\mathrm{i}kl}\\ KCe^{KL}-KDe^{-KL}=\mathrm{i}kA'e^{\mathrm{i}kL}\end{cases}\Rightarrow\begin{cases}-B+C+D=A\\ \mathrm{i}kB+KC-KD=\mathrm{i}kA\\ Ce^{KL}+De^{-KL}-A'e^{\mathrm{i}kl}=0\\ KCe^{KL}-KDe^{-KL}-\mathrm{i}kA'e^{\mathrm{i}kL}=0\end{cases}\tag{11.2.754}$$

We will choose to express all the constants from A. To do this we multiply the first line by $\mathrm{i}l$ and we sum it to the second line. We then get:

$$\begin{array}{r}-\mathrm{i}kB+\mathrm{i}kC+\mathrm{i}kD=\mathrm{i}kA\\ +\quad \mathrm{i}kB+KC-KD=\mathrm{i}kA\\ \hline (K+\mathrm{i}k)C-(K-\mathrm{i}k)D=2\mathrm{i}kA\end{array}\tag{11.2.755}$$

and then we multiply the third line by $-\mathrm{i}k$ and the sum it to the fourth line. We have then:

$$\begin{array}{r}-\mathrm{i}kCe^{KL}-\mathrm{i}kDe^{-KL}+\mathrm{i}kA'e^{\mathrm{i}kl}=0\\ +\quad KCe^{KL}-KDe^{-KL}-\mathrm{i}kA'e^{\mathrm{i}kl}=0\\ \hline (K-\mathrm{i}k)e^{KL}C-(K+\mathrm{i}k)e^{-KL}D=0\end{array}\tag{11.2.756}$$

Therefore we have the two relations:

$$\begin{gathered}(K+\mathrm{i}k)C-(K-\mathrm{i}k)D=2\mathrm{i}kA\\(K-\mathrm{i}k)e^{KL}C-(K+\mathrm{i}k)e^{-KL}D=0\end{gathered}\tag{11.2.757}$$

or by putting $\alpha=k/K$:

$$\begin{gathered}(1+\mathrm{i}\alpha)C-(1-\mathrm{i}\alpha)D=2\mathrm{i}\alpha A\\(1-\mathrm{i}\alpha)e^{KL}C-(1+\mathrm{i}\alpha)e^{-KL}D=0\end{gathered}\tag{11.2.758}$$

From the second relation, it comes:

$$D=\frac{(1-\mathrm{i}\alpha)e^{KL}C}{(1+\mathrm{i}\alpha)e^{-KL}}\tag{11.2.759}$$

And injected into the first one:

$$(1+\mathrm{i}\alpha)C-(1-\mathrm{i}\alpha)\frac{(1-\mathrm{i}\alpha)e^{KL}C}{(1+\mathrm{i}\alpha)e^{-KL}}=2\mathrm{i}\alpha A\tag{11.2.760}$$

Therefore:

$$C\frac{(1+\mathrm{i}\alpha)^2e^{-KL}-(1-\mathrm{i}\alpha)^2e^{KL}}{(1+\mathrm{i}\alpha)e^{-KL}}=2\mathrm{i}\alpha A\tag{11.2.761}$$

Then we have:

$$C=\frac{2\mathrm{i}\alpha(1+\mathrm{i}\alpha)e^{-KL}}{(1+\mathrm{i}\alpha)^2e^{-KL}-(1-\mathrm{i}\alpha)^2e^{KL}}A\tag{11.2.762}$$

and if we put:

$$F=\frac{1}{2}\left((1+\mathrm{i}\alpha)^2e^{-KL}-(1-\mathrm{i}\alpha)^2e^{KL}\right)\tag{11.2.763}$$

Therefore it comes:

$$C=\frac{\mathrm{i}\alpha(1+\mathrm{i}\alpha)e^{-KL}}{F}A\tag{11.2.764}$$

Similarly, re-starting from:

$$\begin{gathered}(1+\mathrm{i}\alpha)C-(1-\mathrm{i}\alpha)D=2\mathrm{i}\alpha A\\(1-\mathrm{i}\alpha)e^{KL}C-(1+\mathrm{i}\alpha)e^{-KL}D=0\end{gathered}\tag{11.2.765}$$

From the second relation, it comes:

$$C=\frac{(1+\mathrm{i}\alpha)e^{-KL}D}{(1-\mathrm{i}\alpha)e^{KL}}\tag{11.2.766}$$

And injected into the first one:

$$(1+\mathrm{i}\alpha)\frac{(1+\mathrm{i}\alpha)e^{-KL}D}{(1-\mathrm{i}\alpha)e^{KL}}-(1-\mathrm{i}\alpha)D=2\mathrm{i}\alpha A\tag{11.2.767}$$

Therefore:

$$D=\frac{(1+\mathrm{i}\alpha)^2e^{-KL}-(1-\mathrm{i}\alpha)^2e^{KL}}{(1-\mathrm{i}\alpha)e^{KL}}=2\mathrm{i}\alpha A \tag{11.2.768}$$

We then get:

$$D=\frac{2\mathrm{i}\alpha(1-\mathrm{i}\alpha)e^{KL}}{(1+\mathrm{i}\alpha)^2e^{-KL}-(1-\mathrm{i}\alpha)^2e^{KL}}A \tag{11.2.769}$$

and let us still put:

$$F=\frac{1}{2}\left((1+\mathrm{i}\alpha)^2e^{-KL}-(1-\mathrm{i}\alpha)^2e^{KL}\right) \tag{11.2.770}$$

Therefore it comes:

$$D=\frac{\mathrm{i}\alpha(1-\mathrm{i}\alpha)e^{KL}}{F}A \tag{11.2.771}$$

Notice that we also have:

$$\begin{aligned}
F&=2\mathrm{i}\alpha\cosh(KL)-(1-\alpha)^2\sinh(KL)=2\mathrm{i}\alpha\frac{e^{KL}+e^{-KL}}{2}-(1-\alpha^2)\frac{e^{KL}-e^{-KL}}{2}\\
&=\frac{2\mathrm{i}\alpha e^{KL}+2\mathrm{i}\alpha e^{-KL}-(1-\alpha^2)\left(e^{KL}-e^{-KL}\right)}{2}\\
&=\frac{1}{2}\left(2\mathrm{i}\alpha e^{KL}+2\mathrm{i}\alpha e^{-KL}-e^{KL}+e^{-KL}+\alpha^2e^{KL}-\alpha^2e^{-KL}\right)\\
&=\frac{1}{2}\left(\alpha^2e^{KL}+2\mathrm{i}\alpha e^{KL}-e^{KL}+2\mathrm{i}\alpha e^{-KL}-\alpha^2e^{-KL}+e^{-KL}\right)\\
&=\frac{1}{2}\left[\left(\alpha^2+2\mathrm{i}\alpha-1\right)e^{KL}+\left(2\mathrm{i}\alpha-\alpha^2+1\right)e^{-KL}\right]\\
&=\frac{1}{2}\left[\left(2\mathrm{i}\alpha-\alpha^2+1\right)e^{-KL}+\left(\alpha^2+2\mathrm{i}\alpha-1\right)e^{KL}\right]\\
&=\frac{1}{2}\left[\left(2\mathrm{i}\alpha-\alpha^2+1\right)e^{-KL}-\left(-\alpha^2-2\mathrm{i}\alpha+1\right)e^{KL}\right]\\
&=\frac{1}{2}\left[\left(1+2\mathrm{i}\alpha-\alpha^2\right)e^{-KL}-\left(1-2\mathrm{i}\alpha-\alpha^2\right)e^{KL}\right]=\frac{1}{2}\left[(1+\mathrm{i}\alpha)^2e^{-KL}-(1-\mathrm{i}\alpha)^2e^{KL}\right]
\end{aligned} \tag{11.2.772}$$

We can now express the constants A' and B as a function of A with the help of the preceding relations. Let us first begin with B:

$$\begin{aligned}
B &= C+D-A=\frac{\mathrm{i}\alpha(1+\mathrm{i}\alpha)e^{-KL}}{F}A+\frac{\mathrm{i}\alpha(1-\mathrm{i}\alpha)e^{KL}}{F}A-A\\
&=A\frac{\mathrm{i}\alpha(1+\mathrm{i}\alpha)e^{-KL}+\mathrm{i}\alpha(1-\mathrm{i}\alpha)e^{KL}-F}{F}\\
&=A\frac{\mathrm{i}\alpha e^{-KL}-\alpha^2e^{-KL}+\mathrm{i}\alpha e^{KL}+\alpha^2e^{KL}-F}{F}\\
&=A\frac{\mathrm{i}\alpha(e^{KL}+e^{-KL})+\alpha^2(e^{KL}-e^{-KL})-F}{F}=A\frac{\mathrm{i}\alpha 2\cosh(KL)+\alpha^2 2\sinh(KL)-F}{F}\\
&=A\frac{\mathrm{i}\alpha 2\cosh(KL)+\alpha^2 2\sinh(KL)-2\mathrm{i}\alpha\cosh(KL)+(1-\alpha^2)\sinh(KL)}{F}\\
&=A\frac{\alpha^2 2\sinh(KL)+(1-\alpha^2)\sinh(KL)}{F}=A\frac{(1+\alpha^2)\sinh(KL)}{F}
\end{aligned} \tag{11.2.773}$$

and:

$$Ce^{KL}+De^{-KL}-A'e^{\mathrm{i}kl}=0 \tag{11.2.774}$$

Therefore:

$$\begin{aligned}
A' &= e^{-\mathrm{i}kl}\left(Ce^{KL}+De^{-KL}\right)\\
&=e^{-\mathrm{i}kl}\left(\frac{\mathrm{i}\alpha(1+\mathrm{i}\alpha)e^{-KL}}{F}Ae^{KL}+\frac{\mathrm{i}\alpha(1-\mathrm{i}\alpha)e^{KL}}{F}Ae^{-KL}\right)\\
&=\frac{\mathrm{i}\alpha Ae^{-\mathrm{i}kl}}{F}\left((1+\mathrm{i}\alpha)+(1-\mathrm{i}\alpha)\right)=\frac{\mathrm{i}\alpha Ae^{-\mathrm{i}kl}}{F}2=\frac{2\mathrm{i}\alpha Ae^{-\mathrm{i}kl}}{F}
\end{aligned} \tag{11.2.775}$$

So finally we have:

$$\begin{aligned}
\Psi_{\mathrm{I}} &= Ae^{\mathrm{i}kx}+Be^{-\mathrm{i}kx}=Ae^{\mathrm{i}kx}+A\frac{(1+\alpha^2)\sinh(KL)}{F}e^{-\mathrm{i}kx}\\
&=A\left(e^{\mathrm{i}kx}+\frac{(1+\alpha^2)\sinh(KL)}{F}e^{-\mathrm{i}kx}\right)\\
\\
\Psi_{\mathrm{II}} &= Ce^{kx}+De^{-kx}=\frac{\mathrm{i}\alpha(1+\mathrm{i}\alpha)e^{-KL}}{F}Ae^{Kx}+\frac{\mathrm{i}\alpha(1-\mathrm{i}\alpha)e^{KL}}{F}Ae^{-Kx}\\
&=A\left(\frac{\mathrm{i}\alpha(1+\mathrm{i}\alpha)e^{K(x-L)}+\mathrm{i}\alpha(1-\mathrm{i}\alpha)e^{-K(x-L)}}{F}\right)\\
\\
\Psi_{\mathrm{III}} &= A'e^{\mathrm{i}kx}+B'e^{-\mathrm{i}kx}=A'e^{\mathrm{i}kx}=\frac{2\mathrm{i}\alpha Ae^{-\mathrm{i}kl}}{F}e^{\mathrm{i}kx}=\frac{2\mathrm{i}\alpha Ae^{\mathrm{i}k(x-L)}}{F}
\end{aligned} \tag{11.2.776}$$

and therefore:

$$T=\frac{\left|\Psi^T\right|^2}{\left|\Psi^{\mathrm{I}}\right|^2}=\frac{\left|\frac{2\mathrm{i}\alpha Ae^{\mathrm{i}k(x-L)}}{F}\right|^2}{|Ae^{\mathrm{i}kx}|^2} \tag{11.2.777}$$

using the properties of the complex module (see section Numbers page 245):

$$T=\frac{\left|\frac{2\mathrm{i}\alpha Ae^{-\mathrm{i}kL}}{F}\right|^2\left|Ae^{\mathrm{i}kx}\right|^2}{\left|Ae^{\mathrm{i}kx}\right|^2}=\left|\frac{2\mathrm{i}\alpha Ae^{-\mathrm{i}kL}}{F}\right|^2=\left|2\mathrm{i}\alpha\right|^2\left|\frac{e^{-\mathrm{i}kL}}{F}\right|^2=4\alpha^2\frac{\left|e^{-\mathrm{i}kL}\right|^2}{|F|^2}=4\alpha^2\frac{1}{|F|^2} \tag{11.2.778}$$

It remains for us to calculate:

$$\begin{aligned}|F|^2=F\cdot\bar{F}&=|2\mathrm{i}\alpha\cosh(KL)-(1-\alpha^2)\sinh(KL)|\\&=\big(2\mathrm{i}\alpha\cosh(KL)-(1-\alpha^2)\sinh(KL)\big)\big(-2\mathrm{i}\alpha\cosh(KL)-(1-\alpha^2)\sinh(KL)\big)\\&=4\alpha^2\cosh^2(KL)-2\mathrm{i}\alpha(1-\alpha^2)\sinh(KL)\cosh(KL)+2\mathrm{i}\alpha\cosh(KL)(1-\alpha^2)\sinh(KL)\\&+(1-\alpha^2)^2\sinh^2(KL)\\&=4\alpha^2\cosh^2(KL)+(1-\alpha^2)^2\sinh^2(KL)\\&=4\alpha^2\cosh^2(KL)+(1-2\alpha^2+\alpha^4)\sinh^2(KL)\\&=4\alpha^2\cosh^2(KL)+\sinh^2(KL)-2\alpha^2\sinh^2(KL)+\alpha^4\sinh^2(KL)\\&=2\alpha^2\cosh^2(KL)+\sinh^2(KL)+2\alpha^2+\alpha^4\sinh^2(KL)\\&=2\alpha^2(1+\cosh^2(KL))+(1+\alpha^4)\sinh^2(KL)=2\alpha^2(2+\sinh^2(KL))+(1+\alpha^4)\sinh^2(KL)\\&=4\alpha^2+2\alpha^2\sinh^2(KL)+\sinh^2(KL)+\alpha^4\sinh^2(KL)\\&=4\alpha^2+(2\alpha^2+1+\alpha^4)\sinh^2(KL)=4\alpha^2+(1+\alpha^2)^2\sinh^2(KL)\end{aligned} \tag{11.2.779}$$

Therefore:

$$\begin{aligned}T=4\alpha^2\frac{1}{4\alpha^2+(1+\alpha^2)^2\sinh^2(KL)}&=\frac{1}{1+\dfrac{(1+\alpha^2)^2}{4\alpha^2}\sinh^2(KL)}\\&=\frac{1}{1+\dfrac{\left(1+\dfrac{k^2}{K^2}\right)^2}{4\dfrac{k^2}{K^2}}\sinh^2(KL)}=\frac{1}{1+\dfrac{\left(1+\dfrac{E_{\text{tot}}}{E_p-E_{\text{tot}}}\right)^2}{4\dfrac{E_{\text{tot}}}{E_p-E_{\text{tot}}}}\sinh^2(KL)}\\&=\frac{1}{1+\dfrac{E_p-E_{\text{tot}}}{4E_{\text{tot}}}\left(1+\dfrac{E_{\text{tot}}}{E_p-E_{\text{tot}}}\right)^2\sinh^2(KL)}\\&=\frac{1}{1+\dfrac{E_p-E_{\text{tot}}}{4E_{\text{tot}}}\left(1+2\dfrac{E_{\text{tot}}}{E_p-E_{\text{tot}}}+\dfrac{{E_{\text{tot}}}^2}{(E_p-E_{\text{tot}})^2}\right)\sinh^2(KL)}\end{aligned} \tag{11.2.780}$$

$$\begin{aligned}
&=\frac{1}{1+\dfrac{1}{4}\left(\dfrac{E_p-E_{\text{tot}}}{E_{\text{tot}}}+2+\dfrac{E_{\text{tot}}}{E_p-E_{\text{tot}}}\right)\sinh^2(KL)}\\
&=\frac{1}{1+\dfrac{1}{4}\dfrac{(E_p-E_{\text{tot}})^2+2E_{\text{tot}}(E_p-E_{\text{tot}})+E_{\text{tot}}^2}{E_{\text{tot}}(E_p-E_{\text{tot}})}\sinh^2(KL)}\\
&=\frac{1}{1+\dfrac{E_p^2}{4E_{\text{tot}}(E_p-E_{\text{tot}})}\sinh^2(KL)}
\end{aligned}\tag{11.2.781}$$

We have therefore:

$$T=\frac{1}{1+\dfrac{E_p^2}{4E_{\text{tot}}(E_p-E_{\text{tot}})}\sinh^2(KL)}\tag{11.2.782}$$

But as (see section Trigonometry page 2532):

$$\sinh(KL)=\frac{e^{KL}-e^{-KL}}{2}\tag{11.2.783}$$

If $KL\gg 1$ (so at the atomic scale it is rather K which is huge relatively to L) we have:

$$\sinh(KL)\cong\frac{e^{KL}}{2}\tag{11.2.784}$$

Therefore:

$$T\cong\frac{1}{1+\dfrac{E_p^2e^{2KL}}{16E_{\text{tot}}(E_p-E_{\text{tot}})}}\cong\frac{1}{\dfrac{E_p^2e^{2KL}}{16E_{\text{tot}}(E_p-E_{\text{tot}})}}=\frac{16E_{\text{tot}}(E_p-E_{\text{tot}})}{E_p^2}e^{-2KL}\tag{11.2.785}$$

relation that we can find in many textbooks (but without detailed proof as above). Below we have plotted T:

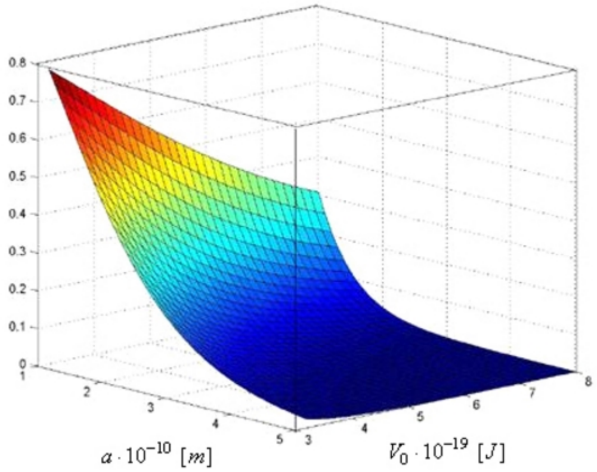

Figure 11.57: **Plot of the transmission T coefficient with MATLAB® 5.0.0.473 for tunneling effect**

following the relation:

$$\boxed{T \cong \frac{16E_{\text{tot}}(V_0 - E_{\text{tot}})}{V_0^2} e^{-2Ka}} \tag{11.2.786}$$

The above relation is often denoted:

$$T \propto e^{-G} \tag{11.2.787}$$

where G is named the "Gamow factor" and defined when we model the Coulomb barrier as a succession of thin barries of varying height by:

$$G = \frac{2}{\hbar}\int_{R}^{r_{\text{C}}} \left[2m\left|V_{\text{Coul.}}(r) - E_{\alpha}\right|\right]^{1/2} \mathrm{d}r \tag{11.2.788}$$

We thus find in the (special) above example that the coefficient T is very sensitive (exponentially) to a small variation of the width of the barrier, a, when the potential of this barrier is small. We can thus visualize atomic sites, for example in Silicium, using a point very close to the material (or "scanning tunneling microscope (STM)") to be observed. This is the principle of the tunneling microscope where, by approaching a very finely cut conductive point (a few atoms) to a proximity of about 5 Angstroms of a conductive surface, and imposing a potential difference of a few [mV], we measures a current of a few nanoamperes. The number of electrons passing through the potential barrier (here the vacuum between the two conductive electrodes) decreases exponentially with the width of the barrier.

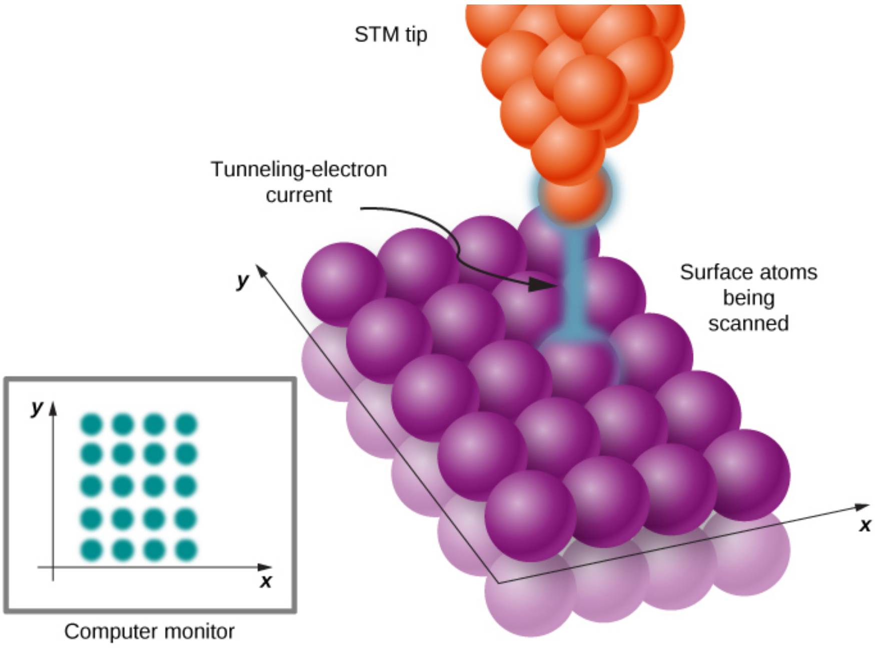

Figure 11.58: **Scanning tunneling microscope concept (source: OpenStax)**

By analysing the signal of the current passing through the circuit, one can access a very precise mapping of the measured surface of the order of 0.1 Angstroms in vertical.

We also notice according to the relation obtained that the not "heavy" particles like the electrons have a greater probability of making a tunnel effect than heavier particles because of the term of mass involved.

STM images are in therefore gray scale, and colouring is added to bring up details to the human eye:

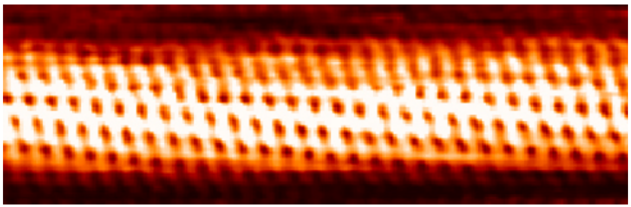

Figure 11.59: **An STM image of a carbon nanotube (source: OpenStax)**

Using the relation obtained previously, one can quite simply calculate the probability that a human being of mass m crosses a wall with a height h (it is then easy to calculate the potential energy) and a thickness a. The probability is of the order of $10^{-4\cdot 10^{30}}$....

However, the most famous example of Quantum tunnelling that can be treated is that of the emission of α particles by radioactive heavy nuclei, the explanation of which was given by the Russian physicist G. Gamov in 11928 (holocene calendar).

The proof is relatively simple, but since it constitutes a particular practical case, we have not detailed it in this section, but in that of Nuclear Physics. However, to solve this problem, we need to use an approximation method known as the "W.K.B. method" Named after the physicists Wentzel, Kramers and Brillouin.

The results therefore give a transmission factor T for the α "particle" of:

$$T \cong 2\cdot 10^{-39} \tag{11.2.789}$$

For the Uranium atom ${}^{238}_{92}\text{U}$. Moreover, in the semi-classical approximation, the particle α has, in the well, a velocity of the order of 10^7 $[\text{m}\cdot\text{s}^{-1}]$, and it goes back and forth in a nucleus whose radius is of the order of 10^{-14} [m]. It thus performs approximately 10^{21} oscillations per second where each time it has a probability T to cross the potential barrier. This probability per unit time is thus determined by:

$$\lambda \cong \frac{v}{r}\cdot T \cong 10^{21}\cdot T \cong 2\cdot 10^{-18}\ [\text{s}^{-1}] \tag{11.2.790}$$

Experimentally, we find:

$$\lambda \cong 5\cdot 10^{-18}\ [\text{s}^{-1}] \tag{11.2.791}$$

Caution!!! Although a radioactive decay event seems spontaneous and is unpredictable (i.e. without cause), it is indeed triggered by a physical agent. That physical agent is a vacuum fluctuation (the latter having no cause!). Due to the quantum nature of our universe, a vacuum always contains vacuum fluctuations!!!

Remark

As we will see in the section of Cosmology, looking far in space is equivalent at looking in the past (because light takes time to travel from one place to another, we see objects not as they are now but as they were at the time when they released the light that has travelled across the universe to us). Therefore modern telescopes are like time machines as we can go back as 13 billion years in the past by spectral observation. Thanks to spectroscopy we can check hydrogen spectral series that directly depends on the fine-structure constant (see page 4655) - as for the relation of activity decay that we have derived earlier above that depends only in constant parameters involved in the fine-structure constant - and see if the latter has changed these last 13 billion years. Experimental evidence as presented in [574] find a spatial variation of the order of $\sim 10^{-5}$ is preferred over a no-variation model at the 3.9σ level:

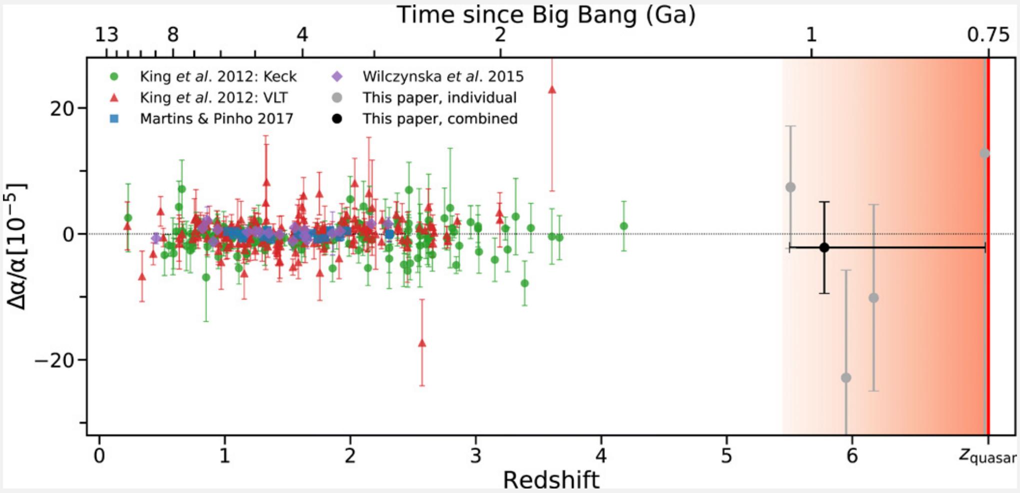

Figure 11.60: Direct measurements of $\Delta\alpha/\alpha$, taken from quasar absorption measurements

This variation of $\sim 10^{-5}$ of the fine-structure constant would lead in a relative variation in the radioactivity decay of the order of $\sim 10^{-4}$.

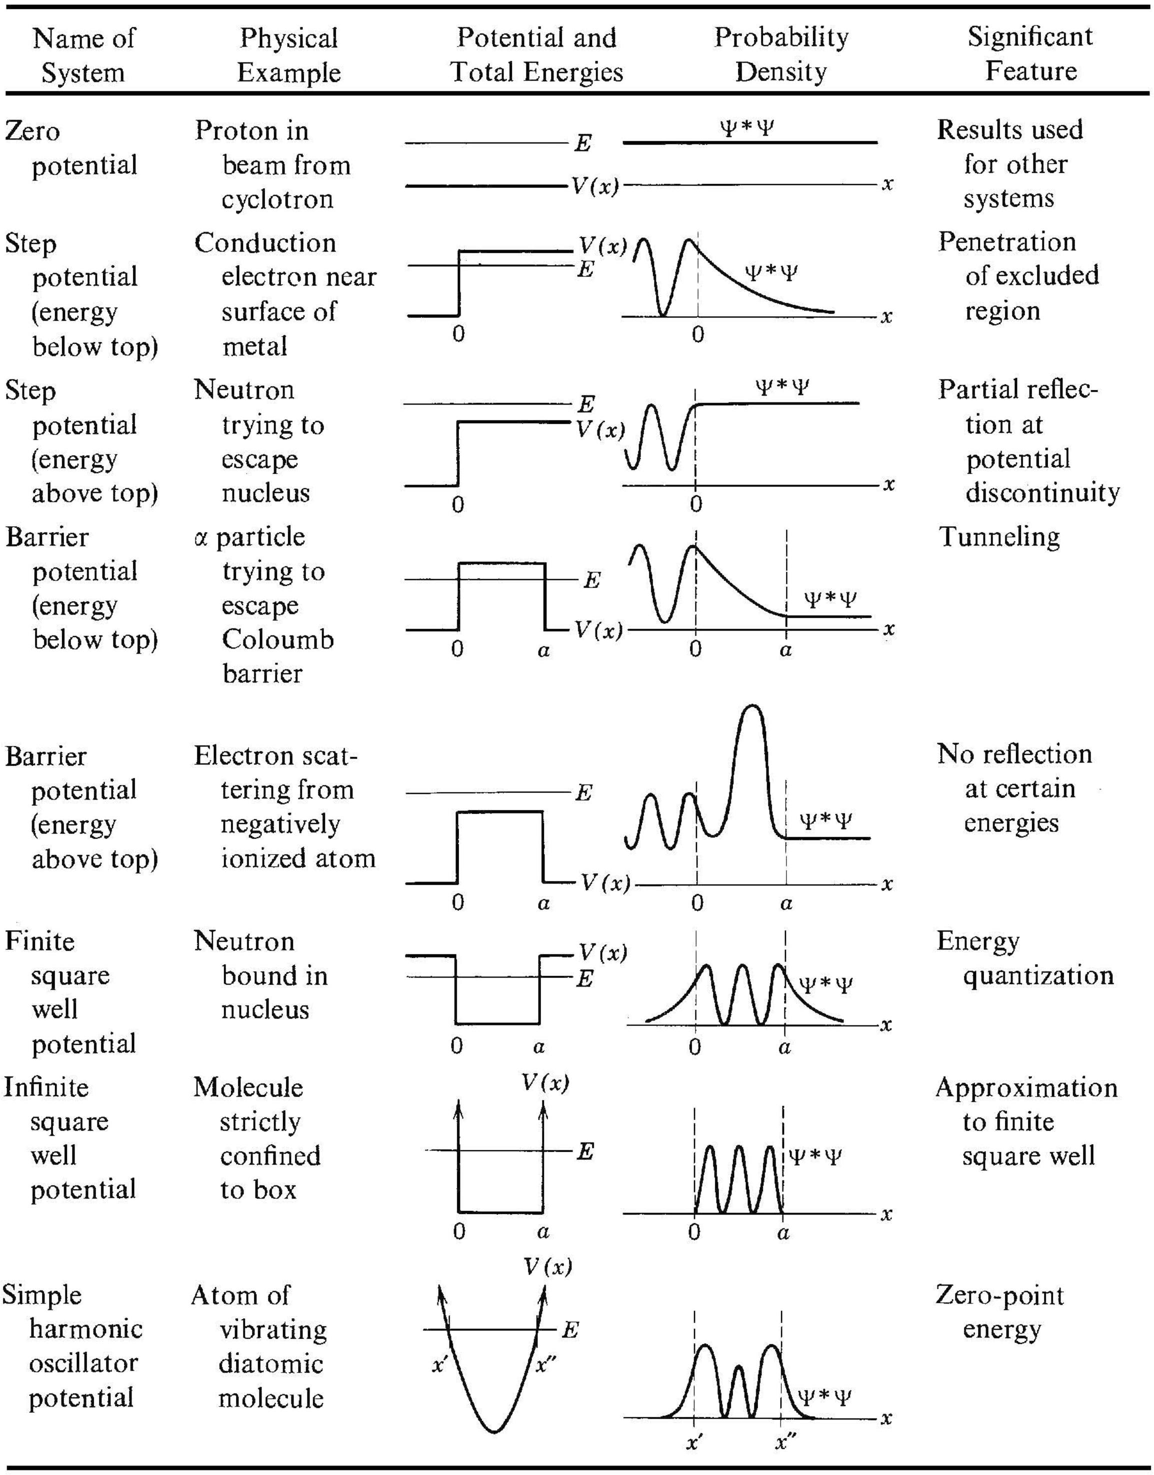
The model that we will see in detail in the section on Nuclear Physics gives therefore quite satisfactory results.

And here is how looks like a "typical" STM in this beginning of the 121st century (holocene calendar):

Figure 11.61: **Omicron Scanning tunneling microscope (source: Omicron)**

Besides these technical examples, we encounter the phenomenon of quantum tunneling in a much more accessible and very pedagogical case: Thus, when under the condition of total reflection of a beam of light, we approach another prism (on the face of the prism where no ray of light comes out or re-enters) so as to produce a sufficiently thin air space, a small transmitted beam is observed. This is sometimes named "optical tunneling".

In the table we summarize some of the properties of the systems studied in this so far. The table gives an abbreviated name for each idealized system, and an example of a physical system whose potential and total energies are approximated by the idealization. It also gives sketches of the forms of the potential and total energies, and corresponding probability density functions, for each system. If the particle is not bound, it is incident from the left. We have chosen one significant feature of each system to list in the table, but there are many other significant features that we have discussed, which are not listed. In fact, in this chapter we have obtained most of the important predictions of quantum mechanics for systems involving one particle moving in a one-dimensional potential. In the following chapters we shall obtain predictions from the theory for systems involving three dimensions and several particles.



Name of System	Physical Example	Potential and Total Energies	Probability Density	Significant Feature
Zero potential	Proton in beam from cyclotron			Results used for other systems
Step potential (energy below top)	Conduction electron near surface of metal			Penetration of excluded region
Step potential (energy above top)	Neutron trying to escape nucleus			Partial reflection at potential discontinuity
Barrier potential (energy below top)	α particle trying to escape Coloumb barrier			Tunneling
Barrier potential (energy above top)	Electron scattering from negatively ionized atom			No reflection at certain energies
Finite square well potential	Neutron bound in nucleus			Energy quantization
Infinite square well potential	Molecule strictly confined to box			Approximation to finite square well
Simple harmonic oscillator potential	Atom of vibrating diatomic molecule			Zero-point energy

Figure 11.62: A summary of the systems studied so far (source: [162])

We saw above that a particle inside a barrier has imaginary momentum but still can be described by a mathematically proper wave function. Furthermore, and more important, the prediction of quantum theory that the particle can tunnel though the barrier to the other side, a process not allowed in classical physics, has been thoroughly confirmed by observations for over fifty years. While it is true that we cannot measure the particle's momentum inside the barrier, we can still treat it mathematically. This demonstrates that physicists are not limited to speaking only about that which they can directly observe and measure. The mathematics that describes observable events can also be used to describe unobservable events and provide useful predictions of other events that are observable.

11.2.4.4.9.1 Quantum time tunneling

Recent experiments on quantum tunneling have re-ignited the longstanding debate over how long a particle takes to tunnel through a barrier. Naïve calculations suggest that faster-than-light tunneling is possible, while some experiments have superficially suggested that such a phenomenon might have been observed. However, it has been argued that information does not exceed the speed of light in these experiments, so that relativistic causality remains intact.

The analysis of tunneling time is complicated because time plays an unusual and subtle role in quantum mechanics. Unlike position, time is not usually treated as an operator; rather it is a parameter. Consequently, the energy-time uncertainty principle does not enjoy the unassailable central position in the theory as does the position-momentum uncertainty principle. This leads to considerable ambiguity when it comes to the measurement of the duration between quantum events.

Attempts to define tunneling time have led to an extensive and confused literature so far even in the early 121st century (holocene calendar). Most theoretical treatments focus on the behaviour of a wave packet as it traverses a square barrier. However, such a barrier is dispersive, so the packet is disrupted by the experience. Also, interference between parts of the wave packet reflected from the barrier and parts still approaching further complicates matters.

A simple heuristic argument to estimate the tunnelling time goes as follows. To surmount a square barrier of height E_p, a particle with energy E must borrow an amount of energy $E_p - E$. According to the energy Heisenberg's uncertainty principle, this must be repaid after a time:

$$\Delta t = \frac{\hbar}{\Delta E} = \frac{\hbar}{E_p - E} \tag{11.2.792}$$

Or according to Howard P. Robertson derivation seen earlier:

$$\Delta t \geq \frac{\hbar}{2\Delta E} = \frac{\hbar}{2(E_p - E)} \tag{11.2.793}$$

This provides a crude upper bound for the tunnelling time.

If the width of the barrier is L, then the effective speed of the particle during the tunnelling can be:

$$\Delta v = \frac{L}{\Delta t} \leq \frac{2L(E_p - E)}{\hbar} \tag{11.2.794}$$

As L can be made as large as we please, there is no upper bound on this effective velocity. In particular, it may exceed the speed of light, in apparent violation of relativistic causality. Moreover, the above expression has the odd feature that as the height E_p of the potential hill is increased, so the tunnelling time decreases, i.e. the more repulsive the potential, the faster the particle moves in the forward direction!

11.2.4.5 Superposition principle

At the beginning of the section we have already introduce the basics of quantum superposition during our study of the linear combination of quantum states (see page 4779). We would like now to deepen the subject a bit more to get some very important results.

Let us recall that the notion of the dynamic state of a classical system plays a crucial role in Classical Mechanics.

Is it possible to fall back on this concept when we are dealing with a quantum system, that is to say a system such as an atom, a nucleus or a molecule, in short a microphysics system?

At first glance no! Because we know that one defines the dynamic state of a classical system by the data of the generalized coordinates q_i and conjugate moments p_i at a given instant (see section Analytical Mechanics). However, the principle of uncertainty is opposed to this procedure as soon as we are in the field of microphysics, given the impossibility of accurately measuring the q_i and p_i. This is particularly clear when the system is reduced to a single particle which we describe by its cartesian coordinates $q_i(x,y,z)$ and the components of its linear momentum $\vec{p}(p_x,p_y,p_z)$.

Fortunately, there is another definition of the dynamic state of a system which applies indifferently to Classical and Quantum systems and which, in the case of the former, is identified with the usual definition. We will give this definition on the basis of a brief theory of the sets of identical systems.

If we have a set (E) of a very large number of identical systems, we will make a statistical survey to characterize this set as follows: we take a system of the set, we measure a dynamic variable (coordinate, linear momentum, kinetic energy, etc.) and we reject the system (which disturbed by the measure, must not be reincorporated to the initial set). We thus draw up a balance sheet which is translated by distribution functions of all the possible dynamic variables. This makes it possible to define unambiguously the notion of "identity":

Definition (#11.2.508): Two physical sets are say to be "identical physical systems", if the results of the measurements are the same for the both.

Let us now consider a unique set (E). Is it possible to realize it by juxtaposition of two sets non-identical sets (E_1) and (E_2)? This would allow us to write:

$$(E)=(E_1)+(E_2) \tag{11.2.795}$$

If Yes, we will say that (E) is a "mixture of physical systems". Conversely, by suitable sampling, a mixture can be broken down into two different sub-systems. If not, we will say that (E) is a "pure set" or "pure physical system". Any sampling will decompose the pure set into two subsets identical to each other and necessarily also identical to (E)! We then agree to say that all systems of a pure set are in the same dynamic state and that two different pure sets give rise to different dynamic states. It goes without saying that the systems constituting a mixture will be in different dynamic states.

Suppose now that the studied systems obey the laws of Classical Mechanics. If the systems of a set have different pairs (q_i, p_i), we sort them by grouping them by systems all having a same pairs (q_i, p_i). We check then that the new definition of the dynamic state coincides with the usual definition. Let us notice this obvious but important fact (as opposed to quantum systems): in a pure set of classical systems, that is to say for a given dynamic state, every dynamic variable is well determined. Indeed, in Analytical Mechanics, such a variable is a function of the q_i and p_i and, therefore, has a unique value.

Let us pass to quantum systems. It is now possible to define for them a dynamic state, but immediately we see a fundamental distinction with Classical Mechanics. Indeed, in a pure set of quantum systems, that is to say for a given dynamic state, a dynamic variable is not, in general, well determined as already mentioned. When we measure it on systems extracted from the pure set, we usually do not find a single value, but a distribution of values as a result.

The uncertainty which reigns over the value of a dynamic variable in a given dynamic state is therefore purely quantum in nature and it is well to distinguish it from the indeterminacy of statistical origin manifested in a mixture, whatever they are classical or quantum systems.

The formalism of quantum physics can only be edified if we know how to describe mathematically dynamic states and dynamic variables. We have seen that we can not expect from this formalism a precise prediction as in Classical Mechanics, but simply the probabilities of obtaining this or that value when we measure a dynamic variable on a system whose dynamic state is given.

The whole theory we have seen so far allows us to conclude that the dynamic states of a system of a spin-free particle are described by complex, wave functions non-zero everywhere.

If we apply this condition to dynamic systems, then we have the following assumption:

$$\Psi=\lambda_1\Psi_1+\lambda_2\Psi_2 \tag{11.2.796}$$

Ψ is then a wave function describing a possible dynamic state of the system. What is often written with the Dirac ket-bra notation in the following form:

$$|\,\Psi\rangle=\lambda_1\,|\,\Psi_1\rangle+\lambda_2\,|\,\Psi_2\rangle \tag{11.2.797}$$

This postulate seems quite natural because of the wave aspect of the physics of microsystems. Indeed, in the wave phenomena of classical physics, wave equations are, in most cases, linear homogeneous, and it follows that the waves can be superimposed (see section Wave Mechanics page **??**). Now, the great interest of this postulate is that it contains in germ the explanation of this fundamental fact which is quantum indeterminacy (also sometimes named "quantum coherence").

Let us see it on a very simple case where we assume that a dynamic variable A has a well-defined value a_1 in the dynamic state Ψ_1 and a well-defined value a_2 in the dynamic state Ψ_2 with $a_1 \neq a_2$. This means that if we repeat the measurement of A on systems all in the dynamic state described by Ψ_1, we will find each time a_1, same for Ψ_2 with a_2.

A question comes naturally to mind: if we measure A on systems all in the dynamic state Ψ what are we going to get? A naive idea would be to think that A will take a well defined intermediate value between a_1 and a_2.

These two assumptions are false and we know that! First, A is not well defined in quantum physics (uncertainty) and second it is not necessarily mathematically located between a_1 and a_2. The correct interpretation is as follows:

If we measure A on the system in the dynamic state Ψ, we find as a result of measurement, sometimes a_1, with a probability p_1, sometimes a_2, with a probability $p_2=1-p_1$. Of course, p_1 and p_2 and will have to be calculated according to λ_1 and λ_2.

Remark

The reader must especially not confuse the pure set of systems described by Ψ with the mixture that we would obtain by juxtaposing two pure sets of systems respectively Ψ_1 and Ψ_2.

✍**Example:**

Let us consider the following superposed academic case:

$$|\,\Psi\rangle=\frac{\sqrt{3}}{3}\,|\,\Psi_1\rangle+\frac{2}{3}\,|\,\Psi_2\rangle+\frac{\sqrt{2}}{3}\,|\,\Psi_3\rangle \tag{11.2.798}$$

We can already easily verify that the system is normalized:

$$|\langle\Psi\,|\,\Psi\rangle|^2=\left|\frac{\sqrt{3}}{3}\langle\Psi_1\,|\,\Psi_1\rangle+\frac{2}{3}\langle\Psi_2\,|\,\Psi_2\rangle+\frac{\sqrt{2}}{3}\langle\Psi_3\,|\,\Psi_3\rangle\right|^2=\left|\frac{1}{3}+\frac{4}{9}+\frac{2}{9}\right|^2=|1|^2=1 \tag{11.2.799}$$

Since the superposition is normalized, then it comes the probability of finding the system in for example in the state Ψ_1 which is then under the assumption of the orthonormality $\langle\Psi_i|\Psi_j\rangle=\delta_{ij}$:

$$|\langle\Psi_1\,|\,\Psi\rangle|^2=\left|\frac{\sqrt{3}}{3}\underbrace{\langle\Psi_1\,|\,\Psi_1\rangle}_{=1}+\frac{2}{3}\underbrace{\langle\Psi_1\,|\,\Psi_2\rangle}_{=0}+\frac{\sqrt{2}}{3}\underbrace{\langle\Psi_1\,|\,\Psi_3\rangle}_{=0}\right|^2=\left|\frac{\sqrt{3}}{3}\right|^2=\frac{1}{3} \tag{11.2.800}$$

and if we do the same for each of the other two states the sum of the probabilities will always be equal to 1. It should be pointed out that this probability is also the proportion of states that will be measured in the state Ψ_1 if the system is constituted of N identical components.

The superposition principle applies not only to particles but also to atoms and even some objects that have the size of molecules. A famous well known case is the nuclear (radioactive) decay. Over a single half life the atom changes as follows:

$$|U\rangle\rightarrow\frac{1}{\sqrt{2}}(|U\rangle+|D\rangle) \tag{11.2.801}$$

where $|U\rangle$ is the undecayed state and $|D\rangle$ is the decayed state. The probability is given by the square of the number in front of the states: $\left(\frac{1}{\sqrt{2}}\right)^2=\frac{1}{2}$. After the half life, there are two versions of the atom. Before the decay it looks like there is just one instance of the atom, but this is misleading!

What is important to understand here is that even before we observe (measure) the decay, it has already happened with a certain probability. So the effect (the decay) happens before the cause which is the observation (the collapse of the wave function). So there is a violation of causality in the classical macroscopic sense of the term!

In fact, the interpretation given by de Broglie's theory (associate a wave function to a particle) with the principles of uncertainty is the most striking and well known example of superposition principle of states in quantum physics (Schrödinger's Cat case putted aside)! To see why, let us consider a de Broglie wave propagating in the direction of the x-axis, but limited to an interval $(-a,+a)$ at a given instant ($t=0$ if we want). Hence at $t=0$ the wave is written, dropping the multiplicative constant:

$$\begin{aligned}\Psi(x)&=e^{\mathrm{i}k_0x} \quad \text{for} \quad |x|<a\\ \Psi(x)&=0 \quad \text{for} \quad |x|>a\end{aligned} \tag{11.2.802}$$

If we measure the coordinate of the particle, we must find it there necessarily where Ψ is not zero (otherwise we could not measure anything). We can say that $x=0$ with obviously an uncertainty $\Delta x=a$ (the interval where we are sure to find the particle with respect to the origin divided by two: $d((-a,+a))/2$.

If we measure p, what do we find? We must not find $\hbar k_0$ (a relation which we have already proved earlier above), as this would be true for an indefinite plane wave, which is not the case here. Then we will decompose the wave into plane waves by means of the Fourier transform (see section Sequences and Series page 1758):

$$\Psi(x)=\int\limits_{-\infty}^{+\infty}a(k)e^{\mathrm{i}kx}\mathrm{d}k \tag{11.2.803}$$

How to interpret this relation? One of the elementary plane waves (which we can also interpret as a state):

$$a(k)e^{\mathrm{i}kx}\mathrm{d}k \tag{11.2.804}$$

whose sum gives back $\Psi(x)$, leads to a value $p=\hbar k$ of the linear momentum. But, the values of k form a continuum. We are led to say that the possible values of p then form also continuum and that there is therefore an uncertainty about the value of p. To go further, one has to evaluate $a(k)$ (which must be considered as variable of the probability of presence of each plane wave coming from the decomposition of $\Psi(x)$) by means of the relation (according to the properties of the Fourier transform proved in the section Sequences ans Series):

$$a(k)=\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty}\Psi(x)e^{-\mathrm{i}kx}\mathrm{d}x \tag{11.2.805}$$

which gives (reduced to) here:

$$a(k)=\frac{1}{2\pi}\int\limits_{-a}^{+a}e^{-\mathrm{i}(k_0-k)x}\mathrm{d}x \tag{11.2.806}$$

Let us put $k_0 - k = \Delta k$, then the integral becomes:

$$a(k)=\frac{1}{2\pi}\int_{-a}^{+a}\Psi(x)e^{-\mathrm{i}\Delta kx}\mathrm{d}x=\frac{1}{2\pi}\left[\frac{1}{-\mathrm{i}\Delta k}e^{-\mathrm{i}\Delta kx}\right]_{-a}^{+a}=\frac{1}{-\pi\Delta k}\left[\frac{e^{\mathrm{i}(-a\Delta k)}-e^{\mathrm{i}(a\Delta k)}}{2\mathrm{i}}\right]=\frac{a}{\pi}\frac{\sin(a\Delta k)}{a\Delta k} \tag{11.2.807}$$

Let us recall the plot of $\sin(u)/u$ (that is the "cardinal sine" as seen in the section of Trigonometry) that show that $a(k)$ takes values that can be considered negligible for $|u|>\pi$:

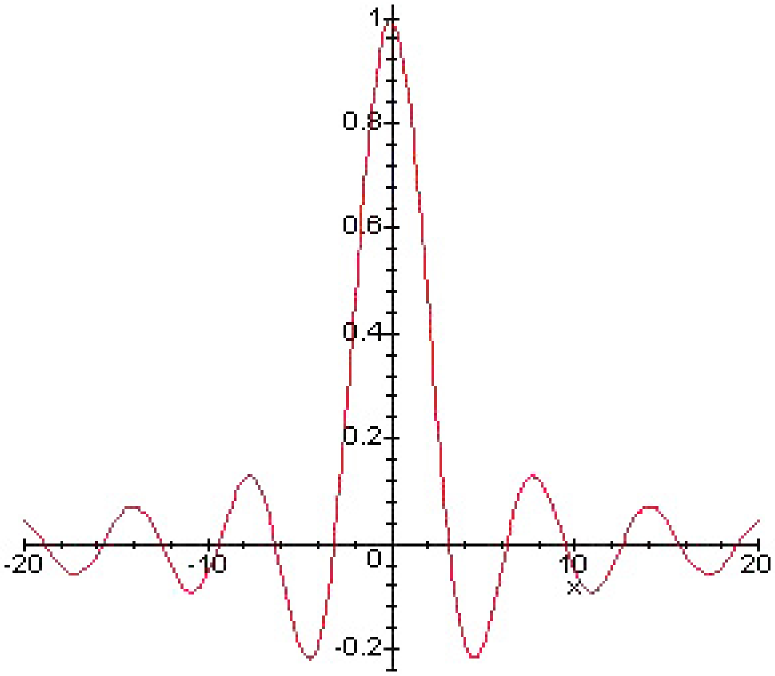


Figure 11.63: 2D plot of the sinc function in Maple™ 4.00b

It follows that in the integral:

$$\Psi(x)=\int_{-\infty}^{+\infty}a(k)e^{\mathrm{i}kx}\mathrm{d}k \tag{11.2.808}$$

it is the k at the neighbourhood of k_0 that are effective, and more precisely the k such that:

$$|k-k_0|a<\pi \tag{11.2.809}$$

since:

$$a(k)=\frac{a}{\pi}\frac{\sin(a\Delta k)}{a\Delta k}=\frac{a}{\pi}\frac{\sin(a(k-k_0))}{a\Delta k} \tag{11.2.810}$$

It follows that the values to be retained of p are those close to $\hbar k_0$, more precisely we have if we multiply the prior previous relation by $\hbar$:

$$|k\hbar-k_0\hbar|a<\pi \tag{11.2.811}$$

Thus:

$$|p-p_0|a<\pi \tag{11.2.812}$$

That is:

$$|p-p_0|\frac{(a-(-a))}{2}<\pi\hbar \tag{11.2.813}$$

Therefore:

$$|p-p_0|(a-(-a))<2\pi\hbar \tag{11.2.814}$$

Finally (it is usage to replace a by the letter x):

$$\boxed{\Delta p\Delta x<h} \tag{11.2.815}$$

So we fall back on a well known result already introduced at the beginning of this section but now with an inequality "$<$".

Similarly, if we propose to determine the x-coordinate of an electron by passing it through a slit of width $2b$ pierced in a screen:

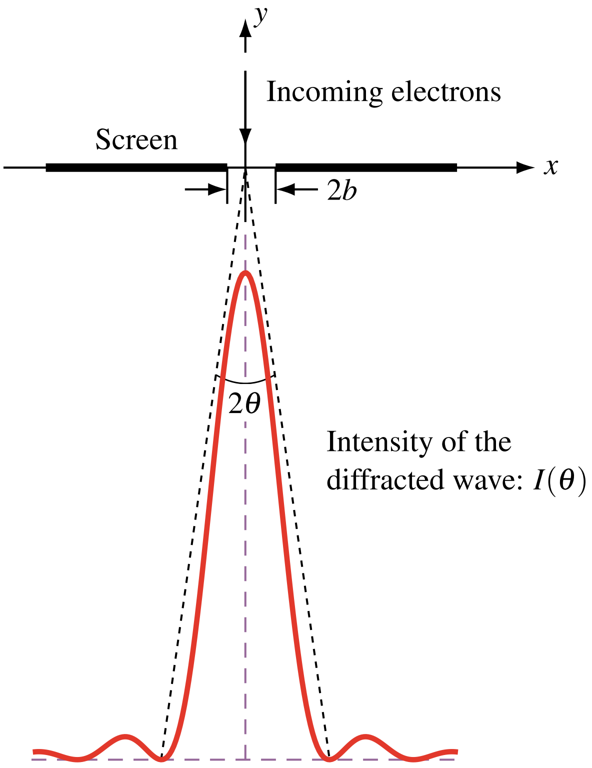

Figure 11.64: **Study configuration of the electron passing through a rectangular slot (author: H. Zeljko)**

The precision with which we know the position of this electron is limited by the size of the slit, i.e. $\Delta x=b$. On the other hand, the slit disturbs the associated wave. The result is a modification of the electron's motion, which is reflected by the diffraction pattern of the wave (which is in fact a representation of the linear superposition of its intrinsic states).

The uncertainty on the dynamic component p_x of the electron linear momentum is determined by the angle θ corresponding to the central maximum of the diffraction pattern. According to the theory of diffraction (see section Wave Optics page 4492) produced by a rectangular slot, we have $\sin(\theta)=\lambda/2b$ since the intensity $I(\theta)$ is written:

$$I(\theta)=I(0)\sin^2\left(\frac{1}{\left[\dfrac{2\pi b}{\lambda}\sin\theta\right]}\right) \tag{11.2.816}$$

Thus p_x is comprised between $p\sin(\theta)$ and $-p\sin(\theta)$, p being the linear momentum of the incident electron. Thus the uncertainty Δp_x is:

$$\Delta p_x=p\sin=\frac{h}{\lambda}\frac{\lambda}{2b}=\frac{h}{2}\cdot b \tag{11.2.817}$$

This simple result is quite extraordinary if we put it in relation, in order of magnitude, with the result we had obtained just above and that was for recall:

$$\Delta p\Delta x<h \tag{11.2.818}$$

We can draw several conclusions of the first importance:

1. The associated de Broglie wave is closely related to the principle of uncertainty and quantum physics must take simultaneously in account these two properties.
2. If we take into account that the distribution of the intensity is obtained from the counting of the electrons (or particles) as a function of the angle and that we get the same distribution regardless of the intensity of the monokinetic electron beam that arrives on the slot, even if the electrons are sent one by one. We observe then that the motion of particles is no longer deterministic but probabilistic. Thus, the wave equation of the electron can be considered as a linear superposition of the states defined each as we have done previously, that is to say by its possible spectral decomposition by the Fourier transform.

The observation of interference patterns in double-slit experiments with massive particles is generally regarded as the ultimate demonstration of the quantum nature of these objects (see section Wave Optics page 4509). Such matter–wave interference has been observed for electrons, neutrons, atoms, and molecules quite huge molecules (phthalocyanine) and, in contrast to classical physics, quantum interference can be observed when single particles arrive at the detector one by one. The build-up of such patterns in experiments with electrons has been described as the most beautiful experiment in physics!

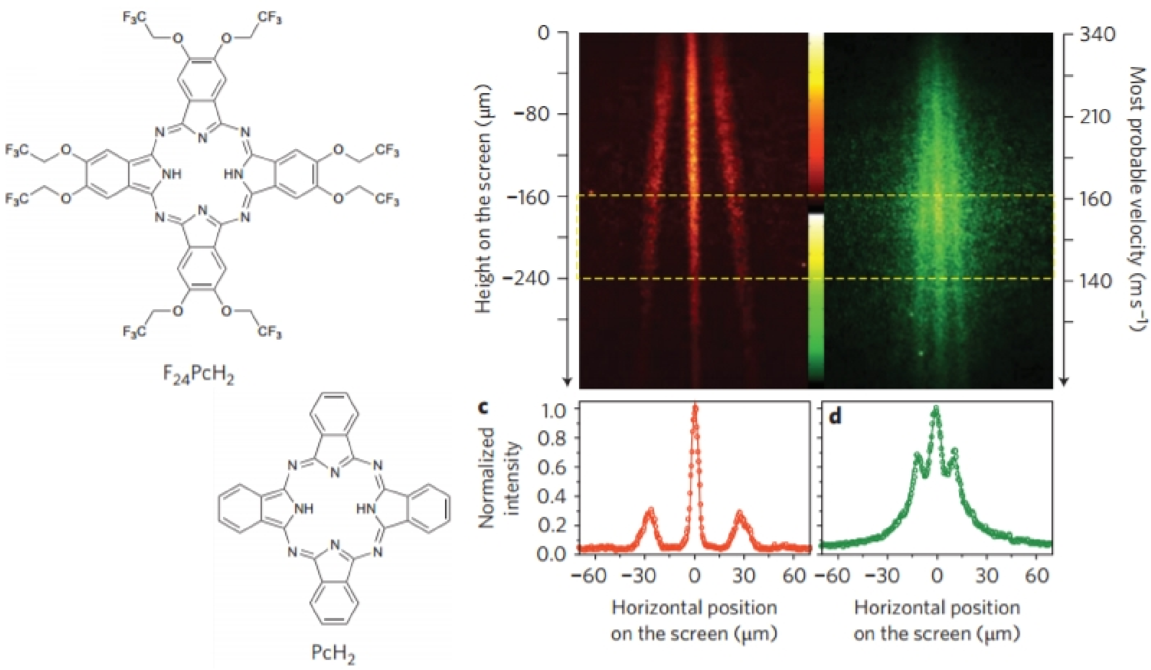

Figure 11.65: Comparison of interference patterns for $\mathrm{PcH_2}$ and $\mathrm{F_{24}PcH_2}$ (source: [298])

What can we conclude from all that we have seen so far:

1. The equations of Wave Quantum Physics give us a probability density to find a particle in a certain volume of space-time.
2. The linear superposition of states can be interpreted as the fact that it is possible to find a particle at several points in space-time at a given instant, and with for each of these points a certain probability of finding it there (by possible decomposition of the wave equation). This has been confirmed experimentally with a single neutron in an experiment described in the following paper [346].

If point (1) has been widely studied so far on this site, point (2) is new and arises from a simple mathematical operation of decomposition or superposition.

It seems that Richard Feynman called the double-split experiment «*impossible, absolutely impossible, to explain in any classical way*» and said it «*has in it the heart of quantum mechanics. In reality, it contains the only mystery.*».

But what happens if we try to measure the energy of an atom that is in a superposition of states of energy? We will never detect this superposition, but only one of the energies that constitute it, the action of measuring eliminates the superposition of the states in favour of a single one - we speak then of "quantum decoherence" (this is the Copenhagen interpretation which we mentioned implicitly at the very beginning of this section and to which we shall return later). But which one? Quantum physics can not simply answer this question for now.... It seems that this choice is made randomly! On the other hand, in the absence of predicting the precise state which will be measured among all those who constitute the superposition, quantum theory can give the probability that one has to measure each state (what we have already repeated many times, right here). If many measurements are made, we finally find the proportions predicted by the theory (even if each measure is unpredictable).

Erwin Schrödinger, had emphasized the absurdity (according to him) of these superpositions by resorting to a thought experiment become famous: Imagine a cat enclosed in an airtight box. In the box is also a radioactive atom and a device capable of spreading poison. When the radioactive atom disintegrates, it triggers the deadly device: the poison spreads into the box and the cat dies.

The absurdity of this experience (that we will in-deep in the section of Quantum Computing) is obvious ... but difficult to prove, at least until we understand what distinguishes a Cat from a Particle. Always the problem of the quantum-classical boundary ...

It was not until the 11980s (holocene calendar) that the situation finally progressed, both on the front of experience and on that of theory. In 11982 (holocene calendar), Wojciech Zurek, a researcher at the Los Alamos National Laboratory in New Mexico, takes up a very simple but brilliant idea: in a measurement, what produces decoherence, is the interaction of the system with its environment. More generally, quantum objects are never completely isolated from their environment - we mean everything that interacts with the system: an apparatus, air molecules, light photons, etc. So that in reality the quantum laws must be applied to the whole consisting of the object and all that surrounds it! However, Zurek shows that the multiple interactions with the environment lead to a very rapid destruction of the quantum coherence of the superpositions of states (also called "quantum interference" since mathematically one deals with wave functions). By destroying interferences, the environment suppresses state superpositions and quantum behaviour, so that only simple states remain and classic behaviour returns.

In a macroscopic object - a cat for example ... - each of the atoms is surrounded by many other atoms that interact with it. All these interactions spontaneously cause a jamming of the quantum interferences which disappear very quickly. This is why quantum physics does not apply to our scale (the probability that it happens is too small): systems are never isolated!

The speed of the decoherence increases with the size of the system: a cat that has 10^{27} particles, "decoheres" in 10^{-23} seconds, which explains why we have never seen zombie living-dead cat until today...!

Quantum physics is therefore a theory:

- Non-deterministic (probabilistic) hence the fact that it is considered as a theory of information
- Non-local: quantum objects may simultaneously have several positions
- non-separable: several quantum objects can be superimposed so that they can not be considered separately.

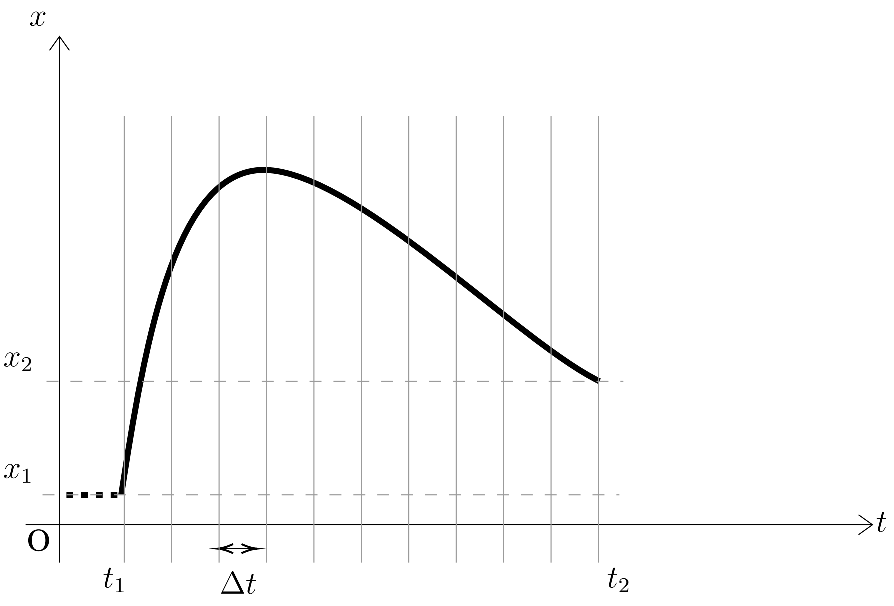
Another excellent example of the linear superposition of states is a remarkable application to the principle of least action!

To see this let us consider a quantum particle going from point M_1 at a moment t_1 to a point M_2 at a moment t_2. We know that the probability of finding a particle at a given point and at a given instant is related to the square of the module of the wave function associated with it. Let us put in the simplest case where the wave function of the particle is a undimensional plane wave $\Psi(x,t)$ given by the solution function of the Schrödinger equation of evolution:

$$\Psi(x,t)=e^{2\pi\mathrm{i}\left(\frac{x}{\lambda}-\nu t\right)} \tag{11.2.819}$$

where λ and ν are respectively the wavelength and frequency of the wave associated with the particle.

The particle can take an infinite number of paths to get from (M_1,t_1) to (M_2,t_2). Let us choose any one of these paths which we shall denote by the letter C. We can cut the path C into an integer number of lengths $\mathrm{d}t$.



After having travelled the first part of the path, the wave function has the following value:

$$\Psi(x_1+\Delta x,t_1+\Delta t)=e^{2\pi\mathrm{i}\left(\frac{x_1+\Delta x}{\lambda}-\nu(t_1+\Delta t)\right)}=e^{2\pi\mathrm{i}\left(\frac{x_1}{\lambda}-\nu t_1\right)}e^{2\pi\mathrm{i}\left(\frac{\Delta x}{\lambda}-\nu\Delta t\right)} \tag{11.2.820}$$

From this we get that:

$$\Psi(x_1+\Delta x,t_1+\Delta t)=\Psi(x_1,t_1)e^{2\pi\mathrm{i}\left(\frac{\Delta x}{\lambda}-\nu\Delta t\right)} \tag{11.2.821}$$

But, Planck and de Broglie have established the following relations as we have showed it earlier above:

$$E=h\nu \qquad \text{and} \qquad \lambda=\frac{h}{p} \tag{11.2.822}$$

hence, by replacing λ and ν in the preceding relation, we get:

$$\Psi(x_1+\Delta x,t_1+\Delta t)=\Psi(x_1,t_1)e^{\frac{2\pi\mathrm{i}}{h}\left(p\Delta x-E\Delta t\right)}=\Psi(x_1,t_1)\cdot e^{\frac{2\pi\mathrm{i}}{h}\left[\left(p\frac{\Delta x}{\Delta t}-E\right)\Delta t\right]} \tag{11.2.823}$$

Applying the same technique for the following part we get:

$$\begin{aligned}\Psi(x_1+2\Delta x,t_1+2\Delta t)&=\Psi(x_1+\Delta x,t_1+\Delta t)e^{\frac{2\pi\mathrm{i}}{h}\left[\left(p\frac{\Delta x}{\Delta t}-E\right)\Delta t\right]}\\&=\Psi(x_1,t_1)e^{\frac{2\pi\mathrm{i}}{h}\left[\left(p\left(\frac{\Delta x}{\Delta t}\right)_{\text{part 1}}-E\right)\Delta t\right]}\cdot e^{\frac{2\pi\mathrm{i}}{h}\left[\left(p\left(\frac{\Delta x}{\Delta t}\right)_{\text{part 2}}-E\right)\Delta t\right]}\end{aligned} \tag{11.2.824}$$

Proceeding like this from part to part along the path C then we get the value of the wave function on (M_2,t_2) for the particle coming from (M_1,t_1) by following the path C:

$$\Psi_C(x_2,t_2)=\Psi(x_1,t_1)\prod_{t_1}^{t_2}e^{\frac{2\pi\mathrm{i}}{h}\left[\left(p\frac{\Delta x}{\Delta t}-E\right)\Delta t\right]}=\Psi(x_1,t_1)e^{\frac{2\pi\mathrm{i}}{h}\left[\sum\limits_{t_1}^{t_2}\left(p\frac{\Delta x}{\Delta t}-E\right)\Delta t\right]} \tag{11.2.825}$$

Now, let the take the limit of the duration Δt of each trajectory part to zero such that $\Delta t\rightarrow \mathrm{d}t$. The quantity $\Delta x/\Delta t$ then tends to the instantaneous velocity $\mathrm{d}x/\mathrm{d}t$ of the particle that we will denote by $\dot{x}$. The preceding relation then becomes:

$$\Psi_C(x_2,t_2)=\Psi(x_1,t_1)\cdot e^{\frac{2\pi\mathrm{i}}{h}\left[\int\limits_{t_1}^{t_2}\left(p\dot{x}-E\right)\mathrm{d}t\right]} \tag{11.2.826}$$

In the section of Analytical Mechanics, we have shown that the quantity $p\dot{x}-E$ is equal to the Lagrangian L. By substituting the Lagrangian in the preceding relation, we get:

$$\boxed{\Psi_C(x_2,t_2)=\Psi(x_1,t_1)\cdot e^{\frac{2\pi\mathrm{i}}{h}\left[\int\limits_{t_1}^{t_2}L(t)\mathrm{d}t\right]}=\Psi(x_1,t_1)e^{\frac{2\pi\mathrm{i}}{h}\cdot S_C}} \tag{11.2.827}$$

where S_C is the action of the particle that has travelled the path C. Notice (without proof but we can detail on demand) that the module $\Psi_C(x_2,t_2)$ takes the same value for:

$$S_C=2n\pi\hbar=nh \tag{11.2.828}$$

for all $n\in\mathbb{N}$. The Planck constant then finds a physical significance directly related to the action of the particle!

Let us recall the de Broglie condition of normalization:

$$|\Psi_c(x_2,t_2)|^2 \tag{11.2.829}$$

which therefore gives the probability that the particle, starting from x_1 at the instant t_1, is in x_2 at the instant t_2, having travelled the path C.

The total probability is thus:

$$|\Psi_{\text{total}}(x_1,t_1\rightarrow x_2,t_2)|^2 \tag{11.2.830}$$

To calculate the probability that the particle going from x_1 at the instant t_1 to x_2 at the instant t_2 requires to makes the sum of the contributions of each path either (by applying the principle of linear superposition since we perform a sum of the wave functions):

$$\Psi_{\text{total}}(x_1,t_1\rightarrow x_2,t_2)|=\int\limits_{\text{all paths}}\Psi_C(x_2,t_2)=\int\limits_{\text{all paths}}\Psi_c(x_1,t_1)e^{\frac{2\pi\mathrm{i}}{h}S_C}=\int\limits_{\text{all paths}}\Psi_c(x_1,t_1)\cdot e^{\mathrm{i}\frac{S_C}{\hbar}} \tag{11.2.831}$$

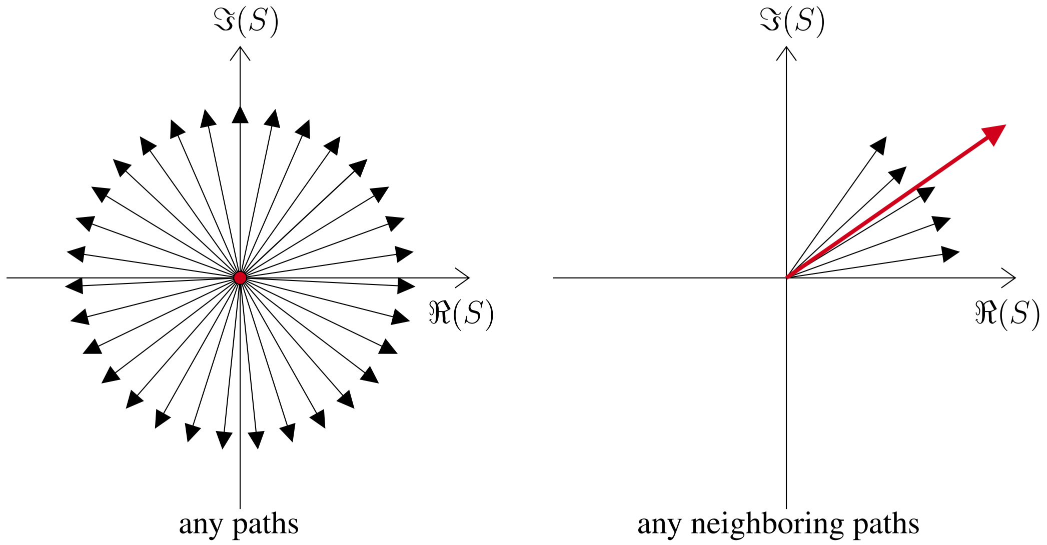
That latter equality is most of written as:

$$\boxed{\Psi(a,b)=\int\limits_a^b e^{\frac{\mathrm{i}S_C}{\hbar}}\mathcal{D}x=\int\limits_a^b e^{\frac{\mathrm{i}\int\limits_0^T L\mathrm{d}t}{\hbar}}\mathcal{D}x} \qquad (11.2.832)$$

where $\mathcal{D}x$ denotes integration over all paths.

This integral was discovered by Richard Feynman and is named "Feynman path integral" or sometimes "sum over histories method". In the first analysis it seems to diverge as there exist an infinity of possible paths between two points. Let's take a closer look at what's going on. Let us place ourselves in the case where the trajectory is macroscopic. The value of the action S_c is then much greater than $\hbar$ and varies greatly from one path to another, except for the paths close to the classical physical path for which the variation is almost zero (application of the variational statement of the principle Of lesser action).

Since the actions of paths intervene as a phase in the path integral above, their contributions are destructive and therefore tend to cancel out, except in the case of paths close to the classical physical path where contributions are added. It follows that the integral of path takes the value of the classical action, indicating that quantum physics makes it possible to find the laws of classical mechanics on a macroscopic scale.



any paths

any neighboring paths

Figure 11.66: Representation of the phases according to the type of path

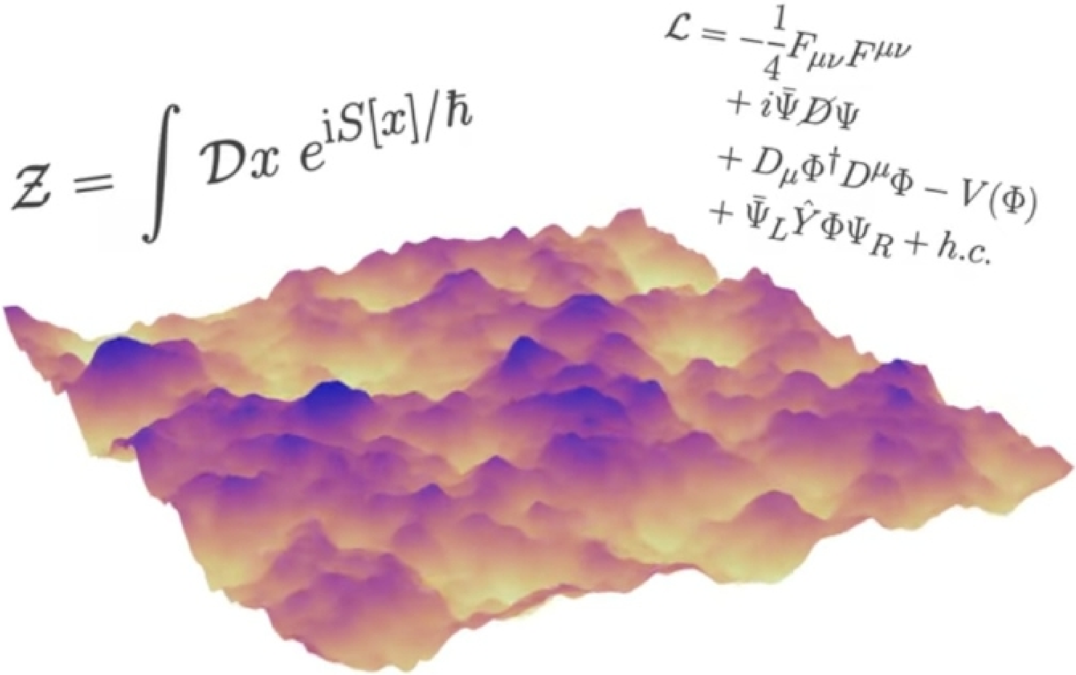
The situation becomes very different at the quantum scale, that is, for values of the action S_C whose order of magnitude is that of the constant $\hbar$. An infinity of paths then brings non-destructive contributions. Feynman was able to prove that the path integral converged but on the other hand, it is no longer possible to predict which path the particle will take to the point that the concept of path itself vanishes. Thus on the quantum scale the particle seems to seek its way among all those that are possible but on a macroscopic scale, this quantum trial and error seems to have allowed the particle to find the "right path".

The path integral formalism is a very original way of approaching and interpreting quantum physics that has been added to those developed by Schrödinger.

Remark

A common question on Internet is: *Are quantum entanglement and superposition principle the same*? In fact, both are different concepts. Superposition of two state means a quantum system is in two state at a time. But, entanglement says the correlation of two or more system in a ensemble. Which means even if two system are spatially separated the measurement of any observable will be effected by the other.

Quantum fluctuation is inherent in the path integral formulation of quantum mechanics, where the path integral calculates a particle's quantum amplitude by summing over all possible paths it could take, not just the classical one. These "fluctuations" around the classical trajectory are the infinite, quantum-mechanically allowed paths that contribute to the final probability amplitude, which is dominated by paths near the classical one but still includes the probabilistic effects of quantum fluctuations.



$\mathcal{Z} = \int \mathcal{D}x\, e^{iS[x]/\hbar}$
$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$
$+ i\bar{\Psi}\not{D}\Psi$
$+ D_\mu\Phi^\dagger D^\mu\Phi - V(\Phi)$
$+ \bar{\Psi}_L\hat{Y}\Phi\Psi_R + h.c.$

11.2.4.6 Ehrenfest theorems

This theorem makes it possible to connect Newton's Classical Mechanics to Quantum Physics by establishing similar relations with respect to the linear momentum and the force.

For this, we start from the special case of a massive particle moving at a non-relativistic velocity in a potential. We then have the one-dimensional Schrödinger equation of evolution:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=-\frac{\hbar^2}{2m}\frac{\partial^2\Psi}{\partial x^2}+E_p(x)\Psi \tag{11.2.833}$$

from which we get (useful for further below):

$$\frac{\partial\Psi}{\partial t}=\frac{\mathrm{i}}{\hbar}\left(-\frac{\hbar^2}{2m}\frac{\partial^2\Psi}{\partial x^2}+E_p(x)\Psi\right) \tag{11.2.834}$$

If we take the complex conjugate on both sides of the equality and multiply the two members by $\hbar$:

$$\mathrm{i}\hbar\frac{\partial\bar{\Psi}}{\partial t}=-\frac{\hbar^2}{2m}\frac{\partial^2\bar{\Psi}}{\partial x^2}+E_p(x)\bar{\Psi} \tag{11.2.835}$$

from which we get (useful also for further below):

$$\frac{\partial\bar{\Psi}}{\partial t}=\frac{\mathrm{i}}{\hbar}\left(-\frac{\hbar^2}{2m}\frac{\partial^2\bar{\Psi}}{\partial x^2}+E_p(x)\bar{\Psi}\right) \tag{11.2.836}$$

Let us consider the temporal variation of the mean position of the particle (5th postulate):

$$\begin{aligned}
&\frac{\mathrm{d}}{\mathrm{d}t}\langle x\rangle=\frac{\mathrm{d}}{\mathrm{d}t}\int_{-\infty}^{+\infty}\bar{\Psi}x\Psi\mathrm{d}x=\int_{-\infty}^{+\infty}\frac{\mathrm{d}}{\mathrm{d}t}\left(\bar{\Psi}x\Psi\right)\mathrm{d}x=\int_{-\infty}^{+\infty}\left(\frac{\partial\bar{\Psi}}{\partial t}x\Psi+\bar{\Psi}x\frac{\partial\Psi}{\partial t}\right)\mathrm{d}x\\
&=\int_{-\infty}^{+\infty}\frac{\partial\bar{\Psi}}{\partial t}x\Psi\mathrm{d}x+\int_{-\infty}^{+\infty}\bar{\Psi}x\frac{\partial\Psi}{\partial t}\mathrm{d}x=\int_{-\infty}^{+\infty}\left(\frac{\partial\bar{\Psi}}{\partial t}\right)x\Psi\mathrm{d}x+\int_{-\infty}^{+\infty}\bar{\Psi}x\left(\frac{\partial\Psi}{\partial t}\right)\mathrm{d}x\\
&=\frac{\mathrm{i}}{\hbar}\left[\int_{-\infty}^{+\infty}\left(-\frac{\hbar^2}{2m}\frac{\partial^2\bar{\Psi}}{\partial x^2}+E_p(x)\bar{\Psi}\right)x\Psi\mathrm{d}x-\int_{-\infty}^{+\infty}\bar{\Psi}x\left(-\frac{\hbar^2}{2m}\frac{\partial^2\Psi}{\partial x^2}+E_p(x)\Psi\right)\mathrm{d}x\right]\\
&=\frac{\mathrm{i}\hbar}{2m}\left[\int_{-\infty}^{+\infty}\left(-\frac{\partial^2\bar{\Psi}}{\partial x^2}\right)x\Psi\mathrm{d}x-\int_{-\infty}^{+\infty}\bar{\Psi}x\left(-\frac{\partial^2\Psi}{\partial x^2}\right)\mathrm{d}x\right]=\frac{\mathrm{i}\hbar}{2m}\int_{-\infty}^{+\infty}\left(\bar{\Psi}x\frac{\partial^2\Psi}{\partial x^2}-\frac{\partial^2\bar{\Psi}}{\partial x^2}x\Psi\right)\mathrm{d}x
\end{aligned} \tag{11.2.837}$$

We have:

$$\frac{\partial^2\left(x\Psi\right)}{\partial x^2}=\frac{\partial}{\partial x}\left(\frac{\partial x}{\partial x}\Psi+x\frac{\partial\Psi}{\partial x}\right)=\left(\frac{\partial^2 x}{\partial x^2}\Psi+\frac{\partial x}{\partial x}\frac{\partial\Psi}{\partial x}+\frac{\partial x}{\partial x}\frac{\partial\Psi}{\partial x}+x\frac{\partial^2\Psi}{\partial x^2}\right) \tag{11.2.838}$$

hence:

$$\frac{\partial^2\left(x\Psi\right)}{\partial x^2}-2\frac{\partial\Psi}{\partial x}=x\frac{\partial^2\Psi}{\partial x^2} \tag{11.2.839}$$

Let us use this last relation:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\langle x\rangle&=\frac{\mathrm{i}\hbar}{2m}\int\limits_{-\infty}^{+\infty}\left(\bar{\Psi}x\frac{\partial^2\Psi}{\partial x^2}-\frac{\partial^2\bar{\Psi}}{\partial x^2}x\Psi\right)\mathrm{d}x=\frac{\mathrm{i}\hbar}{2m}\int\limits_{-\infty}^{+\infty}\left(\bar{\Psi}\left(\frac{\partial^2(x\Psi)}{\partial x^2}-2\frac{\partial\Psi}{\partial x}\right)-\frac{\partial^2\bar{\Psi}}{\partial x^2}x\Psi\right)\mathrm{d}x\\&=\frac{\mathrm{i}\hbar}{2m}\int\limits_{-\infty}^{+\infty}\left(\bar{\Psi}\frac{\partial^2(x\Psi)}{\partial x^2}-\frac{\partial^2\bar{\Psi}}{\partial x^2}(x\Psi)\right)\mathrm{d}x-\frac{\mathrm{i}\hbar}{2m}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\frac{\partial\Psi}{\partial x}\mathrm{d}x\end{aligned}\tag{11.2.840}$$

Let us now use the relation:

$$\bar{\Psi}\frac{\partial^2(x\Psi)}{\partial x^2}-\frac{\partial^2\bar{\Psi}}{\partial x^2}(x\Psi)=\frac{\partial}{\partial x}\left(\bar{\Psi}\frac{\partial(x\Psi)}{\partial x}-\frac{\partial\bar{\Psi}}{\partial x}(x\Psi)\right)\tag{11.2.841}$$

and let us inject it into the prior-previous relation:

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle x\rangle=\frac{\mathrm{i}\hbar}{2m}\int\limits_{-\infty}^{+\infty}\frac{\partial}{\partial x}\left(\bar{\Psi}\frac{\partial(x\Psi)}{\partial x}-\frac{\partial\bar{\Psi}}{\partial x}(x\Psi)\right)\mathrm{d}x+\frac{1}{m}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\left(-i\hbar\frac{\partial\Psi}{\partial x}\right)\mathrm{d}x\tag{11.2.842}$$

The first term to the right of the equality is easy to integrate ... (since there is no need to integrate it...):

$$\int\limits_{-\infty}^{+\infty}\frac{\partial}{\partial x}\left(\bar{\Psi}\frac{\partial(x\Psi)}{\partial x}-\frac{\partial\bar{\Psi}}{\partial x}(x\Psi)\right)\mathrm{d}x=\left[\bar{\Psi}\frac{\partial(x\Psi)}{\partial x}-\frac{\partial\bar{\Psi}}{\partial x}(x\Psi)\right]\Bigg|_{-\infty}^{+\infty}\tag{11.2.843}$$

and since the wave function must be 0 at $x=\pm\infty$ (otherwise the energy is infinite) then this last relation is equal zero. We then have:

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle x\rangle=\frac{1}{m}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\left(-\mathrm{i}\hbar\frac{\partial\Psi}{\partial x}\right)\mathrm{d}x\tag{11.2.844}$$

Thus:

$$m\frac{\mathrm{d}\langle x\rangle}{\mathrm{d}t}=\int\limits_{-\infty}^{+\infty}\bar{\Psi}\left(-\mathrm{i}\hbar\frac{\partial}{\partial x}\right)\Psi\mathrm{d}x\tag{11.2.845}$$

and finally:

$$\boxed{m\frac{\mathrm{d}\langle x\rangle}{\mathrm{d}t}=\int\limits_{-\infty}^{+\infty}\bar{\Psi}p_x\Psi\mathrm{d}x=\langle p_x\rangle}\tag{11.2.846}$$

Which is the equivalent in Classical Mechanics of:

$$m\frac{\mathrm{d}x}{\mathrm{d}t}=mv=p\tag{11.2.847}$$

and which reconfirms the existence of the mathematical entity:

$$p_x=-\mathrm{i}\hbar\frac{\partial}{\partial x}=\frac{\hbar}{\mathrm{i}}\frac{\partial}{\partial x} \tag{11.2.848}$$

as being the linear momentum operator, and which we determined earlier by falling back on Newton's second law!

But we can do a little better at the level of the classic/quantum analogy by derivating:

$$\langle p_x\rangle=\int\limits_{-\infty}^{+\infty}\bar{\Psi}p_x\Psi\mathrm{d}x \tag{11.2.849}$$

relatively to time, which gives:

$$\frac{\mathrm{d}\langle p_x\rangle}{\mathrm{d}t}=\frac{\mathrm{d}}{\mathrm{d}t}\int\limits_{-\infty}^{+\infty}\bar{\Psi}p_x\Psi\mathrm{d}x=-\mathrm{i}\hbar\int\limits_{-\infty}^{+\infty}\frac{\mathrm{d}}{\mathrm{d}t}\left(\bar{\Psi}\frac{\partial\Psi}{\partial x}\right)\mathrm{d}x=-\mathrm{i}\hbar\int\limits_{-\infty}^{+\infty}\left(\frac{\partial\bar{\Psi}}{\partial t}\frac{\partial\Psi}{\partial x}+\bar{\Psi}\frac{\partial}{\partial t}\frac{\partial\Psi}{\partial x}\right)\mathrm{d}x \tag{11.2.850}$$

hence:

$$-\frac{1}{\mathrm{i}\hbar}\frac{\mathrm{d}\langle p_x\rangle}{\mathrm{d}t}=\int\limits_{-\infty}^{+\infty}\frac{\partial\bar{\Psi}}{\partial t}\frac{\partial\Psi}{\partial x}\mathrm{d}x+\int\limits_{-\infty}^{+\infty}\bar{\Psi}\frac{\partial}{\partial t}\frac{\partial\Psi}{\partial x}\mathrm{d}x=\int\limits_{-\infty}^{+\infty}\frac{\partial\bar{\Psi}}{\partial t}\frac{\partial\Psi}{\partial x}\mathrm{d}x+\int\limits_{-\infty}^{+\infty}\bar{\Psi}\frac{\partial}{\partial x}\frac{\partial\Psi}{\partial t}\mathrm{d}x \tag{11.2.851}$$

Using:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=H\Psi\Leftrightarrow\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=\left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}+E_p(x)\right)\Psi \tag{11.2.852}$$

It comes:

$$\begin{aligned}-\frac{1}{\mathrm{i}\hbar}\frac{\mathrm{d}\langle p_x\rangle}{\mathrm{d}t}&=-\frac{1}{\mathrm{i}\hbar}\int\limits_{-\infty}^{+\infty}H\bar{\Psi}\frac{\partial\Psi}{\partial x}\mathrm{d}x+\frac{1}{\mathrm{i}\hbar}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\frac{\partial(H\Psi)}{\partial x}\mathrm{d}x\\&=-\frac{1}{\mathrm{i}\hbar}\int\limits_{-\infty}^{+\infty}\left(-\frac{\hbar^2}{2m}\frac{\partial^2\bar{\Psi}}{\partial x^2}+E_p(x)\bar{\Psi}\right)\frac{\partial\Psi}{\partial x}\mathrm{d}x+\frac{1}{\mathrm{i}\hbar}\int\limits_{-\infty}^{+\infty}\bar{\Psi}\frac{\partial\left(-\frac{\hbar^2}{2m}\frac{\partial^2\Psi}{\partial x^2}+E_p(x)\Psi\right)}{\partial x}\mathrm{d}x\\&=\frac{1}{\mathrm{i}\hbar}\left[-\int\limits_{-\infty}^{+\infty}\left(-\frac{\hbar^2}{2m}\frac{\partial^2\bar{\Psi}}{\partial x^2}+E_p(x)\bar{\Psi}\right)\frac{\partial\Psi}{\partial x}\mathrm{d}x+\int\limits_{-\infty}^{+\infty}\bar{\Psi}\frac{\partial\left(-\frac{\hbar^2}{2m}\frac{\partial^2\Psi}{\partial x^2}+E_p(x)\Psi\right)}{\partial x}\mathrm{d}x\right]\\&=\frac{1}{\mathrm{i}\hbar}\left[\frac{\hbar^2}{2m}\int\limits_{-\infty}^{+\infty}\left(\frac{\partial^2\bar{\Psi}}{\partial x^2}\frac{\partial\Psi}{\partial x}-\bar{\Psi}\frac{\partial}{\partial x}\frac{\partial^2\Psi}{\partial x^2}\right)\mathrm{d}x+\int\limits_{-\infty}^{+\infty}\left(\bar{\Psi}\frac{\partial\big(E_p(x)\Psi\big)}{\partial x}-E_p(x)\bar{\Psi}\frac{\partial\Psi}{\partial x}\right)\mathrm{d}x\right]\end{aligned} \tag{11.2.853}$$

Let us focus on:

$$\int\limits_{-\infty}^{+\infty}\left(\frac{\partial^2\bar{\Psi}}{\partial x^2}\frac{\partial\Psi}{\partial x}-\bar{\Psi}\frac{\partial}{\partial x}\frac{\partial^2\Psi}{\partial x^2}\right)\mathrm{d}x \tag{11.2.854}$$

Let us integrate the first term twice according to the relation proved in the section of Differential and Integral Calculus:

$$\int\limits_a^b f(t)g'(t)\mathrm{d}t = f(t)g(t)\Big|_a^b - \int\limits_a^b f'(t)g(t)\mathrm{d}t \tag{11.2.855}$$

We then have (always considering Ψ as a decreasing function to infinity):

$$\int\limits_{-\infty}^{+\infty} \frac{\partial^2\bar{\Psi}}{\partial x^2}\frac{\partial\Psi}{\partial x}\mathrm{d}x = \int\limits_{-\infty}^{+\infty} \frac{\partial\Psi}{\partial x}\frac{\partial^2\bar{\Psi}}{\partial x^2}\mathrm{d}x = \frac{\partial\Psi}{\partial x}\frac{\partial\bar{\Psi}}{\partial x}\Bigg|_{-\infty}^{+\infty} - \int\limits_{-\infty}^{+\infty} \frac{\partial}{\partial x}\frac{\partial\Psi}{\partial x}\frac{\partial\bar{\Psi}}{\partial x}\mathrm{d}x = -\int\limits_{-\infty}^{+\infty} \frac{\partial^2\Psi}{\partial^2 x}\frac{\partial\bar{\Psi}}{\partial x}\mathrm{d}x \tag{11.2.856}$$

and once again:

$$-\int\limits_{-\infty}^{+\infty} \frac{\partial^2\Psi}{\partial^2 x}\frac{\partial\bar{\Psi}}{\partial x}\mathrm{d}x = -\frac{\partial^2\Psi}{\partial^2 x}\bar{\Psi}\Bigg|_{-\infty}^{+\infty} + \int\limits_{-\infty}^{+\infty} \frac{\partial}{\partial x}\frac{\partial^2\Psi}{\partial^2 x}\bar{\Psi}\mathrm{d}x = \int\limits_{-\infty}^{+\infty} \frac{\partial}{\partial x}\frac{\partial^2\Psi}{\partial^2 x}\bar{\Psi}\mathrm{d}x \tag{11.2.857}$$

So finally:

$$\int\limits_{-\infty}^{+\infty} \left(\frac{\partial^2\bar{\Psi}}{\partial x^2}\frac{\partial\Psi}{\partial x} - \bar{\Psi}\frac{\partial}{\partial x}\frac{\partial^2\Psi}{\partial x^2}\right)\mathrm{d}x = \int\limits_{-\infty}^{+\infty} \left(\frac{\partial}{\partial x}\frac{\partial^2\Psi}{\partial^2 x}\bar{\Psi} - \bar{\Psi}\frac{\partial}{\partial x}\frac{\partial^2\Psi}{\partial x^2}\right)\mathrm{d}x = 0 \tag{11.2.858}$$

We then have:

$$\begin{aligned}
\frac{\mathrm{d}\langle p_x\rangle}{\mathrm{d}t} &= -\left[\int\limits_{-\infty}^{+\infty} \left(\bar{\Psi}\frac{\partial\big(E_p(x)\Psi\big)}{\partial x} - E_p(x)\bar{\Psi}\frac{\partial\Psi}{\partial x}\right)\mathrm{d}x\right] \\
&= -\left[\int\limits_{-\infty}^{+\infty} \left(\bar{\Psi}\frac{\partial\big(E_p(x)\big)}{\partial x}\Psi + \cancel{\bar{\Psi}E_p(x)\frac{\partial\Psi}{\partial x}} - \cancel{E_p(x)\bar{\Psi}\frac{\partial\Psi}{\partial x}}\right)\mathrm{d}x\right] = -\int\limits_{-\infty}^{+\infty} \bar{\Psi}\frac{\partial E_p(x)}{\partial x}\Psi\mathrm{d}x \\
&= -\int\limits_{-\infty}^{+\infty} \bar{\Psi}\left(-\frac{dE_p}{\mathrm{d}x}\right)\Psi\mathrm{d}x
\end{aligned} \tag{11.2.859}$$

However, we have demonstrated in the section of Classical Mechanics that:

$$\vec{F} = -\vec{\nabla}E_p \tag{11.2.860}$$

It therefore comes that:

$$\boxed{\frac{\mathrm{d}\langle p_x\rangle}{\mathrm{d}t} = \int\limits_{-\infty}^{+\infty} \bar{\Psi}F_x\Psi\mathrm{d}x} = \langle F_x\rangle \tag{11.2.861}$$

This extraordinarily simple result constitutes the "Ehrenfest theorem". We thus find the fundamental law of Classical Dynamics in the sense of mean values of position and force, calculated using the probability of presence!

11.2.4.6.1 Generalized Ehrenfest Theorem

The text that follows is almost a copy/paste of the content of the video on YouTube made by Sam Dietterich!

When we think of the Ehrenfest Theorem, we usually think of these two equations:

$$m\frac{\mathrm{d}}{\mathrm{d}t}\langle x\rangle=\langle p\rangle \quad \frac{\mathrm{d}}{\mathrm{d}t}\langle p\rangle=\left\langle -\frac{\partial}{\partial x}V(x)\right\rangle \tag{11.2.862}$$

The reader has probably seen the long derivations for each of them earlier above. This may leave the reader thinking two things:

- First, are there analogous equations for other observables, or even a general one for an arbitrary observable?
- And second, we would expect that the derivation of such a general equation would have to be at least as long as the derivation of these two equations.

It turns out that there is a Generalized Ehrenfest Theorem equation, but its derivation is actually shorter then either of the above! It turns out that when one does the general derivation with abstract notation instead of appealing to the position representation, then the derivation is extremely short. It is simply the following:

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle Q\rangle=\frac{\mathrm{d}}{\mathrm{d}t}\langle\psi|Q|\psi\rangle=\left[\frac{\partial}{\partial t}\langle\psi|\right]Q|\psi\rangle+\langle\psi|\frac{\partial Q}{\partial t}|\psi\rangle+\langle\psi|Q\frac{\partial}{\partial t}|\psi\rangle \tag{11.2.863}$$

But we have from Schrödinger equation:

$$\begin{matrix}\mathrm{i}\hbar\frac{\partial}{\partial t}|\psi\rangle=H|\psi\rangle & \rightarrow & \frac{\partial}{\partial t}|\psi\rangle=-\frac{\mathrm{i}}{\hbar}H|\psi\rangle\\ -\mathrm{i}\hbar\frac{\partial}{\partial t}\langle\psi|=\langle\psi|H & \rightarrow & \frac{\partial}{\partial t}\langle\psi|=\frac{\mathrm{i}}{\hbar}\langle\psi|H\end{matrix} \tag{11.2.864}$$

So substitute that and rearranging give us:

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle Q\rangle=\frac{\mathrm{d}}{\mathrm{d}t}\langle\psi|Q|\psi\rangle=\left[\frac{\mathrm{i}}{\hbar}\langle\psi|H\right]Q|\psi\rangle-\frac{\mathrm{i}}{\hbar}\langle\psi|QH|\psi\rangle+\langle\psi|\frac{\partial Q}{\partial t}|\psi\rangle \tag{11.2.865}$$

The Hamiltonian is Hermitian as it is given by:

$$H:=-\frac{\hbar^2}{2m}\Delta+V(\vec{x}) \tag{11.2.866}$$

and can therefore act equivalently to the left or to the right. Therefore we can drop the brackets:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\langle Q\rangle&=\frac{\mathrm{i}}{\hbar}\langle\psi|HQ|\psi\rangle-\frac{\mathrm{i}}{\hbar}\langle\psi|QH|\psi\rangle+\langle\psi|\frac{\partial Q}{\partial t}|\psi\rangle\\&=\frac{\mathrm{i}}{\hbar}\langle\psi|(HQ-QH)|\psi\rangle+\langle\psi|\frac{\partial Q}{\partial t}|\psi\rangle\\&=\frac{\mathrm{i}}{\hbar}\langle\psi|[H,Q]|\psi\rangle+\langle\psi|\frac{\partial Q}{\partial t}|\psi\rangle\end{aligned} \tag{11.2.867}$$

Therefore we get the "general Ehrenfest theorem":

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}t}\langle Q\rangle=\frac{\mathrm{i}}{\hbar}\langle[H,Q]\rangle+\left\langle\frac{\partial Q}{\partial t}\right\rangle} \tag{11.2.868}$$

Then all we have to do to derive ehrenfest theorem for any special case is evaluate the commutator of the hamiltonian with that operator and the time derivative if it's explicitly time dependent and this does easily reproduce the results we had for the position and momentum Ehrenfest theorem that we derived earlier above!

This result will be useful to us to derive rigorously the Energy-Time Heisenberg's uncertainty principle (see page 4739)!

But let us check if we can fall back, on the previous results!

We start with:

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle\hat{x}\rangle=\frac{1}{i\hbar}\langle[\hat{x},\hat{H}]\rangle \tag{11.2.869}$$

And remember that:

$$H=\frac{p^2}{2m}+V(x) \tag{11.2.870}$$

Therefore:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\langle\hat{x}\rangle&=\frac{1}{\mathrm{i}\hbar}\left\langle\left[\hat{x},\frac{\hat{p}^2}{2m}\right]\right\rangle=\frac{1}{\mathrm{i}\hbar 2m}\langle[\hat{x},\hat{p}\hat{p}]\rangle\\&=\frac{1}{\mathrm{i}\hbar 2m}\langle[\hat{x},\hat{p}]\hat{p}+\hat{b}[\hat{x},\hat{p}]\rangle=\frac{1}{\mathrm{i}\hbar 2m}\langle[\hat{x},\hat{p}]\hat{p}+\hat{p}[\hat{x},\hat{p}]\rangle\\&=\frac{1}{\mathrm{i}\hbar 2m}\langle\mathrm{i}\hbar\hat{p}+\mathrm{i}\hbar\hat{p}\rangle=\frac{1}{m}\langle\hat{p}\rangle\end{aligned} \tag{11.2.871}$$

And now:

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle\hat{p}\rangle=\frac{1}{\mathrm{i}\hbar}\langle[\hat{p},\hat{H}]\rangle \tag{11.2.872}$$

always keeping in mind that:

$$H=\frac{p^2}{2m}+V(x) \tag{11.2.873}$$

Therefore:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\langle\hat{p}\rangle\varphi&=\frac{1}{\mathrm{i}\hbar}\left\langle\left[-\mathrm{i}\hbar\frac{\partial}{\partial x},V(x)\right]\varphi\right\rangle=-\left\langle\left[\frac{\partial}{\partial x},V(x)\right]\varphi\right\rangle\\&=-\left\langle\frac{\partial(V\varphi)}{\partial x}-V\frac{\partial\varphi}{\partial x}\right\rangle=-\left\langle V\frac{\partial\varphi}{\partial x}+\varphi\frac{\partial}{\partial x}V-V\frac{\partial\varphi}{\partial x}\right\rangle\\&=-\varphi\left\langle\frac{\partial V}{\partial x}\right\rangle\end{aligned} \tag{11.2.874}$$

Hence:

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle\hat{p}\rangle=-\left\langle\frac{\partial V}{\partial x}\right\rangle=\langle F\rangle \qquad (11.2.875)$$

There is no direct "empirical evidence" for the Ehrenfest theorem itself, as it is a mathematical proof showing the link between quantum and classical mechanics, not a prediction that can be directly tested with a single experiment. Instead, its "evidence" is the successful and consistent way quantum mechanics (and thus the Ehrenfest theorem) can be used to predict the behavior of quantum systems, which then transitions to the predictions of classical mechanics in the macroscopic limit, as explained by the correspondence principle. Experiments that confirm the predictions of quantum mechanics for microscopic particles serve as indirect validation for the theorem's derivation.

11.2.5 Angular momentum and Spin

In classical physics, angular momentum is commonly divided into two types: orbital and rotational. In the case of the Earth, for example, the orbital angular momentum is associated with the revolution of the Earth about the Sun, while rotational angular momentum is associated with the Earth rotating on its axis. Rotational angular momentum is often known as spin, for fairly obvious reasons.

In classical physics, of course, there is really only one type of angular momentum, since both the orbital and rotational types are associated with the rotation of masses about some axis. The division into the two types is purely a computational convenience.

In quantum physics, the situation is quite different is quite different as we will see (it is important that the reader refers to the Corpuscular Quantum Physics section where we have proved the it is seems not acceptable ton consider the electron spinning on itself).

Like the harmonic oscillator, the notion of angular momentum is of main importance in quantum theory and has many applications in all fields of physics: atomic and molecular physics, nuclear and subnuclear physics, physics of condensed state, etc. Thus, it plays an essential role in the study of the motion of a particle in a potential with spherical symmetry, as we shall see in the section of Quantum Chemistry (which is an excellent practical example). The angular momentum is also at the base of the group of rotations (see section Set Algebra page 1424) which satisfies the algebra of the angular momentum operators. Thus, it not only allows to construct the wave function of a given quantum system of symmetry, but also to predict if an optical transition is allowed and to determine its intensity (for example, during the study optical transitions between impurity states (in solid state), molecular states (quantum chemistry), nuclear physics, etc.).

Finally, we will see that the algebraic method applied to the study of angular momentum will allow us to introduce quite naturally the notion of intrinsic angular momentum of a particle, i.e. the "spin", which has in fact no classical equivalent (so it's not an angular momentum!).

The following developments may seem rather disconcerting in the sense that it is no longer necessary to rely on intuition but only on the properties and results of mathematics. As usual, if the reader need additional information, he must not hesitate to contact us.

Remark

"Spintronics" (a portmanteau meaning "spin transport electronics"), also known as "spinelectronics" or "fluxtronics", is the study of the intrinsic spin of the electron and its associated magnetic moment, in addition to its fundamental electronic charge, in solid-state devices or in Quantum computers. The simplest method of generating a spin-polarised current in a metal is to pass the current through a ferromagnetic material. The most common applications of this effect involve giant magnetoresistance (GMR) devices. For more, see the excellent introductory textbook [40].

To begin, let us recall that the angular momentum of a particle relatively to their origin is given by (see section Classical Mechanics page 3244):

$$\vec{b}=m\vec{r}\times\vec{v}=\vec{r}\times\vec{p} \tag{11.2.876}$$

Since the linear momentum is quantified (it is an eigenvalue related to energy in one way or another), the angular momentum is necessarily also quantified (the angular momentum is therefore an eigenvalue) and the experience has supported this result (Stern-Gerlach experiment).

Given z the component of the resulting vector product:

$$\boxed{b_z = xp_y - yp_x \quad \text{cycl.}} \tag{11.2.877}$$

This relationship being cyclic, we can change the indices to get the other coordinates.

Since x and y commute (in the sense that their commutator is equal to zero) and that we have proved earlier above that:

$$p_x = \mathrm{i}\hbar\frac{\partial}{\partial x} \qquad p_y = \mathrm{i}\hbar\frac{\partial}{\partial y} \tag{11.2.878}$$

We then have:

$$b_z = xp_y - yp_x = \frac{\hbar}{\mathrm{i}}x\frac{\partial}{\partial y} - \frac{\hbar}{\mathrm{i}}y\frac{\partial}{\partial x} = \frac{\hbar}{\mathrm{i}}\left(x\frac{\partial}{\partial y} - y\frac{\partial}{\partial x}\right) \tag{11.2.879}$$

Which gives:

$$b_z = \frac{\hbar}{\mathrm{i}}\left(x\frac{\partial}{\partial y} - y\frac{\partial}{\partial x}\right) \quad \text{cycl.} \tag{11.2.880}$$

Using the gradient (we will see again this relation in the section of Relativistic Quantum Physics during our study of the Pauli equation!!):

$$\boxed{\vec{b} = \frac{\hbar}{\mathrm{i}}\vec{r}\times\vec{\nabla} = -\mathrm{i}\hbar\vec{r}\times\vec{\nabla}} \tag{11.2.881}$$

and putting for the "operator of the orbital angular momentum":

$$\frac{1}{\mathrm{i}}\vec{r}\times\vec{\nabla} = \frac{1}{\hbar}\vec{r}\times\vec{p} = \vec{l} \tag{11.2.882}$$

Which lead us to write:

$$\boxed{\vec{b} = \hbar\vec{l}} \tag{11.2.883}$$

with:

$$\begin{pmatrix} l_x \\ l_y \\ l_z \end{pmatrix} = \frac{1}{\hbar}\begin{pmatrix} yp_z - zp_y \\ zp_x - xp_z \\ xp_y - yp_x \end{pmatrix} \tag{11.2.884}$$

Remark

Most often in the literature the orbital angular momentum is denoted $\vec{L}$ (we have already made this remark in the section of Classical Mechanics) but we avoided this notation here in order to differentiate the orbital angular momentum and the total orbital angular momentum.

We will establish some commutation relations concerning $\vec{l}$ which will play an essential role in our study of the spin. Using the following commutation relations (proved during our study of the Heisenberg's classical uncertainty principles page 4704):

$$[x,p_x]=\mathrm{i}\hbar \quad \text{cycl.} \tag{11.2.885}$$

and:

$$[y,p_x]=0 \quad \text{cycl.} \tag{11.2.886}$$

We have the relation (it is traditional to do the analysis on the component z of the projection of $\vec{l}$):

$$[\hbar l_z,x]=[xp_y,x]-[yp_x,x]=-y[p_x,x]=\mathrm{i}\hbar y \tag{11.2.887}$$

Therefore:

$$[l_z,x]=\mathrm{i}y \quad \text{cycl.} \tag{11.2.888}$$

and proceeding in the same way:

$$\boxed{[l_z,y]=-\mathrm{i}x \quad \text{cycl.}} \qquad \text{and} \qquad \boxed{[l_z,z]=0 \quad \text{cycl.}} \tag{11.2.889}$$

Remark

We find analogous relations with the linear momentum:

$$\begin{aligned}
&[l_z,p_x]=\mathrm{i}p_y\\
&[l_z,p_y]=-\mathrm{i}p_x \qquad \text{cycl.}\\
&[l_z,p_z]=0
\end{aligned} \tag{11.2.890}$$

Let ow now evaluate the quantity (following the request of a reader, we put all the details):

$$\begin{aligned}
[l_x,\hbar l_y]&=[l_x,zp_x-xp_z]=[l_x,zp_x]-[l_x,xp_z]=\left[\frac{1}{\hbar}\left(yp_z-zp_y\right),zp_x\right]-\left[\frac{1}{\hbar}\left(yp_z-zp_y\right),xp_z\right]\\
&=\left[\frac{1}{\hbar}yp_z,zp_x\right]-\left[\frac{1}{\hbar}zp_y,zp_x\right]-\left[\frac{1}{\hbar}yp_z,xp_z\right]+\left[\frac{1}{\hbar}zp_y,xp_z\right]\\
&=\left(\frac{1}{\hbar}yp_zzp_x-\frac{1}{\hbar}z\underbrace{p_xy}_{=-\mathrm{i}\hbar\frac{\partial}{\partial x}y=0}p_z\right)-\left(\frac{1}{\hbar}z\underbrace{p_yz}_{=-\mathrm{i}\hbar\frac{\partial}{\partial y}z=0}p_x-\frac{1}{\hbar}z\underbrace{p_xz}_{=-\mathrm{i}\hbar\frac{\partial}{\partial x}z=0}p_y\right)\\
&-\left(\frac{1}{\hbar}y\underbrace{p_zx}_{=-\mathrm{i}\hbar\frac{\partial}{\partial z}x=0}p_z-\frac{1}{\hbar}x\underbrace{p_zy}_{=-\mathrm{i}\hbar\frac{\partial}{\partial z}y=0}p_z\right)+\left(\frac{1}{\hbar}z\underbrace{p_yx}_{=-\mathrm{i}\hbar\frac{\partial}{\partial y}x=0}p_z-\frac{1}{\hbar}xp_zzp_y\right)\\
&=\frac{1}{\hbar}yp_zzp_x-\frac{1}{\hbar}xp_zzp_y=\frac{1}{\hbar}y\left(-\mathrm{i}\hbar\frac{\partial}{\partial z}z\right)p_x-\frac{1}{\hbar}x\left(-\mathrm{i}\hbar\frac{\partial}{\partial z}z\right)p_y=\frac{1}{\hbar}y(-\mathrm{i}\hbar)p_x-\frac{1}{\hbar}x(-\mathrm{i}\hbar)p_y\\
&=-\mathrm{i}yp_x+\mathrm{i}xp_y=\mathrm{i}\left(xp_y-yp_x\right)=\mathrm{i}\hbar l_z
\end{aligned} \tag{11.2.891}$$

Either after simplification (it is rather annoying for the experience that this does not commute):

$$\boxed{[l_x,l_y]=\mathrm{i}l_z} \tag{11.2.892}$$

By the way, at this stage, the reader that has already covered the Spinor Calculus section beforehand (if not already done we strongly recommend the reader to go take a look at it!), he will notice that the Pauli matrices satisfy the preceding relations if we put ourselves in natural units (the reduced Planck constant then being equal to 1):

$$\begin{aligned}\sigma_x\sigma_y-\sigma_y\sigma_x&=2\mathrm{i}\sigma_z\\ \sigma_y\sigma_z-\sigma_z\sigma_y&=2\mathrm{i}\sigma_x\\ \sigma_z\sigma_x-\sigma_x\sigma_z&=2\mathrm{i}\sigma_y\end{aligned} \tag{11.2.893}$$

This observation will be useful for our study of Relativistic Quantum Physics (see section of the same name page 4919). Indeed, we know from our study of Spinor Calculus that the 2×2 matrices in $\mathbb{C}$ of determinant 1 form the group of rotations in the space $\mathrm{SU}(2)$, whose Pauli matrices are the generators. Basically, the origin of the spin comes from the link between $\mathrm{SU}(2)$ and the group of rotations of our ordinary space, $\mathrm{SO}(3)$ (see section Set Algebra page 1424). Now, let us consider the norm:

$$\|\vec{l}\|^2=l_x^2+l_y^2+l_z^2 \tag{11.2.894}$$

where we must consider the square of one of these operators in the following form:

$$l_z^2=\left(\frac{1}{\mathrm{i}}(x\partial y-y\partial_x)\right)^2=-\left(x\partial y-y\partial_x\right)^2 \tag{11.2.895}$$

Let us study its commutation with a component (without having to explicit the thing!):

$$\begin{aligned}[][l_z,\|\vec{l}\|^2]&=[l_z,l_x^2]+[l_z,l_y^2]+\underbrace{[l_z,l_z^2]}_{0}=l_x[l_z,l_x]+[l_z,l_x]l_x+l_y[l_z,l_y]+[l_z,l_y]l_y\\ &=l_x[l_z,l_x]+[l_z,l_x]l_x-l_y[l_y,l_x]-[l_y,l_z]l_y\end{aligned} \tag{11.2.896}$$

Using the cyclic relation $[l_x,l_y]=\mathrm{i}l_z$ it comes:

$$[l_z,\|\vec{l}\|^2]=l_x[l_z,l_x]+[l_z,l_x]l_x-l_y[l_y,l_x]-[l_y,l_z]l_y=\mathrm{i}\big(l_xl_y+l_yl_x\big)-\mathrm{i}\big(l_xl_y+l_yl_x\big)=0 \tag{11.2.897}$$

Therefore the norm of the orbital angular momentum commutes with its components:

$$\boxed{[l_z,\|\vec{l}\|^2]=0\quad\text{cycl.}} \tag{11.2.898}$$

Conclusions of the results obtained so far: Since the commutator is equal to zero (the quantities commutes), it is therefore possible to simultaneously measure with precision a component as well as the square of the angular momentum (its squared norm), but it is impossible to do the same for two components!

Let us also notice that finally the fact that we have explicitly:

$$[l_x,l_y]=l_xl_y-l_yl_x=\mathrm{i}l_z\quad\text{cycl.} \tag{11.2.899}$$

we can write (its quite an interesting relation):

$$\boxed{\vec{l}\times\vec{l}=\mathrm{i}\vec{l}} \tag{11.2.900}$$

If we have a system of particles numbered by an index k, each has an individual kinetic moment $\hbar\vec{l}^{(k)}$ and the total orbital angular momentum of the system $\hbar\vec{L}$ (not to confuse the notation of the L with that of the Lagrangian that latter being anyway as scalar!!!) is then obviously given by:

$$\hbar\vec{L}=\sum_k \hbar\vec{l}^{(k)} \tag{11.2.901}$$

and if we simplify by $\hbar$ (or if we work in natural units):

$$\vec{L}=\sum_k \vec{l}^{(k)} \tag{11.2.902}$$

But $\vec{L}$ is not really the total angular momentum of the system! Indeed, a particle may possess an intrinsic angular momentum, or "spin". We can give a simple picture of the spin by saying that it translates an infinitesimal rotation of the particle on itself (caution! it is only an image because in fact the particle does not turn on itself!). As we saw in the section of Spinor Calculus, this corresponds mathematically to the limited development of the matrix of rotations in the vicinity of the identity matrix.

Therefore we see that the usual approach to quantum spin is just to postulate that elementary particles have an intrinsic spin, and that this spin isn't due to any physical motion of the particle (again refer to the section of Corpuscular Quantum Physics); it just ***is***, in much the same way that particles have mass, charge and (in the case of the more esoteric particles) several other quantities such as strangeness. This is not terribly satisfactory from an intellectual point of view, but since I'm not qualified to write about the details of particle physics, we have to start somewhere.

We will denote by $\vec{s}^{(k)}$ the intrinsic angular momentum of the k-th particle (in natural units) and the relation:

$$\vec{S}=\sum_k \vec{s}^{(k)} \tag{11.2.903}$$

will be the "total spin" and finally (still in natural units or after simplification of $\hbar$):

$$\boxed{\vec{J}=\vec{L}+\vec{S}=\sum_k \vec{l}^{(k)}+\sum_k \vec{s}^{(k)}} \tag{11.2.904}$$

will be the "total angular momentum" of the system (do not confuse the notation J with the orbital angular momentum or the current density....!) and we will prove during our study of the spin-orbit coupling that this angular momentum is a constant of movement in the presence of this coupling.

Remark

In the weak field case this vector model ($\vec{J}=\vec{L}+\vec{S}$) at left implies that the coupling of the orbital angular momentum $\vec{L}$ to the spin angular momentum $\vec{S}$ is stronger than their coupling to the external field. In this case where spin-orbit coupling is dominant, they can be visualized as combining to form a total angular momentum $\vec{J}$ which then precesses about the magnetic field direction (see further below for an illustration).

In the strong-field case, $\vec{S}$ and $\vec{L}$ couple more strongly to the external magnetic field than to each other, and can be visualized as independently precessing about the external field direction such that $\vec{J}\neq\vec{L}+\vec{S}$. This is what we name the Paschen-Back effect". The fields required to generate Paschen-Back conditions for sodium are unrealistically high. Lithium, on the other hand, has a spin-orbit splitting of only 0.00004 [eV] compared to 0.0021 [eV] for sodium. The Paschen-Back conditions are met in some lithium spectra observed on the Sun, so this effect does have astronomical significance.

We will assume (but this is relatively easy to prove once, among others, spinors are know[19]) that each $\vec{s}^{(k)}$ and $\vec{l}^{(k)}$ also obeys the commutation rules seen previously:

$$[s_x^{(k)},s_y^{(k)}]=\mathrm{i}s_z^{(k)}\quad\text{cycl.}\qquad\text{and}\qquad[l_x^{(k)},l_y^{(k)}]=\mathrm{i}l_z^{k}\quad\text{cycl.}\tag{11.2.905}$$

Therefore to sum up we have:

$$\boxed{[L_i,L_j]=\mathrm{i}\varepsilon_{ijk}L_k\qquad[S_i,S_j]=\mathrm{i}\varepsilon_{ijk}S_k\qquad[J_i,J_j]=\mathrm{i}\varepsilon_{ijk}J_k}\tag{11.2.906}$$

where for recall ε_{ijk} is the Levi-Civita symbol (see section Tensor Calculus page 2045).

We notice that in the matrix representation of Heisenberg there are also other matrices than the 2×2 Pauli matrices that satisfy these relations (we can give the detail of the proof on reader request). For example, the following zero trace Hermitian matrices (of which the conjugate transpose is equal to itself for recall ....):

$$\underbrace{J_z=\begin{bmatrix}0&-\mathrm{i}&0\\ \mathrm{ii}&0&0\\ 0&0&0\end{bmatrix},J_x=\begin{bmatrix}0&0&0\\ 0&0&-\mathrm{i}\\ 0&\mathrm{i}&0\end{bmatrix},J_y=\begin{bmatrix}0&0&\mathrm{i}\\ 0&0&0\\ -\mathrm{i}&0&0\end{bmatrix}}_{(J_i)_{mn}=-\mathrm{i}\varepsilon_{imn}}\tag{11.2.907}$$

Remark

We will see in the section of Relativistic Quantum Physics that in fact the three matrices above are the spin operator of the massless spin-1 particles (photons).

The prior-previous relations implies (also) in the same way as for the orbital angular momentum:

$$[J_z,\|\vec{J}\|^2]=0\quad\text{cycl.}\tag{11.2.908}$$

with obviously the relation:

$$\|\vec{J}\|^2=J_x^2+J_y^2+J_z^2\tag{11.2.909}$$

---

[19] As always we can detail on reader request

named by the mathematicians "Casimir element" or "Casimir operator" (a simple development perfectly similar to that obtained above is sufficient to prove it and we can write it on reader request).

Let us now define in a purely formal way the two non-Hermitian operators named "scale operators" (Pauli's matrices and not only (!) still satisfy these relations!):

$$J_{\pm}=J_x\pm \mathrm{i}J_y \qquad \left(J_+\right)^{\dagger}=J_- \tag{11.2.910}$$

where respectively J_+ is named "elevator operator" and J_- "step-down operator".

The $J_{\pm}$ commutes with $\|\vec{J}\|^2$, since it commutes with J_x and J_y. This allows us to write the product:

$$J_+\cdot\|\vec{J}\|^2=\|\vec{J}\|^2\cdot J_- \tag{11.2.911}$$

Furthermore:

$$\begin{aligned}[J_z,J_+]&=[J_z,J_x+\mathrm{i}J_y]=J_z(J_x+\mathrm{i}J_y)-(J_x+\mathrm{i}Jy)J_z\\&=J_zJ_x+\mathrm{i}J_zJ_y-J_xJ_z+\mathrm{i}J_yJ_z=[J_z,J_x]+\mathrm{i}[J_z,J_y]=\mathrm{i}J_y-\mathrm{i}[J_y,J_z]\\&=\mathrm{i}J_y-\mathrm{ii}J_x=\mathrm{i}J_y+J_x=J_x+\mathrm{i}J_y\end{aligned} \tag{11.2.912}$$

Therefore:

$$[J_z,J_+]=J_zJ_+-J_+J_z=J_+ \tag{11.2.913}$$

Identically (we can detail on reader request):

$$J_zJ_--J_-J_z=J_- \tag{11.2.914}$$

Finally, let us evaluate the products J_+J_- and J_-J_+:

$$J_-J_+=(J_x-i\mathrm{i}J_y)(J_x+\mathrm{i}J_y)=J_x^2+J_y^2+\mathrm{i}(J_xJ_y-J_yJ_x)=\|\vec{J}\|^2-J_z^2-J_z \tag{11.2.915}$$

Identically (we can also detail on reader request):

$$J_+J_-=\|\vec{J}\|^2-J_z^2+J_z \tag{11.2.916}$$

Since the two Hermitian operators $\|\vec{J}\|^2$ and J_z commute they therefore have common states and eigenvalues and, more precisely, they have a common complete common basis. When observables commuted and have their own common base, let us recall that we usually speak of a "CSCO" (Complete Set of Commuting Operators).

To study their eigenvalues let us put:

$$\begin{aligned}\|\vec{J}\|^2\left|\Psi\right\rangle&=K\left|\Psi\right\rangle\\J_z\left|\Psi\right\rangle&=m\left|\Psi\right\rangle\end{aligned} \tag{11.2.917}$$

System which is sometimes denoted in the following form in the specialized literature (...):

$$\boxed{\begin{aligned}\|\vec{J}\|^2\left|K,m\right\rangle&=K\left|K,m\right\rangle\\J_z\left|K,m\right\rangle&=m\left|K,m\right\rangle\end{aligned}} \tag{11.2.918}$$

as it highlights the fact that the associated eigenstates will be defined at least in part by the parameters K, m themselves.

Many times in textbooks the last couple of relations is written:

$$\begin{gathered}\hat{J}^2\big|K,m\rangle = K\big|K,m\rangle\\ \hat{J}_z\big|K,m\rangle = m\big|K,m\rangle\end{gathered}\tag{11.2.919}$$

or even worst...:

$$\begin{gathered}J^2\big|Km\rangle = K\big|Km\rangle\\ J_z\big|Km\rangle = m\big|Km\rangle\end{gathered}\tag{11.2.920}$$

To begin, we know that the eigenvalues K and m are not independent since we have:

$$\|\vec{J}\|^2 - J_z^2 = J_x^2 + J_y^2\tag{11.2.921}$$

The mean being denoted by the brackets $\langle\rangle$, we have by linearity of the mean (see section Statistics page 571):

$$\langle\|\vec{J}\|^2\rangle - \langle J_z^2\rangle = \langle J_x^2\rangle + \langle J_y^2\rangle\tag{11.2.922}$$

What can be written:

$$\langle\|\vec{J}\|^2 - J_z^2\rangle = \langle J_x^2\rangle + \langle J_y^2\rangle\tag{11.2.923}$$

We see that the left-hand side of the above relation is therefore equal by definition to:

$$K - m^2\tag{11.2.924}$$

Since the square of the total orbital angular momentum is anyway Hermitian (it has no complex component in $\mathbb{C}$), we then construct by the postulates of quantum physics:

$$\langle J_x^2\rangle = \langle\Psi\big|J_x^2\big|\Psi\rangle \geq 0\tag{11.2.925}$$

It comes then that:

$$\left.\begin{matrix}\langle J_x^2\rangle \geq 0\\ \langle J_y^2\rangle \geq 0\end{matrix}\right\}\langle\|\vec{J}\|^2 - J_z^2\rangle \geq 0\tag{11.2.926}$$

The latter relation therefore implies that:

$$K \geq m^2\tag{11.2.927}$$

This brings so far to the following informations:

$$\boxed{K \geq 0 \qquad |m| \leq \sqrt{K}}\tag{11.2.928}$$

From $|\Psi\rangle$, we build the state $J_+|\Psi\rangle$, we will show that if this state is not identically zero, it is an eigenvalue of $\|\vec{J}\|^2$ and of J_z. From the relation:

$$J_+\cdot\|\vec{J}\|^2 = \|\vec{J}\|^2\cdot J_-\tag{11.2.929}$$

already introduced previously, we put:

$$\| \vec{J} \|^2 J_+ \big|\Psi\rangle = J_- \| \vec{J} \|^2 \big|\Psi\rangle = K J_+ \big|\Psi\rangle \tag{11.2.930}$$

The $J_{\pm}$ commutate with $\|\vec{J}\|^2$, since it commutes with J_x and J_y. This gives us that the previous relation is zero such that:

$$K J_+ \big|\Psi\rangle = 0 \Leftrightarrow J_+ \big|\Psi\rangle = 0 \tag{11.2.931}$$

From the relation $J_z J_+ - J_+ J_z = J_+$ we put in and identical way (we multiply both side of equality left by $|\Psi\rangle$) and rearrange a bit:

$$J_z J_+ \big|\Psi\rangle = J_+ J_z \big|\Psi\rangle + J_+ \big|\Psi\rangle = (m+1) J_+ \big|\Psi\rangle \tag{11.2.932}$$

Still without forgetting that:

$$J_+ \big|\Psi\rangle = 0 \tag{11.2.933}$$

We finally have the following package of relations so far:

$$\boxed{J_{\pm} \big|\Psi\rangle = 0 \qquad \| \vec{J} \|^2 J_{\pm} \big|\Psi\rangle = K J_{\pm} \big|\Psi\rangle \qquad J_z J_{\pm} \big|\Psi\rangle = (m \pm 1) J_{\pm} \big|\Psi\rangle} \tag{11.2.934}$$

Therefore in the corresponding order, we have that:

1. $J_+|\Psi\rangle$ and $J_-|\Psi\rangle$ are identically zero
2. $J_+|\Psi\rangle$ and $J_-|\Psi\rangle$ are eigenstates of the operator $\|\vec{J}\|^2$ for the eigenvalue K
3. $J_{\pm}|\Psi\rangle$ are eigenstates for the operator J_z and the eigenvalue $m \pm 1$

Since the angular momentum is quantified as we know from our study of Corpuscular Quantum Physics and also from experiments, its eigenvalues must therefore have a minimum and a maximum with for each of these values and associated eigenfunction.

Let us put for what will follow that m' and $|\Psi'\rangle$ are the maximum eigenvalue and eigenstate and m'' and $|\Psi''\rangle$ the minimum eigenvalue and eigenstate.

Given the following three relations proved earlier above:

$$\begin{aligned} J_+ J_- &= \| \vec{J} \|^2 - J_z^2 + J_z \\ J_- J_+ &= \| \vec{J} \|^2 - J_z^2 - J_z \\ J_{\pm} \big|\Psi\rangle &= 0 \end{aligned} \tag{11.2.935}$$

We write using also the properties of eigenvalues (see section Linear Algebra page 1997):

$$\begin{aligned} J_+ J_- \big|\Psi'\rangle &= \| \vec{J} \|^2 |\Psi'\rangle - J_z^2 |\Psi'\rangle + J_z |\Psi'\rangle = (K - m'^2 - m') \big|\Psi'\rangle = 0 \\ J_- J_+ \big|\Psi''\rangle &= \| \vec{J} \|^2 |\Psi''\rangle - J_z^2 |\Psi''\rangle - J_z |\Psi''\rangle = (K - m''^2 - m'') \big|\Psi''\rangle = 0 \end{aligned} \tag{11.2.936}$$

What intuitively is not obvious to put but which mathematically is quite justifiable.

From the last two relations above, we can write by subtracting the first one to the second one (use of the superposition of sate principle), that gives us immediately for the eigenvalue that:

$$m'^2-m''^2+m'+m''=0 \tag{11.2.937}$$

thus:

$$(m'+m'')(m'-m''+1)=0 \tag{11.2.938}$$

As we have m' being the maximum, m'' being the minimum of the same set, we then have:

$$m'-m''\geq 0 \tag{11.2.939}$$

What gives us after simplification of the second parenthesis that is therefore not zero (because if it could be zero we would not be able to simplify this parenthesis):

$$(m'+m'')=0\Leftrightarrow m''=-m' \tag{11.2.940}$$

Let us denote by J the value m' (which corresponds to the maximum eigenvalue of the quantity J_z) since $m''=-m'$ we have:

$$m''=-J \tag{11.2.941}$$

(where often in the literature we find a lowercase j to avoid confusion with the associated operator) therefore:

$$m'-m''=J-(-J)=2J \tag{11.2.942}$$

Since the difference on the left of the equality is necessarily an integer number (based on the known results that we get in the section of Corpuscular Quantum Physics), this imposes that $2J$ is a positive integer or zero, but it also implies directly that J can only be an integer (!), half-integer or zero such that:

$$\boxed{J=0,\frac{1}{2},1,\frac{3}{2},2,\frac{5}{2},\ldots} \tag{11.2.943}$$

Now as for recall: $m'=J$ and $m''=-J$ it follows that if we denote by m the values that can take m'' and m' respectively, then for each value of J we have obviously:

$$-J\leq m\leq J \tag{11.2.944}$$

Finally, as:

$$(K-m'^2-m')=0\Leftrightarrow K=m'^2+m' \qquad \text{and} \qquad (K-m''^2-m'')=0\Leftrightarrow K=m''^2+m'' \tag{11.2.945}$$

Then we have:

$$K=J^2+J=J(J+1) \qquad \text{and} \qquad K=(-J)^2-(-J)=J(J+1) \tag{11.2.946}$$

And finally this gives us the eigenvalue:

$$K=J(J+1) \tag{11.2.947}$$

And since we have put that m' is equal to J and that we have the relation:

$$|m| \leq \sqrt{K} \tag{11.2.948}$$

therefore:

$$J \leq \sqrt{J(J+1)} \tag{11.2.949}$$

In a more explicit and less confused form (be careful not to confuse the eigenvalues with the operators!):

$$J \leq \sqrt{J_z(J_z+1)} \tag{11.2.950}$$

So we have finally:

$$\boxed{b \leq \sqrt{J_z(J_z+1)}\hbar} \tag{11.2.951}$$

As we have introduced earlier above the spin-orbit interaction:

$$\boxed{\|\vec{J}\|^2\,|\Psi\rangle = \hbar^2 J(J+1)|\Psi\rangle} \tag{11.2.952}$$

As we introduced earlier above:

$$J = L + S \tag{11.2.953}$$

(component by component of their respective vector/matrix) and if the particle has no spin ($S=0$) then we have the eigenvalue of the total orbital angular momentum which reduces to the eigenvalue of the angular momentum:

$$b \leq \sqrt{J_z(J_z+1)}\hbar = \sqrt{L(L+1)}\hbar \tag{11.2.954}$$

where we no longer indicate the indices of the components or of the matrix indices (useless!).

If we have only one particle then:

$$L = \sum_{i=1}^{n} l_i = l_1 = l \tag{11.2.955}$$

Therefore, the orbital angular momentum is written by remembering that l is also quantified (see section Corpuscular Quantum Physics page 4666):

$$\boxed{b \leq \sqrt{l(l+1)}\hbar} \tag{11.2.956}$$

If we have $l \gg 1$, then in this case:

$$b \cong l\hbar \tag{11.2.957}$$

We thus fall back on the result obtained at the beginning of our study of the angular momentum.

Roughly, if we now put $l \cong n$, we thus that we fall back on the angular momentum relation postulated by Bohr as seen in the section of Corpuscular Quantum Physics. This is why it is customary to take only the integer values of l!

Remark

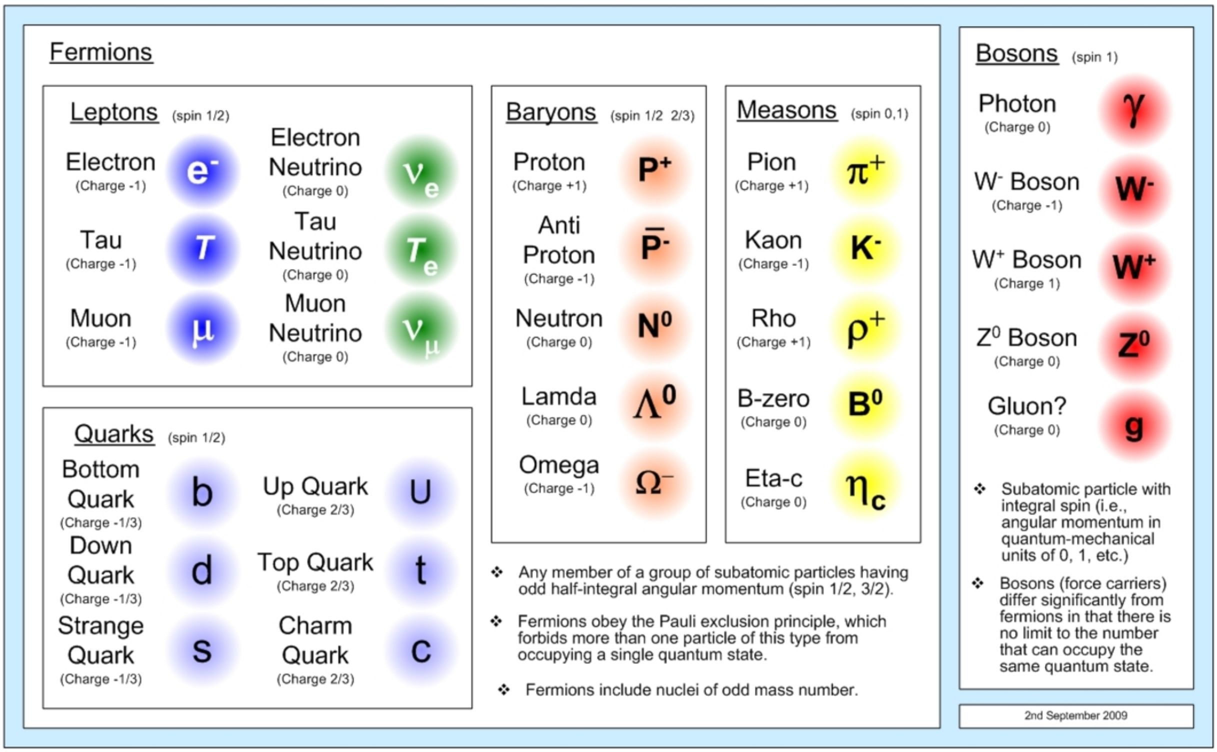
Let us recall that in reality $0 \leq l \leq n-1$ and therefore that unlike the Bohr corpuscular model the angular momentum can be zero wit the above approach...! Another way of accepting the values taken by n, putting apart the fact to refer to the Bohr model seen in the section of Corpuscular Quantum Physics, is to look at the values that can be taken by l in the quantum model of the hydrogen atom of the section of Quantum Chemistry and that if the latter is equal to 0 then the associated Legendre polynomials are no longer defined!

This finding now justifies physically the use of the quantum number l in the periodic table of elements as we saw and defined it (without any real justification) in the previous section of Corpuscular Quantum Physics.

Finally, let us mention that exactly the same reasoning and development leads to the following possible values of the pseudo angular momentum of spin:

$$\boxed{S=0,\frac{1}{2},1,\frac{3}{2},2,\frac{5}{2},\ldots} \qquad (11.2.958)$$

where experiments show us (to list only the most known examples) that spin $S=0$ is a characteristic of the Higgs boson or of certain atoms, spin $S=1/2$ is a characteristic of the electron / positron, spin $S=1$ is a characteristic of the photon, spin $S=2$ would be a still theoretical characteristic of the graviton. At the time of writing, no particles of spin $S=3/2$ or $S=5/2$ are known (some supposed it could be dark energy particles spin).



Fermions
Leptons (spin 1/2)
Electron (Charge -1) e-
Electron Neutrino (Charge 0) νe
Tau (Charge -1) τ
Tau Neutrino (Charge 0) τe
Muon (Charge -1) μ
Muon Neutrino (Charge 0) νμ
Quarks (spin 1/2)
Bottom Quark (Charge -1/3) b
Up Quark (Charge 2/3) U
Down Quark (Charge -1/3) d
Top Quark (Charge 2/3) t
Strange Quark (Charge -1/3) s
Charm Quark (Charge 2/3) c
Baryons (spin 1/2 2/3)
Proton (Charge +1) P+
Anti Proton (Charge -1) P̄-
Neutron (Charge 0) N0
Lamda (Charge 0) Λ0
Omega (Charge -1) Ω-
Measons (spin 0,1)
Pion (Charge +1) π+
Kaon (Charge -1) K-
Rho (Charge +1) ρ+
B-zero (Charge 0) B0
Eta-c (Charge 0) ηc
Any member of a group of subatomic particles having odd half-integral angular momentum (spin 1/2, 3/2).
Fermions obey the Pauli exclusion principle, which forbids more than one particle of this type from occupying a single quantum state.
Fermions include nuclei of odd mass number.
Bosons (spin 1)
Photon (Charge 0) γ
W- Boson (Charge -1) W-
W+ Boson (Charge 1) W+
Z0 Boson (Charge 0) Z0
Gluon? (Charge 0) g
Subatomic particle with integral spin (i.e., angular momentum in quantum-mechanical units of 0, 1, etc.)
Bosons (force carriers) differ significantly from fermions in that there is no limit to the number that can occupy the same quantum state.
2nd September 2009

Figure 11.68: Some particles classification by spin (Author: James Childs)

We will see another diagram of the same type including the Higgs particle in the section of Particle Physics.

We see therefore that the integer or semi-integral value of the spin seems to determine a crucial property of the particle: if its spin is integer, it is a "boson", if its spin is half-integer, it is a "fermion" (this can be proven with the "spin-statistics theorem" that as already mentioned we will perhaps in the future give the proof in this textbook).

The total angular momentum is thus approximately given by:

$$\parallel \vec{J} \parallel = \parallel \vec{L} + \vec{S} \parallel \cong (l+s)\hbar = \sqrt{J(J+1)}\hbar \tag{11.2.959}$$

By analogy (it is really a dubious analogy ...), we write for J sufficiently large...:

$$\parallel \vec{J} \parallel \cong (l+s)\hbar = j\hbar \tag{11.2.960}$$

But since the spin of the electron may have only two possible orientations[20], the values of j will be in the case of a spin particle $1/2$:

$$\begin{aligned} j &\cong l+\frac{1}{2} \qquad \text{parallel spins} \\ j &\cong l-\frac{1}{2} \qquad \text{anti-parallel spins} \end{aligned} \tag{11.2.961}$$

Hence a possible classification of the atomic electrons taking into account their spin:

Orbital type	***s***	***p***	***d***	***f***	...
l	0	1	2	3	...
j	$\frac{1}{2}$	$\frac{1}{2},\frac{3}{2}$	$\frac{3}{2},\frac{5}{2}$	$\frac{5}{2},\frac{7}{2}$	...
Notation:	$s_{1/2}$	$p_{1/2},p_{3/2}$	$d_{3/2},d_{5/2}$	$f_{5/2},f_{7/2}$	...

Table 11.10: **Types of orbital and spin for electrons**

We see above that for a multiplicity of $2l+1$ states. Indeed, for $l=0$ we have 1 states, for $l=1$ we have a total of $1+2=3$ states, for $l=2$ we have a total of $1+2+2=5$ states, and so on....

Either in schematic form with the corresponding energy levels:

---

[20] Electrons spin in all directions, but in the Stern-Gerlach experiment they deflect only in the z direction because there was only a field in the z direction (see section Relativistic Quantum Physics page 4979). This is why we speak of two "privileged" possible orientations.

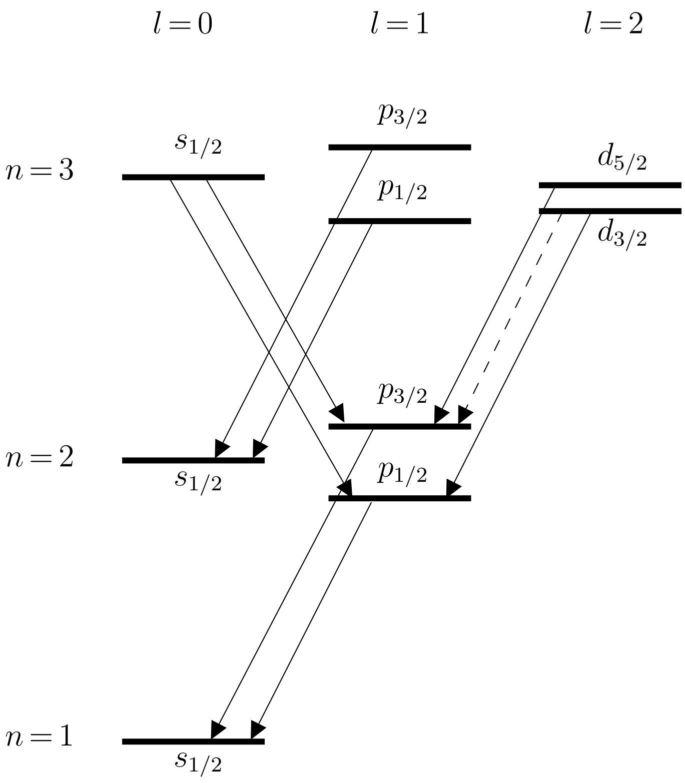


Figure 11.69: Schematic form of associated orbitals and spin energy levels

This table leads us to conclude that we finally:

$$\boxed{|l-s| \leq j \leq |l+s|} \tag{11.2.962}$$

Also we therefore introduce a common nomenclature for naming energy terms when we deal with the details of spin-orbit coupling is[21]:

$$\boxed{n^{2s+1}l_j} \tag{11.2.963}$$

where for recall n is the principal quantum number, s is the spin therm, l the orbital angular momentum and j the total angular momentum.

To return to more practical considerations ... we finally obtained for the norm of total angular momentum (in the case of a single particle and without spin):

$$J \leq \sqrt{l(l+1)}\hbar \tag{11.2.964}$$

where l is an integer (at least in the case where we don't do the approximation done earlier above). We also know from the section of Corpuscular Quantum Physics (see page 4666) that the magnetic moment is given by:

$$\mu_l = m_l\hbar \tag{11.2.965}$$

and that the secondary quantum number l and the magnetic quantum number m_l are in some way indissociable.

---

[21] the spin term is sometimes omitted because it's the same for all the levels

In the same way we get:

$$S \leq \sqrt{s(s+1)}\hbar \tag{11.2.966}$$

where can take for a particle like the electron only the values (don't forget that is doesn't mean it can take only two directions! It just means it can take two states and the famous "two directions" legend is due to the Stern-Gerlach experiment type configuration):

$$s = \pm\frac{1}{2} \tag{11.2.967}$$

Which simply correspond (in natural units) to the two eigenvalues of the eigenmatrices:

$$\frac{1}{2}\sigma_i \tag{11.2.968}$$

which links the spin operator to the Pauli matrices for the electron by the Dirac equation as we will prove it in the section of Relativistic Quantum Physics (see page 4931):

$$S = \frac{\hbar}{2}s_i = \frac{\hbar}{2}\sigma_i \tag{11.2.969}$$

Remark

It is more accurate to say that in reality that the eigenvalues $\pm 1/2\hbar$ are linked to eigenmatrices $\frac{\hbar}{2}\sigma_i$ but as the $\hbar$ simplifies...

Now, what we know of our results obtained in the section of Corpuscular Quantum Physics is that when l is equal to 1 we have the magnetic moment which can take three different values according to whether a magnetic field is applied or not:

$$m_l = -1, 0, +1 \tag{11.2.970}$$

At this time, although the norm of the total angular momentum remains constant (as it is conservative quantity), its components must necessarily change. Since we know only one of the components of the angular momentum by knowing its norm (commutating operators), we choose to focus for pedagogical conventions on J_z.

We choose a reference frame such that one of the spatial components is always equal to zero (this is always possible as we know it!). It is then sufficient, for example, in the chosen planar referential X, Z (i.e. the component Y will be zero) to have the norm of J that is equal to $l = 1$:

$$J \leq \sqrt{1(1+1)}\hbar = \sqrt{2}\hbar \tag{11.2.971}$$

and same with S by imposing that the norm for $s = 1/2$ is equal to:

$$S \leq \sqrt{\frac{1}{2}\left(\frac{1}{2}+1\right)}\hbar = \frac{\sqrt{3}}{2}\hbar \tag{11.2.972}$$

There are then three possibilities to arrive at the same result by simply applying the Euclidean norm if one of the components is always imposed as zero! It is because we have:

$$\left.\begin{array}{l} J_x = \hbar,\ J_z = \hbar \\ J_x = \sqrt{2}\hbar,\ J_z = 0 \\ J_x = \hbar,\ J_z = -\hbar \end{array}\right\} \parallel \vec{J} \parallel = \sqrt{2}\hbar \tag{11.2.973}$$

What we write so (because in fact there is an infinity of possibility) because we want to find a way to introduce the quantum number of orbital projection (which therefore quantifies the projection of the orbital angular momentum along Z and is in multiplicity $2l+1$):

$$\left.\begin{array}{ll} J_x=\hbar, J_z=m_l\hbar & m_l=+1 \\ J_x=\sqrt{2}\hbar, J_z=m_l\hbar & m_l=0 \\ J_x=\hbar, J_z=m_l\hbar & m_l=-1 \end{array}\right\} \|\vec{J}\|=\sqrt{2}\hbar \tag{11.2.974}$$

What some physicists like to represent in a very simplified way by the following diagram:

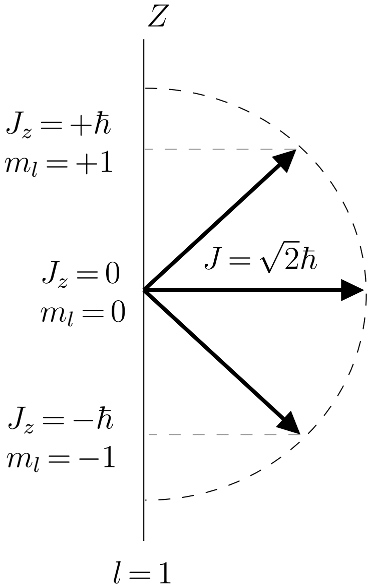

Figure 11.70: **Biased schematic representation of the quantification of total angular momentum in 2D**

But which in reality (by the square of the components of the norm) should be drawn in the following form in 2D (as in 3D this is represented by cones as we will see below):

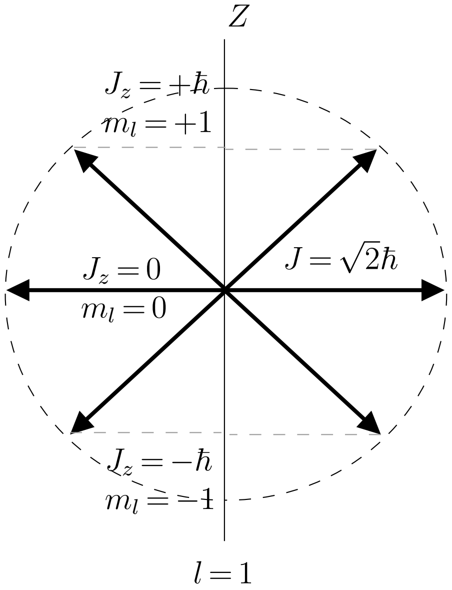

Figure 11.71: **Improved schematic representation of the quantification of total angular momentum in 2D**

This allows us to observe on the way that as we have mention earlier above, we can always rotate the system of axes such that one of the components is zero and earlier we did the choice:

$$\langle J_y \rangle = 0 \tag{11.2.975}$$

Notice that with elementary trigonometry we get:

$$\theta = \arccos\left(\frac{J_z}{\| \vec{J} \|}\right) = \arccos\left(\frac{m_l \hbar}{\hbar\sqrt{J_x^2 + J_z^2}}\right) = \arccos\left(\frac{m_l}{\sqrt{l(l+1)}}\right) \tag{11.2.976}$$

and therefore the angles take the following values:

$$\arccos\left(\frac{-l}{\sqrt{l(l+1)}}\right), \arccos\left(\frac{-l+1}{\sqrt{l(l+1)}}\right), \ldots, \frac{\pi}{2}, \ldots, \arccos\left(\frac{l-1}{\sqrt{l(l+1)}}\right), \arccos\left(\frac{l}{\sqrt{l(l+1)}}\right) \tag{11.2.977}$$

Finally, let us indicate that we then have in the particular case of the figure above where $l = 1$, $m_l = \pm 1$, that the (quite abstract) system introduced earlier above:

$$\begin{aligned} \| \vec{J} \|^2 \big|K, m\rangle &= K \big|K, m\rangle \\ J_z \big|K, m\rangle &= m \big|K, m\rangle \end{aligned} \tag{11.2.978}$$

that will be written as:

$$\begin{aligned} &\| \vec{L} \|^2 \big|l, m_l\rangle = \hbar^2 l(l+1) \big|l, m_l\rangle \Rightarrow \| \vec{L} \|^2 \big|1, +1\rangle = 2\hbar^2 \big|1, +1\rangle \\ &L_z \big|l, m_l\rangle = \hbar l \big|l, m_l\rangle \Rightarrow L_z \big|1, +1\rangle = \hbar \big|1, +1\rangle \end{aligned} \tag{11.2.979}$$

Which is often written in condensed form as following:

$$\begin{aligned} \hat{L}^2 \big|1, +1\rangle &= 2\hbar^2 \big|1, +1\rangle \\ \hat{L}_z \big|1, +1\rangle &= \hbar \big|1, +1\rangle \end{aligned} \tag{11.2.980}$$

In the same way with the spin $1/2$ of electron we have by introducing the quantum number of spin (which therefore quantifies the projection of the spin moment of spin along Z and can take as many values as there are between $-s$ and $+s$ but by increments of 1 as required by the experimental results, for which reason there is no zero Z component below):

$$\left.\begin{aligned} S_x = \frac{\hbar}{\sqrt{2}}, S_z = m_s \hbar \qquad m_s = +\frac{1}{2} \\ S_x = \frac{\hbar}{\sqrt{2}}, S_z = m_s \hbar \qquad m_s = -\frac{1}{2} \end{aligned}\right\} \| \vec{S} \| = \frac{\sqrt{3}}{2}\hbar \tag{11.2.981}$$

What some physicists like to represent in a very simplified way by the following diagram:

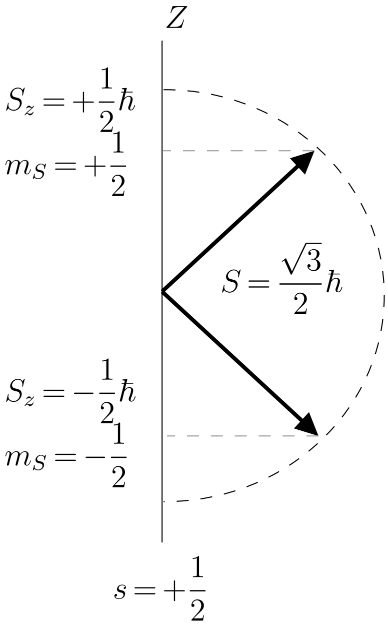

Figure 11.72: **Biased schematic representation of the quantification of spin in 2D**

with for angle:

$$\begin{aligned}\arccos\left(\frac{m_s}{\sqrt{s(s+1)}}\right)&=\arccos\left(\frac{\pm\frac{1}{2}}{\sqrt{\frac{1}{2}\left(\frac{1}{2}+1\right)}}\right)=\arccos\left(\frac{\pm\frac{1}{2}}{\frac{\sqrt{3}}{2}}\right)\\&=\arccos\left(\pm\frac{1}{\sqrt{3}}\right)\cong\pm54.73^\circ\end{aligned}\tag{11.2.982}$$

As before, we have in the particular case where $s=\frac{1}{2}$ and $m_s=\pm\frac{1}{2}$:

$$\begin{aligned}&\|\vec{S}\|^2\left|s,m_s\right\rangle=\hbar^2 s(s+1)\left|s,m_s\right\rangle\Rightarrow\|\vec{S}\|^2\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle=\frac{3}{4}\hbar^2\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle\\&S_z\left|s,m_s\right\rangle=\hbar s\left|s,m_s\right\rangle\Rightarrow S_z\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle=\frac{\hbar}{2}\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle\end{aligned}\tag{11.2.983}$$

This can be written in a more condensed form as following:

$$\begin{aligned}\hat{S}^2\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle&=\frac{3}{4}\hbar^2\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle\\\hat{S}_z\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle&=\frac{\hbar}{2}\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle\end{aligned}\tag{11.2.984}$$

We therefore have the only experimentally measurable variables that are:

$$\boxed{L_z=m_l\hbar}\qquad\text{and}\qquad\boxed{S_z=s\hbar}\tag{11.2.985}$$

Which are therefore discrete observables (bivalent for the spin).

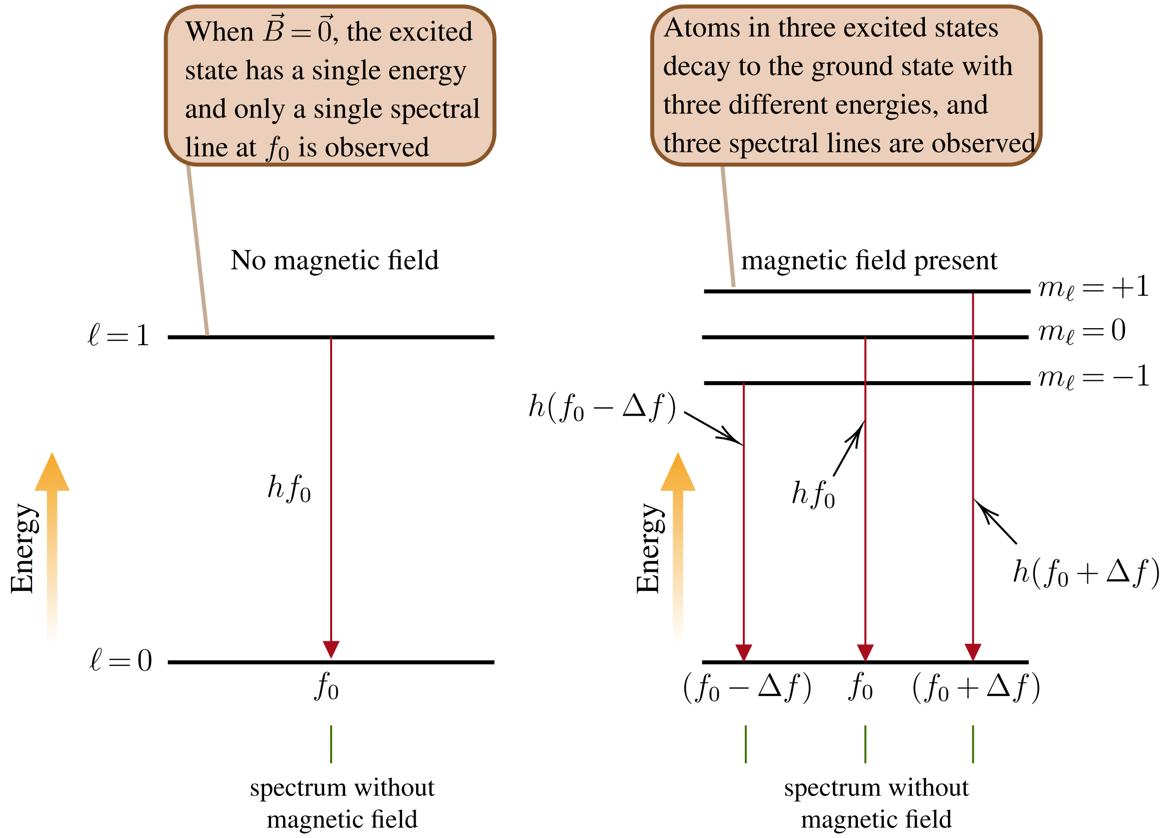
With an artist's view of the concept for the pleasure of the eyes:

Figure 11.73: **Schematic representation of various quantifications of angular momentum by the physicist and sculptor Julian Voss-Andreae**

Therefore, by applying a constant uniform magnetic field, the Pauli Hamiltonian (see section Relativistic Quantum Physics page 4985) will make jumps equivalent to the relation:

$$\boxed{E_p = -\frac{q\hbar}{2m_0}B(m_l + 2s)} \quad (11.2.986)$$

This result means that the energy levels for a given energy (n-layer) are separated into several levels distant of $\dfrac{q\hbar}{2m_0}B$ when the atom is placed in a magnetic field. This result is the Zeeman effect which we have already discussed several times.



When $\vec{B}=\vec{0}$, the excited state has a single energy and only a single spectral line at f_0 is observed
Atoms in three excited states decay to the ground state with three different energies, and three spectral lines are observed
No magnetic field
magnetic field present
$\ell=1$
$\ell=0$

Figure 11.74: Zeeman effect (source: [491])

All this makes it possible to better understand the mathematical origin of the 4 quantum numbers (principal quantum number, secondary or azimuthal quantum number, magnetic quantum number, spin):

$$n,l,m_l,m_s \tag{11.2.987}$$

also written (since in the particular case of the particles studied in this textbook the magnetic quantum number of spin projection has the same value as the spin since we are dealing mainly with the electron):

$$n,l,m_l,s \tag{11.2.988}$$

To sum up a bit all this...:

$$\begin{aligned}
&J=L+S\\
&n=1,2,3,4\ldots\\
&0\leq l\leq n-1\\
&j=0,\frac{1}{2},1,\frac{3}{2},2,\frac{5}{2},\ldots\\
&s=0,\frac{1}{2},1,\frac{3}{2},2,\frac{5}{2},\ldots\\
&|l-s|\leq j\leq |l-s|\\
&m_l=-l,-l+1,-l+2,\ldots,0,\ldots,l-2,l-1,l\\
&-l\leq m_l\leq +l\\
&m_s=-s,-s+1,-s+2,\ldots,0,\ldots,s-2,s-1,l\\
&-s\leq m_s\leq +s
\end{aligned} \tag{11.2.989}$$

The reader must not think that what we have seen so far was developed in one day or even in one year by physicist. Furthermore this abstract approach was highly speculative and needed to be check with experiments. So far it works very good to explain and predict experimental observations but still in this beginning of the 121st century (holocene calendar) the spin matrices theory is confronted and tested by new experimentation!

✍**Example:**

E1. Consider we have an imaginary a system of two electrons whose orbital quantum numbers are $l_1=2$ and $l_2=4$ respectively. What are the possible values of l (total orbital angular momentum quantum number), s (total spin angular momentum quantum number), j (total angular momentum quantum number).

The quantum numbers associated with the total orbital angular momentum will range from a maximum value found by adding the individual quantum numbers together to a minimum value found by taking the absolute value of the difference of the two numbers in integer steps:

$$\begin{aligned} l_{\max} &= l_1+l_2=2+4=6 \\ l_{\min} &= |l_1-l_2|=|2-4|=2 \end{aligned} \tag{11.2.990}$$

Therefore the possible values for L of the system are $2,3,4,5$ and 6.

The quantum numbers associated with the total spin angular momentum will range from a maximum value found by adding the individual quantum numbers together to a minimum value found by taking the absolute value of the difference of the two numbers in integer steps:

$$\begin{aligned} s_{\max} &= s_1+s_2={}^1\!/\!_2+{}^1\!/\!_2=1 \\ s_{\min} &= |s_1-s_2|=|{}^1\!/\!_2-{}^1\!/\!_2|=0 \end{aligned} \tag{11.2.991}$$

The possible values for s of the system are therefore 0 and 1.

The largest possible value for j will be found by adding together the maximum values for both l and s. The minimum value for j will be found by subtracting the largest possible value of s from the smallest possible value for l:

$$\begin{aligned} j_{\max} &= l_{\max}+s_{\max}=6+1=7 \\ j_{\min} &= |l_{\min}-s_{\max}|=|2-1|=1 \end{aligned} \tag{11.2.992}$$

Therefore the possible values for J of the system are $1,2,3,4,5$ and 6.

E2. A hydrogen atom is known to be in a state characterized the quantum numbers $n=3, l=2$. What are the values of the total angular momentum and their corresponding magnitude?

Therefore the values of the total angular momentum are:

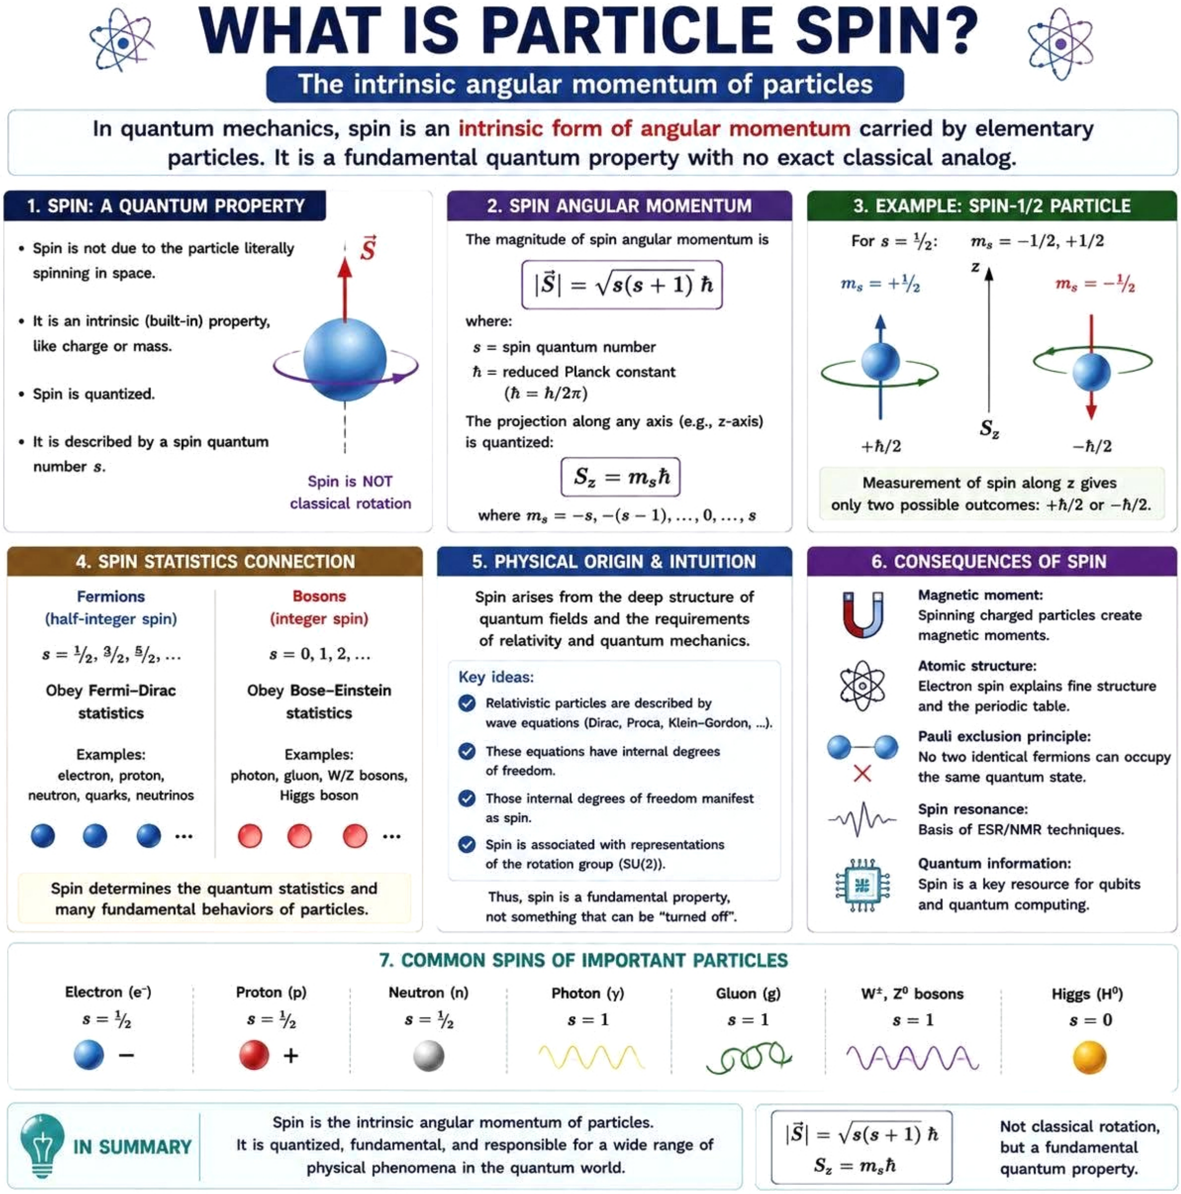
$$\begin{aligned} j_{\max} &= l_{\max}+s_{\max}=2+{}^1\!/\!_2={}^5\!/\!_2 \\ j_{\min} &= l_{\min}+s_{\min}=2-{}^1\!/\!_2={}^3\!/\!_2 \end{aligned} \tag{11.2.993}$$

We have as we have proved above:

$$\|\vec{J}\|^2|j,m\rangle = j(j+1)\hbar^2|j,m\rangle \qquad (11.2.994)$$

Therefore we have for $j_{\text{max}} = {}^5/_2$ and $j_{\text{min}} = {}^3/_2$ the following mangitude:

$$\begin{gathered}\|\vec{J}\|^2|{}^5/_2,m\rangle : j(j+1)\hbar^2 = {}^{35}/_4\hbar^2\\ \|\vec{J}\|^2|{}^3/_2,m\rangle : j(j+1)\hbar^2 = {}^{15}/_4\hbar^2\end{gathered} \qquad (11.2.995)$$



WHAT IS PARTICLE SPIN?

The intrinsic angular momentum of particles

In quantum mechanics, spin is an **intrinsic form of angular momentum** carried by elementary particles. It is a fundamental quantum property with no exact classical analog.

1. SPIN: A QUANTUM PROPERTY

- Spin is not due to the particle literally spinning in space.
- It is an intrinsic (built-in) property, like charge or mass.
- Spin is quantized.
- It is described by a spin quantum number s.

$\vec{S}$

Spin is NOT classical rotation

2. SPIN ANGULAR MOMENTUM

The magnitude of spin angular momentum is

$$\boxed{|\vec{S}| = \sqrt{s(s+1)}\,\hbar}$$

where:

s = spin quantum number
$\hbar$ = reduced Planck constant
($\hbar = h/2\pi$)

The projection along any axis (e.g., z-axis) is quantized:

$$\boxed{S_z = m_s\hbar}$$

where $m_s = -s, -(s-1), \ldots, 0, \ldots, s$

3. EXAMPLE: SPIN-1/2 PARTICLE

For $s = {}^1/_2$: $m_s = -1/2, +1/2$

$m_s = +{}^1/_2$ z $m_s = -{}^1/_2$

$+\hbar/2$ S_z $-\hbar/2$

Measurement of spin along z gives only two possible outcomes: $+\hbar/2$ or $-\hbar/2$.

4. SPIN STATISTICS CONNECTION

Fermions (half-integer spin)	Bosons (integer spin)
$s = {}^1/_2, {}^3/_2, {}^5/_2, \ldots$	$s = 0, 1, 2, \ldots$
Obey Fermi–Dirac statistics	Obey Bose–Einstein statistics
Examples: electron, proton, neutron, quarks, neutrinos	Examples: photon, gluon, W/Z bosons, Higgs boson
● ● ● …	● ● ● …

Spin determines the quantum statistics and many fundamental behaviors of particles.

5. PHYSICAL ORIGIN & INTUITION

Spin arises from the deep structure of quantum fields and the requirements of relativity and quantum mechanics.

Key ideas:

- ✓ Relativistic particles are described by wave equations (Dirac, Proca, Klein–Gordon, ...).
- ✓ These equations have internal degrees of freedom.
- ✓ Those internal degrees of freedom manifest as spin.
- ✓ Spin is associated with representations of the rotation group (SU(2)).

Thus, spin is a fundamental property, not something that can be "turned off".

6. CONSEQUENCES OF SPIN

Magnetic moment:
Spinning charged particles create magnetic moments.

Atomic structure:
Electron spin explains fine structure and the periodic table.

Pauli exclusion principle:
No two identical fermions can occupy the same quantum state.

Spin resonance:
Basis of ESR/NMR techniques.

Quantum information:
Spin is a key resource for qubits and quantum computing.

7. COMMON SPINS OF IMPORTANT PARTICLES

Electron (e^-)	Proton (p)	Neutron (n)	Photon (γ)	Gluon (g)	$W^{\pm}$, Z^0 bosons	Higgs (H^0)
$s = {}^1/_2$	$s = {}^1/_2$	$s = {}^1/_2$	$s = 1$	$s = 1$	$s = 1$	$s = 0$
−	+					

IN SUMMARY

Spin is the intrinsic angular momentum of particles. It is quantized, fundamental, and responsible for a wide range of physical phenomena in the quantum world.

$$\begin{gathered}|\vec{S}| = \sqrt{s(s+1)}\,\hbar\\ S_z = m_s\hbar\end{gathered}$$

Not classical rotation, but a fundamental quantum property.

11.2.5.1 Spin–orbit interaction (LS coupling)

In quantum physics, the "spin–orbit interaction" (also named "spin–orbit effect" or "spin–orbit coupling") is an interaction of a particle's spin with its motion. The first and best known example of this is that spin–orbit interaction causes shifts in an electron's atomic energy levels due to electromagnetic interaction between the electron's spin and the magnetic field generated by the electron's orbit around the nucleus. This is detectable as a splitting of spectral lines, which can be thought of as a Zeeman Effect due to the internal field. A similar effect, due to the relationship between angular momentum and the strong nuclear force, occurs for protons and neutrons moving inside the nucleus, leading to a shift in their energy levels in the nucleus shell model. In the field of spintronics, spin–orbit effects for electrons in semiconductors and other materials are explored for technological applications. The spin–orbit interaction is one cause of magneto-crystalline anisotropy.

Let us now recall that we have pointed out in the section of Corpuscular Quantum Physics that when we analyse the spectral lines of hydrogen in the absence of any external field at high resolution, we see that they are in fact made up of very close doublets, separated of 0.016 [nm] in terms of wavelength. This phenomenon is due to a so-called spin-orbit coupling. It is now time to see where it comes from. So let us also recall that we previously obtained:

$$\vec{J}=\vec{L}+\vec{S} \tag{11.2.996}$$

Hence, the squared norm (what is measured) leads us to write:

$$\|\vec{J}\|^2=\|\vec{L}+\vec{S}\|^2=\left(L_x+S_x\right)^2+\left(L_y+S_y\right)^2+\left(L_z+S_z\right)^2 \tag{11.2.997}$$

Which gives us after grouping:

$$\|\vec{J}\|^2=\|\vec{L}+\vec{S}\|^2=\|\vec{L}\|^2+\|\vec{S}\|^2+2\vec{L}\circ\vec{S} \tag{11.2.998}$$

The term:

$$\boxed{\vec{L}\circ\vec{S}} \tag{11.2.999}$$

is named "spin-orbit coupling". It is the term that during the very precise measurements of spectral lines reveals a splitting of the lines due to the coupling between the electron spin and the orbital angular momentum (this is not an $\|\vec{S}\|^2$ because this term is always positive).

Remark

Let us recall that when we have two bodies in interaction the total angular momentum is a constant of motion as we have proved it in the section of Classical Mechanics. There may thus be a transfer of angular momentum between these two bodies (this is the spin-orbit coupling!). One loses angular momentum and the other gain angular momentum.

The measured deviation is thus attributed to the interaction of the electron spin with its orbital angular momentum. The electron revolves around the nucleus, but if we place ourselves on the electron, we see the nucleus turning (on Earth the Sun revolves around the Earth!). Everything happens as if the nucleus generate a magnetic field at the level of the electron, and this field interacts with the magnetic moment of the electron, the spin, and this differs according to whether the spin is in the direction of the field or opposite, It is this difference that adds or subtracts some energy from the level.

Here is a first simplified diagram that summarizes the whole:

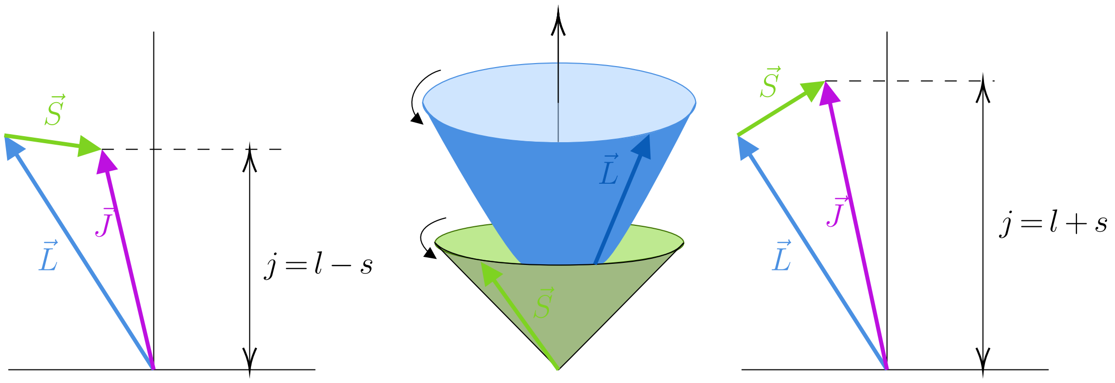


Figure 11.75: **Pictorial representation of the spin-orbit interaction**

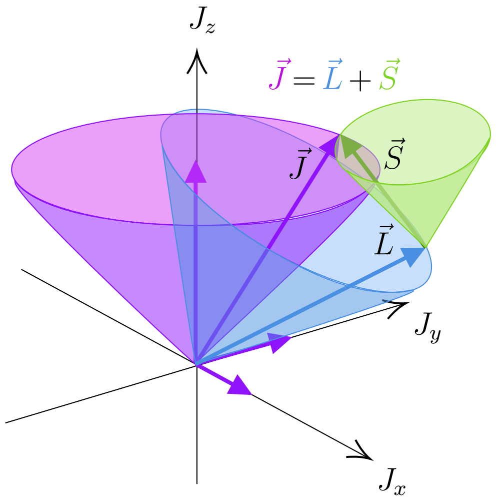
or in 3D perspective and that is a bit more accurate:



Let us prove that $\vec{J}$ as defined is a constant of motion. We have (needless to say that by squaring, these are the components of the vector that we put square and not the vector itself!):

$$\vec{L}\circ\vec{S}=\frac{1}{2}\left[\left(\vec{L}+\vec{S}\right)^2-\vec{L}^2-\vec{S}^2\right] \quad (11.2.1000)$$

Hence:

$$\left[\vec{J},\vec{L}\circ\vec{S}\right]=\frac{1}{2}\left[\vec{J},\vec{J}^2-\vec{L}^2-\vec{S}^2\right] \quad (11.2.1001)$$

Let's make the development for one component:

$$\begin{aligned}\frac{1}{2}\left[J_x,J_x^2-L_x^2-S_x^2\right]=&\frac{1}{2}\left[J_x\left(J_x^2-L_x^2-S_x^2\right)-\left(J_x^2-L_x^2-S_x^2\right)J_x\right]\\&\frac{1}{2}\left[\cancel{J_x^3}-J_xL_x^2-J_xS_x^2-\cancel{J_x^3}+L_x^2J_x+S_x^2J_x\right]\\&=-\frac{1}{2}\left[L_x^2J_x+S_x^2J_x-J_xL_x^2-J_xS_x^2\right]\\&=-\frac{1}{2}\left[J_x,L_x^2+S_x^2\right]\end{aligned}\tag{11.2.1002}$$

But, by definition (of notation) $J_x=L_x+S_x$ therefore:

$$\begin{aligned}\left[\vec{J},\vec{L}\circ\vec{S}\right]_x&=-\frac{1}{2}\left[J_x,L_x^2+S_x^2\right]=-\frac{1}{2}\left[L_x+J_x,L_x^2+S_x^2\right]\\&=-\frac{1}{2}\left[\left(L_xL_x^2+L_xS_x^2+S_xL_x^2+S_xS_x^2\right)-\left(L_x^2L_x+S_x^2L_x+L_x^2S_x+S_x^2S_x\right)\right]\\&=-\frac{1}{2}\left(\left[L_x,L_x^2\right]+\left[S_x,S_x^2\right]+\left[L_x,S_x^2\right]+\left[S_x,L_x^2\right]\right)\end{aligned}\tag{11.2.1003}$$

Now we know that $[L_x,L_x^2]=0$ (because an operator always commutes with itself by construction) and concerning $[S_x,S_x^2,$ we have mentioned it in the section of Spinor Calculus and we will prove it in the framework of the study of the free classical Dirac equation (see section Relativistic Quantum Physics page 4931), that the electron spin is fully described by the Pauli matrices which are linear operators. Let us then write to a constant factor:

$$S_x=c^{te}\cdot\sigma_x=c^{te}\cdot\begin{bmatrix}0&1\\1&0\end{bmatrix}\tag{11.2.1004}$$

and we will see that this is in conformity with the Pauli equation that we introduce and study in the section of Relativistic Quantum Physics (and vice versa) !!!

Therefore, disregarding the multiplicative constant:

$$[S_x,S_x^2]=\begin{bmatrix}0&1\\1&0\end{bmatrix}\left(\begin{bmatrix}0&1\\1&0\end{bmatrix}\right)^2-\left(\begin{bmatrix}0&1\\1&0\end{bmatrix}\right)^2\begin{bmatrix}0&1\\1&0\end{bmatrix}=0\tag{11.2.1005}$$

Which was in any case 100% predictable since in any case, once again, a same operator always commutes with himself.

So finally:

$$\left[\vec{J},\vec{L}\circ\vec{S}\right]_x=-\frac{1}{2}\left(\left[L_x,S_x^2\right]+\left[S_x,L_x^2\right]\right)\tag{11.2.1006}$$

Therefore:

$$\begin{aligned}&[L_x,S_x^2]=L_x\begin{bmatrix}0&1\\1&0\end{bmatrix}^2-\begin{bmatrix}0&1\\1&0\end{bmatrix}^2L_x=L_x\begin{bmatrix}1&0\\0&1\end{bmatrix}-\begin{bmatrix}1&0\\0&1\end{bmatrix}L_x=0\\&[S_x,L_x^2]=\begin{bmatrix}0&1\\1&0\end{bmatrix}\cdot L_x^2-L_x^2\begin{bmatrix}0&1\\1&0\end{bmatrix}=0\end{aligned}\tag{11.2.1007}$$

Hence finally:

$$\left[\vec{J},\vec{L}\circ\vec{S}\right]=0 \tag{11.2.1008}$$

$\vec{J}$ is the indeed total angular momentum which, even in the presence of spin-orbit interaction, is a constant of motion (an obligation for an isolated system!).

Remark

Another way of reading that thing is to say that the measurement on one of the elements of the preceding commutator adapts the other one immediately so that their commutation is zero therefore by extension the total angular momentum is a constant of the motion.

One notable atomic spectral line of sodium vapour is the so-called D-line, which may be observed directly as the sodium flame-test line and also the major light output of low-pressure sodium lamps (these produce pressure sodium lamps (these produce an unnatural yellow. The D-line is one of the classified Fraunhofer lines Sodium vapour in the upper layers of lines. Sodium vapour in the upper layers of the Sun generates a dark line in the emitted spectrum of electromagnetic radiation by absorbing visible light in a band of wavelengths around 589.5 [nm]. This wavelength corresponds to transitions in atomic sodium in which valence-electron transitions from $3s$ to $3p$ electronic state.

The splitting of the sodium doublet in the presence of an external magnetic field was observed by Pieter Zeeman in 11896 (holocene calendar), and the effect was subsequently named the "Zeeman effect". It is remarkable that so much detailed spectroscopy was done long before the Bohr theory, and perhaps even more remarkable that Zeeman's first study of the sodium Zeeman splitting was done the year before J. J.Thomson's discovery of the electron in 11897 (holocene calendar).

Figure 11.77: **General overview of Sodium splitting (source: Hyperphysics)**

After Thomson's work, Zeeman and Lorentz did further study of the influence of magnetic fields on the spectral emissions from atoms. By analysis of the splitting of the sodium doublet, they were able to demonstrate that the charge to mass ratio of the charge responsible for the splitting was the same as Thomson's electron. This was the first direct demonstration that electrons were involved in the production of the spectral line emissions.

11.2.5.2 Spin operator for spin $1/2$ particles

Let us now return to the relation demonstrated earlier above for $1/2$ spin particles:

$$\begin{aligned}\hat{S}^2\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle &= \frac{3}{4}\hbar^2\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle\\ \hat{S}_z\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle &= \frac{\hbar}{2}\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle\end{aligned} \tag{11.2.1009}$$

We have for sure obtained the eigenvalues, but it would be wise to determine the expression of the corresponding Spin operators $\hat{S}^2$ and $\hat{S}_z$. We have seen in the section of Spinor Calculus that:

$$\sigma_z = \begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix} \tag{11.2.1010}$$

and we proved that for the eigenvalue $+1$ the associated eigenvectors were:

$$\pm\begin{pmatrix}1\\0\end{pmatrix} \tag{11.2.1011}$$

We then have:

$$\begin{bmatrix}1 & 0\\0 & -1\end{bmatrix}\begin{pmatrix}1\\0\end{pmatrix}=1\begin{pmatrix}1\\0\end{pmatrix} \tag{11.2.1012}$$

By multiplying to the left and right by a familiar term:

$$\frac{\hbar}{2}\begin{bmatrix}1 & 0\\0 & -1\end{bmatrix}\begin{pmatrix}1\\0\end{pmatrix}=\frac{\hbar}{2}\begin{pmatrix}1\\0\end{pmatrix} \tag{11.2.1013}$$

And by analogy of the fact that the matrix of Pauli are special case of rotations matrices $\text{SU}(2)$ (see section Set Algebra page 1425), we put:

$$\hat{S}_z=\frac{\hbar}{2}\begin{bmatrix}1 & 0\\0 & -1\end{bmatrix} \tag{11.2.1014}$$

And of course we deduce:

$$\hat{S}^2=\left\|\vec{S}\right\|^2=\left(\frac{\hbar}{2}\sigma_x\right)^2+\left(\frac{\hbar}{2}\sigma_y\right)^2+\left(\frac{\hbar}{2}\sigma_z\right)^2=\frac{\hbar^2}{4}\left(\sigma_x^2+\sigma_y^2+\sigma_z^2\right)=\frac{3\hbar^2}{4}\begin{bmatrix}1 & 0\\0 & 1\end{bmatrix} \tag{11.2.1015}$$

Therefore for spin-$1/2$ particles we have:

$$\boxed{\hat{S}^2=\frac{3\hbar^2}{4}\begin{bmatrix}1 & 0\\0 & 1\end{bmatrix}\qquad \hat{S}_z=\frac{\hbar}{2}\begin{bmatrix}1 & 0\\0 & -1\end{bmatrix}} \tag{11.2.1016}$$

and we know that it is not the most explicit form as we should write the one we have determine in the section of Spinor Calculus for the Pauli matrices.

11.2.6 Planck's dimensions

It is time now to open a small parenthesis to finish about the Planck's constant that we promised in the section Principles of the chapter Mechanics to in-deep during our study of Wave Quantum Physics (because many textbooks mention what we will see without the precautions of rigour in our point of view). We have just seen that the measurement of objects depends on the Heisenberg's uncertainty principles. This precision affects both the time measurements and the particle trajectory or the energy density of the Universe. Let's see that by extension ... there are other possible speculative implications that lead to the following table:

Derived Unit	**Expression**	**SI Equivalent (approx.)**
Planck's length	$l_P=\sqrt{\dfrac{G\hbar}{c^3}}$	$1.616\cdot 10^{-35}$ [m]
Planck's surface	$l_P^2=\dfrac{G]\hbar}{c^3}$	$2.6121\cdot 10^{-70}$ [m^2]
Planck's volume	$l_P^3=\left(\dfrac{\hbar G}{c^3}\right)^{3/2}$	$4.2217\cdot 10^{-105}$ [m^3]
Planck's mass	$m_P=\dfrac{\hbar c}{G}$	$2.175\cdot 10^{-8}$ [kg]
Planck's time	$t_P=\dfrac{\hbar G}{c^5}$	$5.391\cdot 10^{-44}$ [s]
Planck's temperature	$T_P=\dfrac{\hbar c^5}{Gk^2}$	$1.416\cdot 10^{32}$ [T]
Planck's energy	$E_P=\sqrt{\dfrac{\hbar c^5}{G}}$	$1.956\cdot 10^{9}$ [J]
Planck's density	$\rho_P=\dfrac{c^5}{G^2\hbar}$	$5.155\cdot 10^{96}$ [kg $\cdot$ m^{-3}]
Planck's power	$P_P=\dfrac{c^5}{G}$	$3.629\cdot 10^{52}$ [W]
Planck's pulsation	$\omega_P=\sqrt{\dfrac{c^5}{G}}$	$1.855\cdot 10^{43}$ [rad $\cdot$ s^{-1}]
Planck's charge	$q_P=\sqrt{c\hbar 4\pi\varepsilon_0}$	$1.875\cdot 10^{-18}$ [C]
Planck's current	$I_P=\sqrt{\dfrac{c^6 4\pi\varepsilon_0}{G}}$	$3.479\cdot 10^{25}$ [A]
Planck's voltage	$U_P=\sqrt{\dfrac{c^4}{G4\pi\varepsilon_0}}$	$1.043\cdot 10^{27}$ [V]
Planck's impedance	$Z_P=\dfrac{1}{4\pi\varepsilon_0 c}$	29.98 [Ω]

Table 11.11: **Various common Planck dimensions**

We have proved previously at the beginning of this section that one of the uncertainties relations is given, when taking the module, by (from the order of Planck's constant to one given factor):

$$\big|\,[x,p_x]\,\big|\propto\hbar \tag{11.2.1017}$$

So, we can say roughly that at a fluctuation Δx of space, we can associate the linear momentum:

$$p_x=\frac{\hbar}{\Delta x} \tag{11.2.1018}$$

To that latter, according to our results of the section of Special Relativity, corresponds the relation of the energy $E=Mc^2=pc$, or the equivalent mass (by dividing by c^2) p/c. By denoting by M this mass associated with the perturbation Δx, we thus have:

$$M=\frac{\hbar}{c\cdot\Delta x} \tag{11.2.1019}$$

The gravitation due to this mass is characterized by a length R which we will determine in order of magnitude by writing that the potential energy associated with it (this assumes that Classical and Quantum gravitation are governed by the same laws...) GM^2/R (see section Astronomy page 5255), is equal to the mass-energy Mc^2. This gives:

$$R=\frac{GM}{c^2} \tag{11.2.1020}$$

or, by replacing M by its previous expression:

$$R=\frac{G\hbar}{c^3\Delta x} \tag{11.2.1021}$$

So that there is no self-amplification (and thus divergence) of the phenomenon of vacuum quantum fluctuation, we must preferably have $R=\Delta x$. By writing the equality between these two quantities, we arrive at a quantity which represents the minimum dimension (in order of magnitude) that physics can conceive according to the interpretation of some physicists. This is the famous "Planck's length" where we replace R by l_p:

$$\boxed{l_P=\sqrt{\frac{G\hbar}{c^3}}\cong 1.616\cdot 10^{-35}\;[\text{m}]} \tag{11.2.1022}$$

For which it corresponds the period or "Planck time", also named "Planck-Wheeler time", $t_P=l_p/c$ hence:

$$\boxed{t_P=\sqrt{\frac{G\hbar}{c^5}}\cong 5.391\cdot 10^{-44}\;[\text{s}]} \tag{11.2.1023}$$

We can now return to another more interesting expression of the fluctuating mass. Since:

$$M=\frac{\hbar}{c\cdot\Delta x}\Rightarrow l_P=\frac{\hbar}{c\cdot M}\quad\text{and}\quad l_P=\sqrt{\frac{G\hbar}{c^3}} \tag{11.2.1024}$$

We have therefore after rearranging the "Planck mass":

$$\boxed{m_P=\sqrt{\frac{\hbar c}{G}}\cong 2.176\cdot 10^{-8}\;[\text{Kg}]} \tag{11.2.1025}$$

Caution!!! The Planck mass is a good an easy example that we must not take all the different Planck values (mass, length, charge, density, energy, etc) as impossible values to reach (or to overtake in one direction or the other...)!

In 11973 (holocene calendar), Jacob Bekenstein published a paper ([47]) where he showed that the surface area of a Black Hole increases by $1A_p$ (i.e. the Planck Area - equal to l_p^2) for every bit of information which crosses the event horizon. Therefore via Bekenstein's result and basic calculus, the change in radius of a Black Hole is much smaller than than the 1 Planck length!

We will see also further below that the same conclusion applies for the Planck energy, the Planck impedance that have no extraordinary values and that can be easily reached and overtaken in laboratories and that Planck charge has a value larger than the electric charge of the electron... Indeed, let us recall that only evidence based experience can validate a Planck value as a limit (like the Planck quantum of action equal to h that is a fact beyond reasonable evidence).

Another way to get the Planck's mass but that gives a slightly different result is first to suppose that the main three universal constant are:

$$h\,[\mathrm{kg}\cdot\mathrm{m}^2\cdot\mathrm{s}] \qquad c\,[\mathrm{m}\cdot\mathrm{s}^{-1}] \qquad G\,[\mathrm{kg}^{-1}\cdot\mathrm{m}^3\cdot\mathrm{s}^{-2}] \tag{11.2.1026}$$

and that we seek to write a mass by combining h, c and G. So this is a dimensional analysis as:

$$m_p = h^{\alpha}c^{\beta}G^{\gamma} \tag{11.2.1027}$$

where we need to find the values of α, β and γ to get a mass...

We see quickly that to for the mass (kg) we must have:

$$1 = \alpha - \gamma \tag{11.2.1028}$$

for the distance (m), we must have:

$$0 = 2\alpha + \beta + 3\gamma \tag{11.2.1029}$$

and for the time (s):

$$0 = -\alpha - \beta - 2\gamma \tag{11.2.1030}$$

So we just need to solve this linear system:

$$\begin{aligned} 0 &= 2\alpha + \beta + 3\gamma \\ 1 &= \alpha - \gamma \\ 0 &= -\alpha - \beta - 2\gamma \end{aligned} \tag{11.2.1031}$$

So first iteration:

$$\begin{aligned} 0 &= 2\alpha + \beta + 3\gamma \\ 1 &= \alpha - \gamma \\ 0 &= \alpha + \gamma \end{aligned} \tag{11.2.1032}$$

Second iteration:

$$\begin{aligned} 0 &= 2\alpha+\beta+3\gamma \\ 2 &= \alpha \\ 1 &= -2\gamma \end{aligned} \quad (11.2.1033)$$

Third iteration:

$$\begin{aligned} \alpha &= \frac{1}{2} \\ \gamma &= -\frac{1}{2} \\ 0 &= 1+\beta-\frac{3}{2} \end{aligned} \quad (11.2.1034)$$

so finally:

$$\alpha=\frac{1}{2} \qquad \beta=\frac{1}{2} \qquad \gamma=-\frac{1}{2} \quad (11.2.1035)$$

Therefore:

$$m_P=h^{1/2}c^{1/2}G^{-1/2}=\sqrt{\frac{hc}{G}} \quad (11.2.1036)$$

to a given multiplicative dimensionless constant... This missing multiplicative constant is known to us as we have determined the Planck's mass earlier before. So with dimensional analysis we should consider $\hbar$ as being more fundamental than h.

Dimensional analysis gives to a given constant factor and according to the virial theorem (see section Continuum Mechanics page 3897):

$$E=kT \quad (11.2.1037)$$

and therefore:

$$E=m_Pc^2=pc=kT\Rightarrow\frac{p}{c}=\frac{kT}{c^2}=m_p\Rightarrow\sqrt{\frac{\hbar c}{G}}=\frac{kT}{c^2} \quad (11.2.1038)$$

Hence the "Planck's temperature":

$$\boxed{T_P=\sqrt{\frac{\hbar c^5}{Gk}}\cong 1.42\cdot 10^{32}\;[\mathrm{K}]} \quad (11.2.1039)$$

and "Planck's energy":

$$\boxed{E_P=m_Pc^2=\sqrt{\frac{\hbar c}{G}}c^2=\sqrt{\frac{\hbar c^5}{G}}\cong 1.956\cdot 10^{9}\;[\mathrm{J}]} \quad (11.2.1040)$$

After all this, we easily get the "Planck's density":

$$\rho_P=\frac{M_P}{\lambda_P^3}=\frac{\sqrt{\dfrac{\hbar c}{G}}}{\sqrt{\dfrac{G\hbar}{c^3}}^3}=\frac{\sqrt{\dfrac{\hbar c}{G}}\sqrt{\dfrac{c^3}{G\hbar}}}{\dfrac{G\hbar}{c^3}}=\sqrt{\frac{c^4}{G^2}\frac{c^3}{G\hbar}}=\sqrt{\frac{c^{10}}{G^4\hbar^2}}=\frac{c^5}{G^2\hbar} \quad (11.2.1041)$$

That is:

$$\boxed{\rho_P \cong 5.1 \cdot 10^{96}\,[\mathrm{kg} \cdot \mathrm{m}^{-3}]} \tag{11.2.1042}$$

We can have fun getting other Planck values, but that have no physical experimental justification excepted for most of them invalid empirical and subjective interpretations (and we could go on for a long time with so many other magnitudes as we have give a quite exhaustive list in the section Principles of the Mechanics chapter). For example:

- The "Planck's force":

$$F_P = m_P \frac{\lambda_P}{t_P^2} = \sqrt{\frac{\hbar c}{G}} \frac{\sqrt{\dfrac{G\hbar}{c^3}}}{\left(\sqrt{\dfrac{G\hbar}{c^5}}\right)^2} = \frac{c^4}{G} \tag{11.2.1043}$$

  Therefore:

$$\boxed{F_P \cong 1.21 \cdot 10^{44}\,[\mathrm{N}]} \tag{11.2.1044}$$

- The "Planck's power":

$$\boxed{P_P = \frac{E_P}{t_P} = \frac{c^5}{G} \cong 3.629 \cdot 10^{52}\,[\mathrm{W}]} \tag{11.2.1045}$$

- The "Planck's pulsation":

$$\boxed{\omega_P = 2\pi f_P = \frac{1}{t_P} = \sqrt{\frac{c^5}{\hbar G}} \cong 1.855 \cdot 10^{43}\,[\mathrm{rad} \cdot \mathrm{s}^{-1}]} \tag{11.2.1046}$$

- By proceeding with the same initial reasoning that the one done with mass, but using the potential electrostatic energy instead of gravitational potential energy we can get the "Planck's electric charge":

$$\boxed{q_P = \sqrt{c\hbar 4\pi\varepsilon_0} \cong 1.875 \cdot 10^{-18}\,[\mathrm{C}]} \tag{11.2.1047}$$

- Then we can calculate a "Planck's current":

$$\boxed{I_P = \frac{Q_P}{T_P} = \sqrt{\frac{c^6 4\pi\varepsilon_0}{G}} \cong 3.479 \cdot 10^{25}\,[\mathrm{A}]} \tag{11.2.1048}$$

- And also the "Planck's voltage":

$$\boxed{U_P = \frac{E_P}{q_P} = \sqrt{\frac{c^4}{G 4\pi\varepsilon_0}} \cong 1.0432 \cdot 10^{27}\,[\mathrm{V}]} \tag{11.2.1049}$$

- ...and the "Planck's impedance" (...):

$$\boxed{Z_P=\frac{V_P}{I_P}=\frac{1}{4\pi\varepsilon_0 c}=\frac{Z_0}{4\pi}=29.98\,[\Omega]} \tag{11.2.1050}$$

- and so on[22]...

Remark

Some physicists have used (and still use) the above results for wacky and dangerous reasonings that are only hazardous interpretations! It is therefore advisable to take with care all the information concerning the Planck dimensions that you could find in textbooks and Internet (even if these latter seem very sympathetic!). The best known example is given by the Compton wavelength λ_C (see section Nuclear Physics page 5098) which depends on the mass-energy of the photon. If this wavelength is equal to the classical Schwarzschild radius for the same mass-energy (see section General Relativity page 5793), then in this case its value is that of the Planck's length and its mass is equal to the Planck's mass. It is then tempting to say that the particle then forms a Black Hole. But this is an analogy because in this case, nothing tells us that the expression of the Schwarzschild radius applies to quantum physics... !

[22] see section Principia of the chapter Mechanics page 3122 to see a most exhaustive and structured list

11.2.7 Wave Quantum Physics Interpretation

Ok now that we have some mathematical basics on Quantum Physics, before we continue with Relativistic Quantum Physics and Quantum Field theory we think that it is the good time to speak about the main existing interpretations of the results and mechanisms of the different models and results we get so far[23]. Indeed, we have seen that Quantum mechanics cannot, for most people, easily be reconciled with everyday language and observation. Its interpretation has often seemed counter-intuitive to physicists, including some of its inventors.

11.2.7.1 Copenhagen interpretation

In 11930 (holocene calendar), the probabilistic interpretation of the wave amplitude of a particle and the Heisenberg's uncertainty principle constitute the elements of the "non-deterministic" standard interpretation of quantum physics as we have already mention it at the beginning of this section. This interpretation is often referred to as the "Copenhagen interpretation", as Niels Bohr who contributed largely to it, headed a renowned institute of physics at that time in this city. However many physicists, such as Albert Einstein and Erwin Schrödinger, who accepted the mathematical formulation of quantum physics, were not at ease with the Copenhagen interpretation of and criticized it. And up to the present day (still in year 12017 according to holocene calendar), the question of the correct interpretation of mathematical formulation remains a problem.

Indeed, we can ask ourselves the following question: Where is the reality? Is there a reality? Niels Bohr answers «*No*»: there is nothing at the quantum level, reality exists or appears only during a measurement. This view shared by most physicists (Copenhagen interpretation) implies that the measure "creates" the position of the electron. In other words: No elementary phenomenon is a real phenomenon before being an observed phenomenon!

Albert Einstein thought that quantum physics, although very effective and very impressive, is not complete and gives only an imperfect picture of the quantum world. For him, there would be something else beyond that which would clarify and refine our present vision (in the same way as the theory of gases for which we had to wait for statistical models, Albert Einstein thought that hidden variables had yet to be discovered).

Thus, in the Copenhagen interpretation of quantum mechanics, the principle of uncertainty means that, at an elementary level, the physical universe no longer exists in a deterministic way, but rather as a series of probabilities or potentials. For example, the pattern produced by millions of photons passing through a diffraction slot can be calculated using quantum mechanics, but the path of each photon can not be predicted by any known method following the Copenhagen interpretation. It is this interpretation that Albert Einstein doubted when he said: «*I can not believe that God is playing dice with the Universe*». From a physical as well as a philosophical point of view, the principle of uncertainty implies the refutation of the universal determinism defended by Laplace at the beginning of the 119th century (holocene calendar).

An instantaneous reduction of all the possible states occurs from the observation of the system according to the Copenhagen interpretation (wave function collapse). This random decision of the observed state respects the probabilities, corresponding to the square of the amplitudes of the states as we have seen it. In addition, the Copenhagen interpretation states that during a measurement, a reduction process, originating from the macroscopic object, eliminates superposition of quantum states.

---

[23] For some physicists, interpret mathematics is a non-sense ans anyway human brain is limited. But as many people like to interpret stuff we still dedicate a subsection about this

The Copenhagen interpretation therefore leads to the problem of measurement, since the Schrödinger cat's thought experiment states that when we measure a quantity, such as position or momentum, we intervene in the process of measurement by causing a radical change of the quantum state of the wave function. We change the quantities measured in an unpredictable manner and this (transition) state can not be described by the Schrödinger equation. Physicists and philosophers have reacted in several ways to this interpretation:

- Either we consider as Niels Bohr and Werner Heisenberg that this principle is law and that it is better not to seek the ultimate interpretation as our brain capacity is anyway limited in comparison to the powerful investigation tool that are mathematics. This attitude is accepted by most physicists.

- Either we consider quantum physics to be an incomplete theory and some, such as Albert Einstein, Eugene Wigner or David Bohm (de Broglie-Bohm pilot-wave interpretation that we will introduce very briefly further below), have not hesitated to seek other solutions, that seems sterile until now.

- Finally, Hugh Everett and many others take Schrödinger's equation very seriously, considering it a representation of reality. They consider that the Copenhagen interpretation really represents the evolution of the wave function. The different terms of the equation would correspond to the different levels of energy in which the system is located. The reduction of the wave packet would be interpreted as a total division of the object and the measuring instrument into parallel universes (many-worlds interpretation).

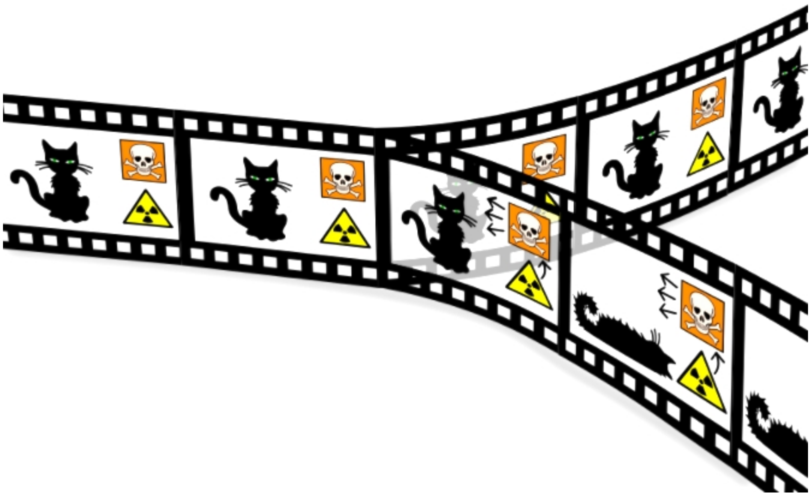

Figure 11.78: Schrödinger's cat paradox is resolved by assuming that different branches of the Universe are created with each possible outcome (source: Wikipedia, author: Christian Schirm)

Today the debate remains open, but several experiments carried out since the 11930s (holocene calendar) allow us, step by step, to dispel the thick fog that covers the bottom of reality and answer a few questions. However, all these experiments confirm that the period of certainties is long gone. The most famous experiment remaining the "EPR paradox" following the publication of an article by Einstein, Podolsky and Rosen whose sole purpose is to undermine the Copenhagen interpretation.

11.2.7.1.1 EPR paradox

The original article being a bit difficult (in a future version of this textbook we will perhaps write the underlying mathematics in details), we will take the simplified version of use in small schools but that is used in laboratories, originally proposed by David Bohm. Whereas originally the paradox was presented with the pair (position, linear momentum), Bohm proposed to use the fermion spin which is a purely binary quantum property much more easy to deal with.

As an electron can have only two states of spin "top" $|+\rangle$ or "bottom" $|-\rangle$ (in the famous z orient magnetic field experiment), so the EPR experiment proposed by David Bohm consists in taking a null spin particle which disintegrates, thus producing two electrons A and B each being in the superposition of states $|-+\rangle$ or $|+-\rangle$. Since their combined spin must remain zero, one of the electrons must have its spin at the top and the other at the bottom when their are measured. The electrons are the driven in opposite directions until the distance separating them is large enough to eliminate any physical interaction between them, and the spin of each electron is measured exactly at the same instant using a spin detector.

According to Niels Bohr, as long as no measurements have been made, neither electron A nor electron B possess a spin pre-existing in any direction. Instead, before being observed, electrons exist in a superposition of states, so that they are up and down at the same time. Since the two electrons are entangled, the information concerning the state of their spin is given by a wave function of the type:

$$\Psi=(A\text{ spin }\uparrow\text{ and }B\text{ spin }\downarrow)\text{ or }(A\text{ spin }\downarrow\text{ and }B\text{ spin }\uparrow)=|+-\rangle+|-+\rangle \tag{11.2.1051}$$

The electron A has no determined spin component before a measurement is performed. The measurement collapses the wave function of the system A and B, after which it is either "top" or "bottom". At that moment, its partner B acquires the opposite spin in the same direction, even though it is at the other side of the Universe violating therefore Special Relativity postulates (no information can go faster than the speed of light c). The Copenhagen interpretation is then named "non-local interpretation" whereas Albert Einstein believed in local realism: that is, a particle can not be instantly influenced by a distant event, and its properties exist independently of any measure.

However, Bohm's approach has a flaw that Albert Einstein would probably have used as an argument: correlations could be explained by arguing that the two electrons each have spin values defined on each of the three axes x, y, z. Whether measured or not. So again, according to Albert Einstein, the fact that the pre-existing spin states of the electron couple can not be taken into account by wave quantum physics would still have been a proof of its incompleteness (hidden variables).

A physicist, John Bell, however, had the idea of an experimental and theoretical means to break the impasse of the EPR paradox by changing the relative orientation of the two spin detectors.

Thus, if the detectors measuring the electron spin A and B are aligned so as to be parallel, then there is a 100% correlation between the two sets of measurements each time the spin is measured at "top" by the first detector, the "bottom" spin is measured by the other detector, and vice versa. If one of the detectors is turned slightly, they are no longer aligned. Now, if we measure the spin state of many pairs of entangled electrons, when we find "top" for electron A, the corresponding measure for B will sometimes give "top" too. Increasing the angle between the axes of the two detectors therefore leads to a reduction in the degree of correlation. If the detectors are at right angles to one another and the experiment is repeated a large number of times, it is only in half of the cases that a spin is detected at the "bottom" for B when we detect a "top" spin for A following the z-axis. If the detectors are oriented 180 degrees apart, the electron couple will be completely anti-correlated. If the measurement gives "top" for the spin state of A, then the spin state of B will be "bottom".

Although it is an imaginary experiment, it is possible to calculate the exact degree of spin correlation for a given orientation of the detectors, as predicted by quantum theory. However, it is not possible to perform a similar calculation by using an archetypal hidden variable theory and conserving the locality. The only thing that such a theory could predict would be an imperfect coupling between the spin states of A and B. However, rigorously, it is insufficient to choose between quantum theory and a local theory with hidden variables. John Bell made an astonishing discovery. It was possible to decide between the predictions of quantum mechanics and those of any hidden-variable theory by measuring the correlations of electron pairs for a given configuration of the detectors and then repeating the experiment with a different orientation. This allowed John Bell to calculate the total correlation for the two orientation configurations in terms of individual results predicted by any local theory with hidden variables. Since, in any such theory, the result of a measurement performed by a detector can not be affected by what is measured with the other, it is possible to distinguish between hidden variables and quantum mechanics.

John Bell succeeded in calculating the limits of the degree of spin correlation between pairs of entangled electrons in a Bohm-modified EPR experiment (if we have the time we will provide the mathematical details in the future). He found that in the ethereal kingdom of quanta there is a greater degree of correlation if quantum mechanics reigns as an absolute rule than in any universe that depends on hidden variables and locality. Bell's theorem stated that no local theory with hidden variables could reproduce the same set of correlations as quantum mechanics. Any local theory with hidden variables would lead to spin correlations generating numbers, name obviously "correlation coefficients", between -2 and $+2$. However, for some orientations of spin detectors, quantum mechanics predicts correlation coefficients that lie outside the range, named "Bell inequalities", ranging from -2 to $+2$.

The Bell theorem thus makes it possible to test face to face the local reality advocated by Albert Einstein with Niels Bohr Copenhagen interpretation, namely that the quantum universe exists independently of observation and that physical effects can not be transmitted to a speed higher than that of light. Bell had carried the Einstein-Bohr debate into a new arena: experimental philosophy. If Bell's inequality resisted, then Einstein's assertion that quantum mechanics was incomplete would be accurate. If this inequality were to be violated, Bohr would triumph. No more thought experiences! It would now be Einstein vs Bohr in the lab.

The first experiment that tested the Bell's inequalities used pairs of photons instead of pairs of electrons. This change was possible because the photons possess the polarization property, which for the needs of the test played the role of the quantum spin (moreover, the photons are easier to manipulate). This is certainly a simplification, but a photon can be considered to be polarized as "top" or "bottom". Like the spin of the electron, if the polarization of one of the photons on the z-axis is measured as "top", then the measurement of the other will give "bottom", since the combined polarizations Of the two photons must result in a zero spin (polarization state).

The results violated Bell's inequalities, which was in favour of Bohr's non-local Copenhagen interpretation and against the local reality supported by Albert Einstein.

Bell derived this inequality from two assumptions (hypothesis):

H1. First, there is a reality independent of the observer. This is reflected in the fact that a particle has a well-defined property such as spin before it is measured.

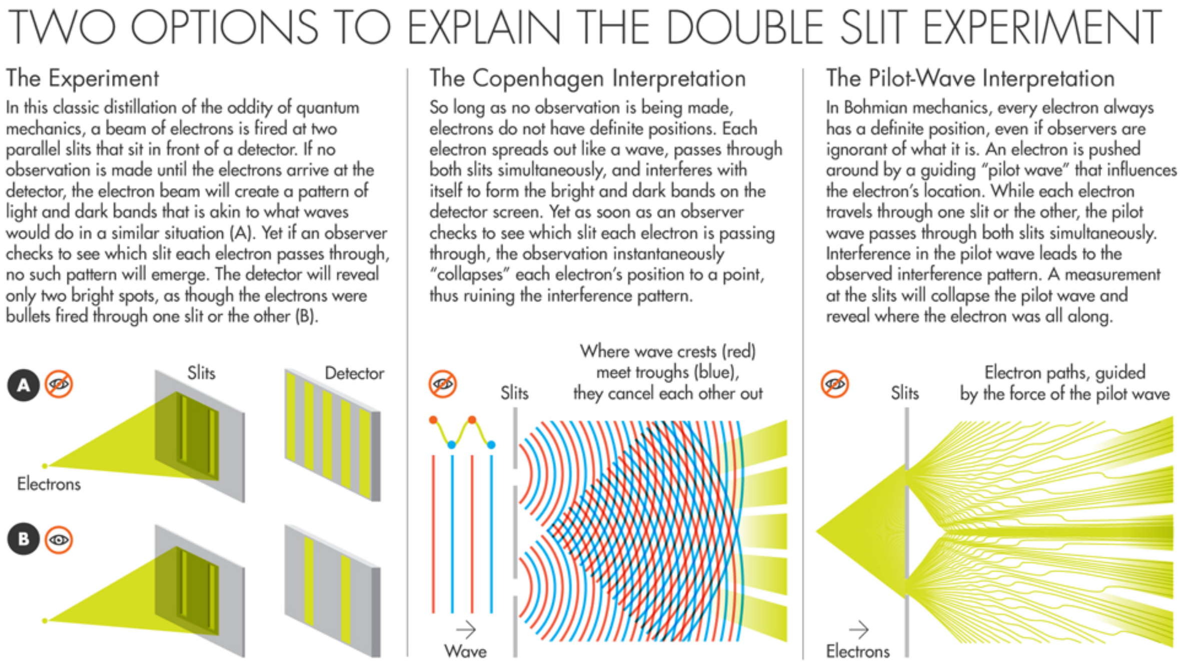
H2. Second, the locality is conserved. There is no supra-luminous influence, so that what happens here can not instantly affect what happens elsewhere.

The experimental results mean that one of these two assumptions must be abandoned, but which one? Bell was willing to abandon the locality.

11.2.7.2 De Broglie-Bohm (pilot-wave) interpretation

The "de Broglie–Bohm theory", also known as the "pilot-wave theory" or "Bohm's interpretation" is another interpretation of quantum theory. The theory is deterministic and explicitly non-local: the velocity of any one particle depends on the value of the guiding equation, which depends on the configuration of the system given by its wavefunction; the latter depends on the boundary conditions of the system, which in principle may be the entire universe...

The theory was historically developed in the 11920s (according to holocene calendar) by de Broglie, who in 11927 (according to holocene calendar) was persuaded to abandon it in favour of the then-mainstream Copenhagen interpretation. David Bohm, dissatisfied with the prevailing orthodoxy, rediscovered de Broglie's pilot-wave theory in 11952 (according to holocene calendar). Bohm's suggestions were not widely received then, partly due to reasons unrelated to their content, connected to Bohm's youthful communist affiliations. De Broglie–Bohm theory was widely deemed unacceptable by mainstream theorists, mostly because of its explicit non-locality. Bell's theorem (11964 according to holocene calendar) was inspired by Bell's discovery of the work of David Bohm and his subsequent wondering whether the obvious non-locality of the theory could be eliminated. Since the 11990s (holocene calendar), there has been renewed interest in formulating extensions to de Broglie–Bohm theory, attempting to reconcile it with Special Relativity and Quantum Field Theory, besides other features such as spin or curved spatial geometries.



TWO OPTIONS TO EXPLAIN THE DOUBLE SLIT EXPERIMENT

The Experiment

In this classic distillation of the oddity of quantum mechanics, a beam of electrons is fired at two parallel slits that sit in front of a detector. If no observation is made until the electrons arrive at the detector, the electron beam will create a pattern of light and dark bands that is akin to what waves would do in a similar situation (A). Yet if an observer checks to see which slit each electron passes through, no such pattern will emerge. The detector will reveal only two bright spots, as though the electrons were bullets fired through one slit or the other (B).

The Copenhagen Interpretation

So long as no observation is being made, electrons do not have definite positions. Each electron spreads out like a wave, passes through both slits simultaneously, and interferes with itself to form the bright and dark bands on the detector screen. Yet as soon as an observer checks to see which slit each electron is passing through, the observation instantaneously "collapses" each electron's position to a point, thus ruining the interference pattern.

The Pilot-Wave Interpretation

In Bohmian mechanics, every electron always has a definite position, even if observers are ignorant of what it is. An electron is pushed around by a guiding "pilot wave" that influences the electron's location. While each electron travels through one slit or the other, the pilot wave passes through both slits simultaneously. Interference in the pilot wave leads to the observed interference pattern. A measurement at the slits will collapse the pilot wave and reveal where the electron was all along.

We strongly recommend the reader to go see on Internet videos about the "walking droplets[24]" also named "walker" to understand better the idea behind the concept of pilot wave.

In the below gallery (read from left to right and up to bottom) thanks to a little layer of air, droplets of silicone oil can continuously bounce on the surface of the pool beneath them without being absorbed. But even though the droplets don't directly connect with the pool beneath them, they still make waves, and then interact with those waves, resulting in a forward momentum.

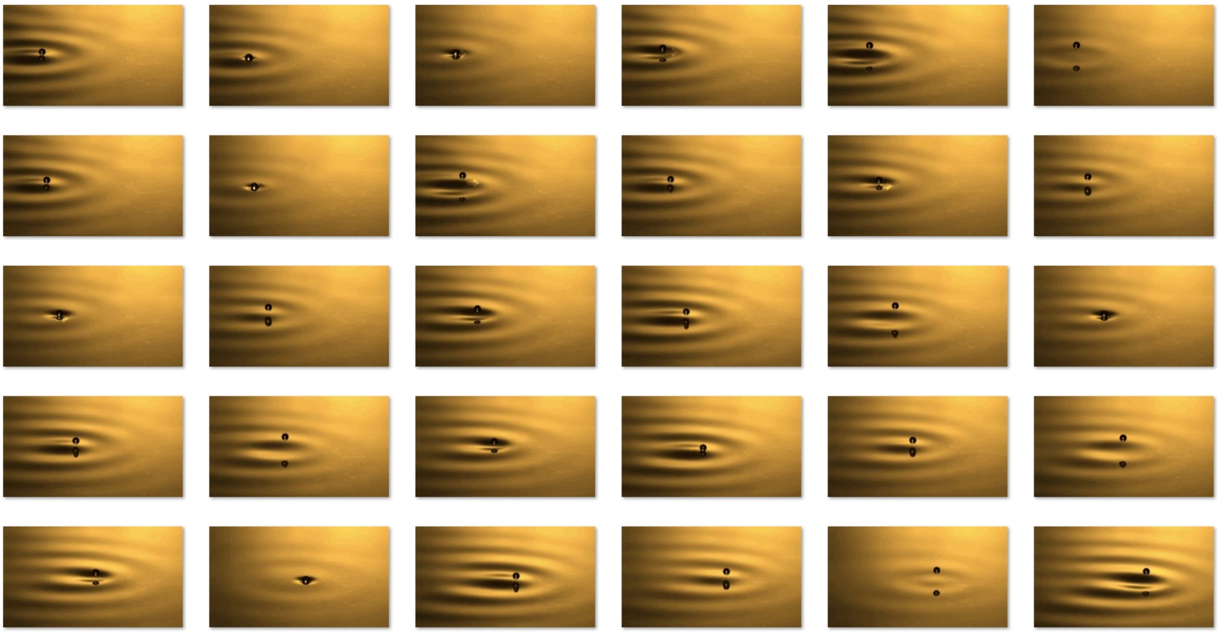

Figure 11.79: **Thirty successive pictures of a walker**

---

[24] hydrodynamic quantum analogue involving bouncing fluid droplets over a vibrating fluid bath

All observed phenomena are related to the particle-wave interaction. The droplet moves in a medium modified by previously generated waves.As the droplet moves, the points of the interface it visits keep emitting waves.The wavefield has thus a complex structure that contains a "memory"of the path.

While this experiment isn't on the quantum scale, it does help to demonstrate the way quantum-scale particles may operate according to the pilot wave theory. And for any lay people who have struggled with grasping why things are so strange on the quantum scale according to the standard interpretation, this pilot wave theory provides a far more palatable framework for understanding quantum mechanics.

And what about walkers facing a double split? Here you are (still read from left to right and up to bottom):

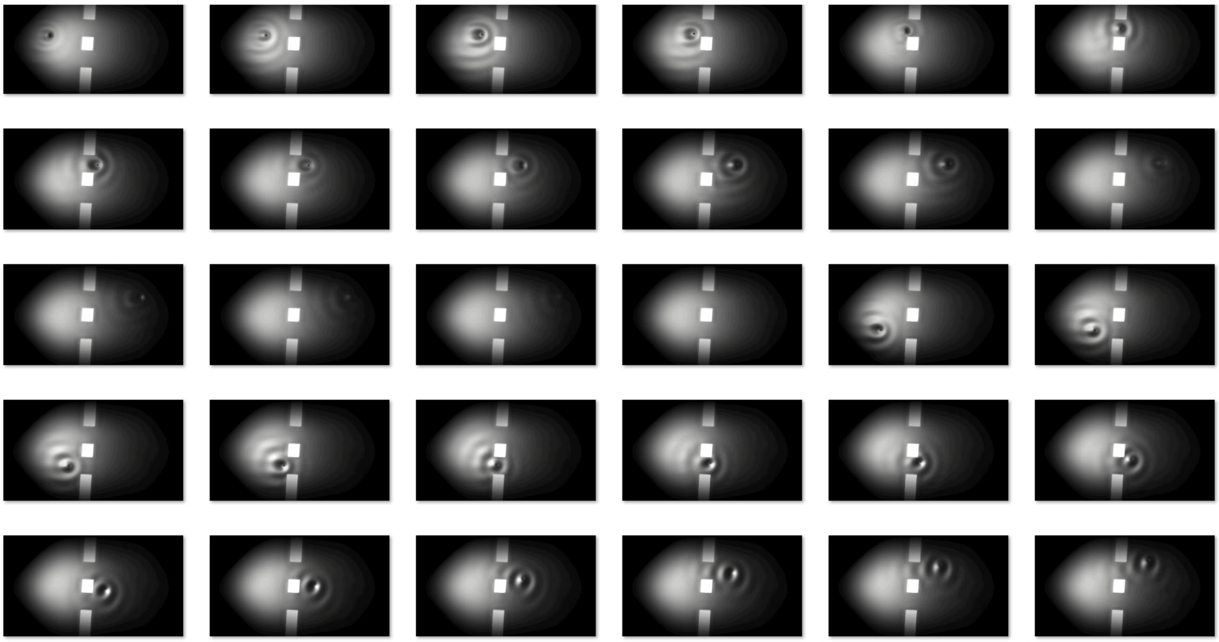

Figure 11.80: **Double split experiment with two walkers**

The diffraction pattern obtained with the walker experiment is highly similar tot that of the diffraction pattern of photon or electron with the same experimental configuration.

In a survey made on 81 professional physicists (see [96]) in 12024 (holocene calendar) we get the following result for the fate of the matter that falls into a Black Hole:

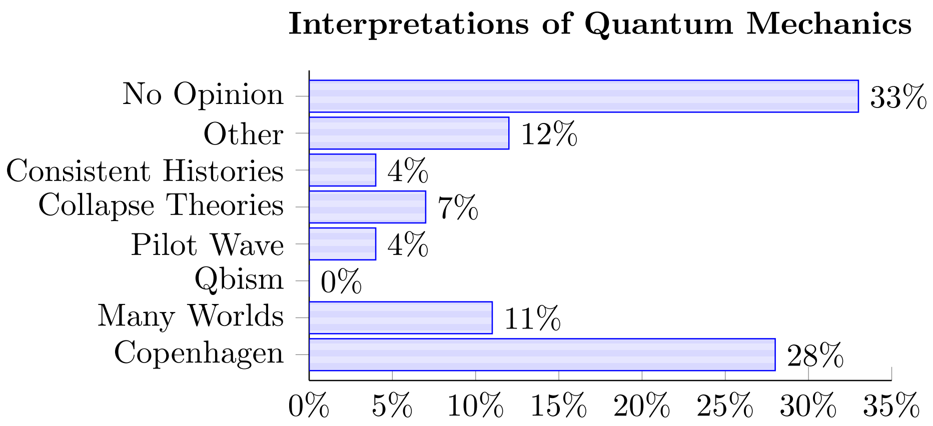

Figure 11.81: **Copenhagen survey on interpretations of Quantum Physics**

If we have the time in the future we will perhaps write a formal introduction (i.e. mathematical introduction) to this theory.

11.3. Relativistic Quantum Physics

THE attentive reader will have noticed that quantum mechanics (wave quantum physics) is a non-relativistic theory: it does not incorporate the principles of Einstein's Special Relativity (see section Relativity page 5628). We will strive to fill this gap by studying now the relativistic version of the wave quantum physics.

Relativistic quantum mechanics (RQM) is any Poincaré covariant formulation of quantum mechanics. This theory is applicable to massive particles propagating at all velocities up to those comparable to the speed of light c, and can accommodate massless particles. The theory has application in high energy physics,particle physics and accelerator physics, as well as atomic physics, chemistry and condensed matter physics. Non-relativistic quantum mechanics refers to the mathematical formulation of quantum mechanics applied in the context of Galilean relativity, more specifically quantizing the equations of classical mechanics by replacing dynamical variables by operators. Relativistic quantum mechanics is quantum mechanics applied with Special Relativity, but not General Relativity. An attempt to incorporate General Relativity into quantum theory is the subject of quantum gravity, yet an unsolved problem in physics, although some theories, such as the Kaluza-Klein, have been proposed but are unfounded and without proof. Although the earlier formulations, like the Schrödinger picture and Heisenberg picture were originally formulated in a non-relativistic background, these pictures of quantum mechanics also apply with Special Relativity.

The relativistic formulation is more successful than the original quantum mechanics in some contexts, in particular: the prediction of antimatter, electron spin, spin magnetic moments of elementary spin-$1/2$ particles, fine structure, and quantum dynamics of charged particles in electromagnetic fields. The key result is the Dirac equation, from which these predictions emerge automatically. By contrast, in quantum mechanics, terms have to be introduced artificially into the Hamiltonian operator to achieve agreement with experimental observations.

Nevertheless, RQM is only an approximation to a fully self-consistent relativistic theory of known particle interactions because it does not describe cases where the number of particles changes; for example in matter creation and annihilation. By yet another theoretical advance, a more accurate theory that allows for these occurrences and other predictions is Relativistic Quantum Field Theory in which particles are interpreted as field quanta (see article for details).

Before we tackle the mathematical part, we emphasize and reiterate that we will limit ourselves only to theoretical developments made between 11910 and about 11935 according to holocene calendar (beyond the complexity of theories requires too many pages to a general textbook like this one).

11.3.1 Relativistic Schrödinger evolution equation

Particle physics can not be properly and completely described in the context of quantum mechanics as described by the Schrödinger equation as the later is constructed on the incomplete version of the Einstein's relation ($E=mc^2$ instead of $E^2=c^2p^2+m_0^2c^4$). As the energies are generally superior to the masses of the particles, it is necessary, in addition, to work in the context of the full theory of Special Relativity. Let's see how to include it in a first basic approach.

The energy-momentum of a free particle of mass m, satisfied as we have proved in the section of Special Relativity the relation:

$$E^2=c^2p^2+m_0^2c^4 \tag{11.3.1}$$

We seek to quantify this equation. For this, we will return to the relations we have proved in the study of functional linear operators and of the evolutionary Schrödinger equation.

Recall that the momentum is described by the relation (using the divergence operator):

$$p=-\mathrm{i}\hbar\vec{\nabla} \tag{11.3.2}$$

and the total energy by:

$$E=\mathrm{i}\hbar\frac{\partial}{\partial t} \tag{11.3.3}$$

Both relations have been proved in details in the section of Wave Quantum Physics!

The substitutions of the two previous relations applied to the equality:

$$E^2=c^2p^2+m_0^2c^4 \tag{11.3.4}$$

leads to:

$$(\mathrm{i}\hbar\partial_t)^2=c^2(-\mathrm{i}\hbar\vec{\nabla})^2+m_0^2c^4 \tag{11.3.5}$$

Applying the squares:

$$-\hbar^2\partial_t^2=-c^2\hbar^2\vec{\nabla}^2+m_0^2c^4 \tag{11.3.6}$$

and rearranging and using the notation $\vec{\nabla}^2=\Delta$:

$$-\hbar^2\partial_t^2+c^2\hbar^2\Delta=m_0^2c^4 \tag{11.3.7}$$

And multiplied by the wave function Ψ on both sides of equality lead to development:

$$(-\hbar^2\partial_t^2+\hbar^2\Delta c^2)\Psi=m_0^2c^4\Psi \tag{11.3.8}$$

Hence:

$$(-\hbar^2\partial_t^2+\hbar^2\Delta c^2)\Psi\Leftrightarrow-\hbar^2\left(\frac{1}{c^2}\partial_t^2-\triangle\right)\Psi=m_0^2c^2\Psi \tag{11.3.9}$$

And rearranged:

$$\left(\hbar^2\left(\frac{1}{c^2}\partial_t^2-\triangle\right)+m_0^2c^2\right)\Psi=0 \tag{11.3.10}$$

Using the d'Alembertian (see section Electrodynamics page 4118), we can write this latter relation in a more condensed form named "relativistic Schrödinger evolution equation" or more frequently "free Klein-Gordon equation" or also named "free Klein-Gordon-Fock equation" (in the absence of a magnetic field!):

$$\boxed{(\hbar^2\Box+m_0^2c^2)\Psi=0} \tag{11.3.11}$$

with the signature $(+,-,-,-)$ for the partial derivative:

$$\Box=\frac{\partial^2}{c^2\partial t^2}-\frac{\partial^2}{\partial x^2}-\frac{\partial^2}{\partial y^2}-\frac{\partial^2}{\partial z^2} \tag{11.3.12}$$

Some authors prefer the signature $(-,+,+,+)$ therefore we have (this is also the choices we will make in the section of Quantum Field Theory as it is the tradition...):

$$(\hbar^2\Box-m_0^2c^2)\Psi=0 \tag{11.3.13}$$

with:

$$\Box=-\frac{\partial^2}{c^2\partial t^2}+\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2} \tag{11.3.14}$$

Remark

In particle physics, the equation $(\hbar^2\Box+m_0^2c^2)\Psi=0$ is sometimes named the "bosons relativistic covariant equation" whatever the chosen signature.

The free Klein-Gordon equation is often given as follows (more aesthetic):

$$\left(\Box+\left(\frac{m_0c}{\hbar}\right)^2\right)\Psi=0 \tag{11.3.15}$$

It is important to note that the Klein-Gordon equation involves scalar and therefore characterizes zero spin particles.

Remarks

R1. We can verify that the plane waves of the form:

$$\Psi=\Psi_0e^{\frac{\mathrm{i}}{\hbar}(\vec{p}\circ\vec{r}-E_{\text{tot}}t)} \tag{11.3.16}$$

are solutions of the free Klein-Gordon equation (we'll go more into details in the section Elementary Particles Physics).

R2. We will come back during our study of the Dirac equation and fermions spins on the free Klein-Gordon equation (to generalize it).

11.3.1.1 Antimatter

When we have proved the free Klein-Gordon equation, we purposely left aside a very interesting case of development that we have made.

Maybe you did not notice it, but the equation:

$$E^2=c^2p^2+m_0^2c^4 \tag{11.3.17}$$

can take two values for a given pulsation:

$$E=\pm\sqrt{c^2p^2+m_0^2c^4} \tag{11.3.18}$$

one positive and the other negative. The value of energy could therefore take all values in $[-\infty,+\infty]$...!!!

So far we have implicitly assumed in Classical Mechanics that negative solutions were not natural and should therefore simply be discarded. This cannot be done in quantified theory without lead to serious inconsistencies. Rather than ignore these negative energy solutions, we should find them a physical interpretation.

We notice first that all the negative energies are authorized by the above equation (as well as for positive energy). We say then that negative energy states are occupied but not observable; the electrons are named "virtual electrons".

Theorem 11.5. Let us imagine a wave packet formed by a superposition of plane waves at a narrow interval in pulse. This packet moves in space. In the one-dimensional case, it propagates at the speed:

$$v=\frac{\mathrm{d}E}{\mathrm{d}p}=\frac{c^2p}{E} \tag{11.3.19}$$

Proof 11.5.1. Always based on the assumption that the potential field is zero, we have:

$$E=\frac{1}{2}mv^2\Rightarrow\frac{\mathrm{d}E}{\mathrm{d}v}=mv\Rightarrow\frac{\mathrm{d}E}{m\mathrm{d}v}=v\Rightarrow\frac{\mathrm{d}E}{\mathrm{d}p}=v \tag{11.3.20}$$

and:

$$\begin{gathered}E^2=c^2p^2+m_0^2c^4\Leftrightarrow\mathrm{d}(E^2)=E\mathrm{d}E+\mathrm{d}EE=2E\mathrm{d}E\\ \Rightarrow\frac{\mathrm{d}E^2}{\mathrm{d}p}=\frac{2E\mathrm{d}E}{\mathrm{d}p}=\frac{\mathrm{d}(c^2p^2+m_0^2c^4)}{\mathrm{d}p}=2c^2p\\ \Rightarrow\frac{2E\mathrm{d}E}{\mathrm{d}p}=2c^2p\Leftrightarrow\frac{E\mathrm{d}E}{\mathrm{d}p}=c^2p\Rightarrow\frac{\mathrm{d}E}{\mathrm{d}p}=\frac{c^2p}{E}\end{gathered} \tag{11.3.21}$$

So to summarize:

$$v=\frac{\mathrm{d}E}{\mathrm{d}p}=\frac{c^2p}{E} \tag{11.3.22}$$

■ Q.E.D.

Let us consider first a particle of positive energy E^+. Its position in function of time is given by:

$$E^+ > 0: \quad x(t) = x_0 + \frac{c^2 p}{E^+} t \tag{11.3.23}$$

A particle of negative energy E^- moves following:

$$E^- < 0: \quad x(t) = x_0 + \frac{c^2 p}{E^-} t = x_0 + \frac{c^2 p}{|E^-|}(-t) \tag{11.3.24}$$

In other words, and this will be our first conclusion, we can say that a particle of negative energy $E^- < 0$ is equivalent to a particle of positive energy $|E^-| > 0$ moving backwards in time and this is what we name an "antiparticle".

Now we have to see what is the interpretation of a particle moving backwards in time:

To simplify, we consider a non-relativistic particle of electric charge $(-q)$ immersed in a static electric field $\vec{E}$ and a static magnetic field $\vec{B}$. It satisfies to the equation of motion:

$$m\frac{\mathrm{d}^2\vec{x}}{\mathrm{d}t^2} = (-q)\vec{E} + (-q)\frac{\mathrm{d}\vec{x}}{\mathrm{d}t} \times \vec{B} \tag{11.3.25}$$

We have studied in the section of Electrodynamics that the fields $\vec{E}$ and $\vec{B}$ could be constructed from a quadripotential $\vec{A}$. So we can rewrite the above equation from the two relation proven in the section of Electrodynamics:

$$\vec{B} = \vec{\nabla} \times \vec{A} \quad \text{and} \quad \vec{E} = -\vec{\nabla}\phi - \frac{\partial \vec{A}}{\partial t} \tag{11.3.26}$$

However, it is always possible to impose the following gauge (we leave it to do reader to do the check by using exactly the same methodology as that used in the section of Electrodynamics):

$$\vec{\nabla}\phi = \vec{0} \tag{11.3.27}$$

The equation of motion becomes:

$$m\frac{\mathrm{d}^2\vec{x}}{\mathrm{d}t^2} = -(-q)\frac{\partial \vec{A}}{\partial t} + (-q)\frac{\mathrm{d}\vec{x}}{\mathrm{d}t} \times (\vec{\nabla} \times \vec{A}) \tag{11.3.28}$$

or also:

$$m\frac{\mathrm{d}^2\vec{x}}{\mathrm{d}(-t)^2} = -(-q)\frac{\partial \vec{A}}{\partial(-t)} + (-q)\frac{\mathrm{d}\vec{x}}{\mathrm{d}(-t)} \times (\vec{\nabla} \times \vec{A}) \tag{11.3.29}$$

Comparing the last two equations, we come to our second conclusion: a particle of charge q moving backwards in time obeys to the same equations of motion that an oppositely charged particle $-q$ moving forward in the time. The physical interpretation of the second particle is obvious ("Feynman-Stückelberg interpretation").

Relativistic quantum physics implies the existence of anti particles, which are actually observed in laboratories (accelerators and not only...!).

All this to get where exactly?

1. First, the theoretical discovery of antimatter provides a possible explanation for the existence of the Universe which previously violated the principle of conservation of energy. The theory we have just seen, therefore predicted that our Universe should contain as much matter as antimatter. Scientists are still looking for the presence of this antimatter.
2. Secondly, if we consider in vacuum a photon of energy $h\nu > 2m_ec^2$, it is capable of carrying a virtual electron to a state of positive energy, where it becomes real. It appears then locally a gap, or "hole" in the region of negative energies. According to the principle of charge conservation, one sees a positive electron, or positron, symmetrical and antimatter equivalent particle of the electron.

Thus, the photon materializes in the form of a pair e^+, e^-, with:

$$h\nu = 2m_ec^2 + E_c \tag{11.3.30}$$

Remark

Some experimental results suggest that antiparticles are not the perfect mirrors of the particles we know. Indeed, the right/left and time symmetries does not appear to be respected (there is symmetry breaking). We do not have anything written about in this textbook at this date but we will do so as soon as we can.

11.3.2 Generalized Klein-Gordon Equation

The free Klein-Gordon equation that we initially presented and proved earlier does not take into account the influence of magnetic field on the observation of the splitting of spectral lines of atoms (experimental observation!). That's why Klein and Gordon have integrated it into their equation the magnetic field. However, they did not take into account the spin of the electron. Only after their work Pauli developed his equation (named "Pauli equation") which then led to the Dirac equation (see further below).

To determine the expression of the Klein-Gordon generalized equation of a charged particle in a magnetic field and an electrostatic potential, we will use the power of the Lagrangian formalism!

The classical equation of motion accepted (see section Analytical Mechanics page 3169), as valid also in Special Relativity, is given as we proved it by (Euler-Lagrange equation):

$$\mathrm{d}_t(\partial_{\dot{q}_i}L) - \partial_{q_i}L \tag{11.3.31}$$

In the section of Special Relativity, we have proved that the Lagrangian of a free particle is expressed as:

$$L_0 = \frac{m_0c^2}{\gamma} \tag{11.3.32}$$

with for recall:

$$\gamma = (1-\beta^2)^{-1/2} \qquad \beta = \frac{v}{c} \tag{11.3.33}$$

and in the section of Electrodynamics that the total Lagrangian was given by:

$$L=\frac{m_0c^2}{\gamma}-qU+q\vec{v}\circ\vec{A} \tag{11.3.34}$$

For future needs, start by calculating:

$$\partial_{\dot{x}}L=\partial_{\dot{x}}\left(\frac{m_0c^2}{\gamma}-qU+q\vec{v}\circ\vec{A}\right)_x \tag{11.3.35}$$

Let us calculate the first term:

$$\partial_{\dot{x}}\frac{1}{\gamma_x}=\partial_{\dot{x}}\left(1-\frac{v_x^2}{c^2}\right)^{1/2}=\frac{1}{2}\left(1-\frac{v_x^2}{c^2}\right)^{-1/2}x-2\frac{v_x}{c^2}=-\gamma\frac{v_x}{c^2} \tag{11.3.36}$$

As the potential does not dependent on the speed, the term:

$$\partial_{\dot{x}}(-qU) \tag{11.3.37}$$

is equal zero.

The vector potential does not depend on the velocity of the particle also, then:

$$\partial_{\dot{x}}qv_xA_x=qA_x \tag{11.3.38}$$

Therefore it comes:

$$\partial_{\dot{x}}L=-m_0c^2\left(-\gamma\frac{v_x}{c^2}\right)+qA_x=\gamma m_0v_x+qA_x=p_x+qAx \tag{11.3.39}$$

The classical Hamiltonian is written (see section Analytical Mechanics page 3181):

$$H=\sum_i p_ix_i-L=\vec{v}\circ\partial_{\vec{v}}L-L \tag{11.3.40}$$

So we have previously proved that:

$$\partial_{\dot{x}}L=p_x+qA_x \tag{11.3.41}$$

We can write the Hamiltonian with this relation in the form:

$$\begin{aligned}H&=\vec{v}\circ(\vec{p}+q\vec{A})+\frac{m_0c^2}{\gamma}+qU-q\vec{v}\circ\vec{A}=\vec{v}\circ\vec{p}+q\vec{v}\circ\vec{A}+\frac{m_0c^2}{\gamma}+qU-q\vec{v}\circ\vec{A}\\&=\vec{v}\circ\vec{p}+\frac{m_0c^2}{\gamma}+qU\end{aligned} \tag{11.3.42}$$

The dot product $\vec{v}\circ\vec{p}$ has for expressed (since $\vec{p},\vec{v}$ are collinear)

$$\vec{v}\circ\vec{p}=v\gamma m_0v=\gamma m_0v^2 \tag{11.3.43}$$

The Hamiltonian is therefore written:

$$H=\gamma m_0v^2+\frac{m_0c^2}{\gamma}+qU \tag{11.3.44}$$

By working on the two first terms:

$$\gamma m_0 v^2 + \frac{m_0 c^2}{\gamma} = \gamma m_0 c^2 \left(\frac{v^2}{c^2} + \frac{1}{\gamma^2}\right) \tag{11.3.45}$$

But:

$$\gamma = \left(1 - \frac{v^2}{c^2}\right)^{-1/2} \Rightarrow \frac{1}{\gamma^2} = 1 - \frac{v^2}{c^2} \tag{11.3.46}$$

Therefore:

$$\gamma m_0 v^2 + \frac{m_0 c^2}{\gamma} = \gamma m_0 c^2 \left(\frac{v^2}{c^2} + 1 - \frac{v^2}{c^2}\right) = \gamma m_0 c^2 \tag{11.3.47}$$

Finally, we get (for a conservative system):

$$H = \gamma m_0 c^2 + qU = E_{\text{tot}} \tag{11.3.48}$$

Always in the case of a particle moving in an electromagnetic field, the relation between the energy and impulsion (which is different from that of momentum by the presence of a term containing the vector potential) is calculated as follows:

As (we have just prove it):

$$E_{\text{tot}} = \gamma m_0 c^2 = H - qU \tag{11.3.49}$$

and as we have prove it in the section of Wave Quantum Physics:

$$p^2 = (m_0 v)^2 2 = m_0^2 (v)^2 = m_0^2 \left(\frac{\vec{p} - q\vec{A}}{m_0}\right)^2 = (\vec{p} - q\vec{A})^2 \tag{11.3.50}$$

where it is necessary to see the last term as an abusive notation for the square of the norm.

Then by substituting into:

$$E^2 = p^2 c^2 + m_0^2 c^4 \tag{11.3.51}$$

we get (we change of notation for the Hamiltonian):

$$(E_{\text{tot}} - qU)^2 - (\vec{p} - q\vec{A})^2 c^2 = m_0^2 c^4 \tag{11.3.52}$$

If we rewrite this relation by making use of the corresponding operators (see section Wave Quantum Physics page 4695) of energy and momentum (canonical quantization):

$$E = \mathrm{i}\hbar\partial_t \quad \text{and} \quad \vec{p} = -\mathrm{i}\hbar\vec{\nabla} \tag{11.3.53}$$

then finally we can write in analogy with the free Klein-Gordon equation (in the absence of field) the "generalized Klein-Gordon equation":

$$\boxed{\left[(\mathrm{i}\hbar\partial_t - qU)^2 - (-\mathrm{i}\hbar\vec{\nabla} - q\vec{A})^2 c^2\right] \Psi = m_0^2 c^4 \Psi} \tag{11.3.54}$$

This equation is that of Klein-Gordon that applies to a particle of charge q without spin moving in an electromagnetic field.

If $U=0$, $\vec{A}=\vec{0}$ the previous relation simplifies in multiple stages:

$$\left[(\mathrm{i}\hbar\partial_t)^2-(-\mathrm{i}\hbar\vec{\nabla})^2c^2\right]\Psi=m_0^2c^4\Psi \tag{11.3.55}$$

$$(-\hbar^2\partial_t^2+\hbar^2\Delta c^2)\Psi=m_0c^4\Psi \tag{11.3.56}$$

$$-\hbar^2\left(\frac{1}{c^2}\partial_t^2+\Delta\right)\Psi=m_0^2c^2\Psi \tag{11.3.57}$$

$$\hbar^2\left(\frac{1}{c^2}\partial_t^2+\Delta\right)\Psi+m_0^2c^2\Psi=0 \tag{11.3.58}$$

$$(\hbar^2\Box+m_0c^2)\Psi=0 \tag{11.3.59}$$

We thus fall back on the Klein-Gordon equation for a free particle without spin!

11.3.2.1 Generalized Klein-Gordon Equation continuity equation

It would be interesting now to look at the expression of the continuity equation (let us recall that it expresses the conservation of energy!!) with the inclusion of the magnetic field (because in fact the continuity equation still makes problem... and even a very big problem!!!). For this, consider the case of a free particle moving with a momentum $\vec{p}$ and having an energy E. We saw that we could associate to it a plane wave of the form:

$$\psi=Ae^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})} \tag{11.3.60}$$

Given the free Klein-Gordon equation and its complex conjugate (we work with natural units):

$$-\partial_t^2\Psi+\Delta\Psi-m_0^2\Psi=0 \tag{11.3.61a}$$

$$-\partial_t^2\bar{\Psi}+\Delta\bar{\Psi}-m_0^2\bar{\Psi}=0 \tag{11.3.61b}$$

We multiply (a) by $-\mathrm{i}\bar{\Psi}$ and (b) by $-\mathrm{i}\Psi$:

$$-\mathrm{i}\bar{\Psi}\left(-\partial_t^2\Psi\right)-\mathrm{i}\bar{\Psi}\Delta\Psi+\mathrm{i}\bar{\Psi}m_0^2\Psi=0 \tag{11.3.62a}$$

$$-\mathrm{i}\Psi\left(-\partial_t^2\bar{\Psi}\right)-\mathrm{i}\Psi\Delta\bar{\Psi}+\mathrm{i}\Psi m_0^2\bar{\Psi}=0 \tag{11.3.62b}$$

Therefore:

$$\mathrm{i}\bar{\Psi}\partial_t^2\Psi-\mathrm{i}\bar{\Psi}\Delta\Psi+\mathrm{i}\bar{\Psi}m_0^2\Psi=0 \tag{11.3.63a}$$

$$\mathrm{i}\Psi\partial_t^2\bar{\Psi}-\mathrm{i}\Psi\Delta\bar{\Psi}+\mathrm{i}\Psi m_0^2\bar{\Psi}=0 \tag{11.3.63b}$$

By difference (a)-(b):

$$\mathrm{i}\boxed{\left(\bar{\Psi}\partial_t^2\Psi-\Psi\partial_t^2\bar{\Psi}\right)}-\mathrm{i}\left(\bar{\Psi}\Delta\Psi-\Psi\Delta\bar{\Psi}\right)=0 \tag{11.3.64}$$

Computing the derivatives with respect to t of the following functions:

$$\partial_t(\bar{\Psi}\partial_t\Psi)=\partial_t\bar{\Psi}\partial_t\Psi+\bar{\Psi}\partial_t^2\Psi \tag{11.3.65a}$$

$$\partial_t(\Psi\partial_t\bar{\Psi})=\partial_t\Psi\partial_t\bar{\Psi}+\Psi\partial_t^2\bar{\Psi} \tag{11.3.65b}$$

By difference (a)-(b):

$$\partial_t(\bar{\Psi}\partial_t\Psi-\Psi\partial_t\bar{\Psi})=\boxed{\bar{\Psi}\partial_t^2\Psi-\Psi\partial_t^2\bar{\Psi}} \tag{11.3.66}$$

Which gives us finally:

$$\partial_t\left[\mathrm{i}(\bar{\Psi}\partial_t\Psi-\Psi\partial_t\bar{\Psi})\right]-\mathrm{i}\boxed{\bar{\Psi}\Delta\Psi-\Psi\Delta\bar{\Psi}}=0 \tag{11.3.67}$$

Let f be a scalar field and $\vec{g}$ and a vector field. The vector analysis gives:

$$\vec{\nabla}\circ(f\cdot\vec{g})=(\vec{\nabla}f)\circ\vec{g}+f(\vec{\nabla}\circ\vec{g})\Rightarrow f(\vec{\nabla}\circ\vec{g})=\vec{\nabla}\circ(f\cdot\vec{g})-(\vec{\nabla}f)\circ\vec{g} \tag{11.3.68}$$

Let us put:

$$f=\Psi \qquad \vec{g}=\vec{\nabla}\cdot\bar{\Psi} \tag{11.3.69}$$

Therefore:

$$\vec{\nabla}\circ(f\cdot\vec{g})=\vec{\nabla}\circ(f\cdot\vec{g})-(\vec{\nabla}f)\circ\vec{g}\Rightarrow\Psi(\vec{\nabla}\circ\vec{\nabla}\bar{\Psi})=\vec{\nabla}\circ(\Psi\vec{\nabla}\bar{\Psi})-(\vec{\nabla}\Psi)\circ\vec{\nabla}\bar{\Psi} \tag{11.3.70}$$

Let us put now:

$$f=\bar{\Psi},\,g=\vec{\nabla}\Psi \tag{11.3.71}$$

Therefore:

$$f(\vec{\nabla}\circ\vec{g})=\vec{\nabla}\circ(f\cdot\vec{g})-(\vec{\nabla})\circ\vec{g}\Rightarrow\bar{\Psi}(\vec{\nabla}\circ\vec{\nabla}\Psi)=\vec{\nabla}\circ(\bar{\Psi}\vec{\nabla}\Psi)-(\vec{\nabla}\bar{\Psi})\circ\vec{\nabla}\Psi \tag{11.3.72}$$

So we have finally two relations:

$$\vec{\nabla}\circ(f\cdot\vec{g})=\vec{\nabla}\circ(f\cdot\vec{g})-(\vec{\nabla}f)\circ\vec{g}\Rightarrow\Psi(\vec{\nabla}\circ\vec{\nabla}\bar{\Psi})=\vec{\nabla}\circ(\Psi\vec{\nabla}\bar{\Psi})-(\vec{\nabla}\Psi)\circ\vec{\nabla}\bar{\Psi} \tag{11.3.73a}$$

$$f(\vec{\nabla}\circ\vec{g})=\vec{\nabla}\circ(f\cdot\vec{g})-(\vec{\nabla})\circ\vec{g}\Rightarrow\bar{\Psi}(\vec{\nabla}\circ\vec{\nabla}\Psi)=\vec{\nabla}\circ(\bar{\Psi}\vec{\nabla}\Psi)-(\vec{\nabla}\bar{\Psi})\circ\vec{\nabla}\Psi \tag{11.3.73b}$$

We subtract (a)-(b) to get:

$$\Psi(\vec{\nabla}\circ\vec{\nabla}\bar{\Psi})-\bar{\Psi}(\vec{\nabla}\circ\vec{\nabla}\Psi)=\vec{\nabla}\circ(\Psi\vec{\nabla}\bar{\Psi})-\vec{\nabla}\circ(\bar{\Psi}\vec{\nabla}\Psi) \tag{11.3.74}$$

As $\vec{\nabla}\circ\vec{\nabla}=\vec{\nabla}^2=\Delta$:

$$\Psi\Delta\bar{\Psi}-\bar{\Psi}\Delta\Psi=\vec{\nabla}\circ(\Psi\vec{\nabla}\bar{\Psi}-\bar{\Psi}\vec{\nabla}\Psi) \tag{11.3.75}$$

By changing the signs:

$$\bar{\Psi}\Delta\Psi-\Psi\Delta\bar{\Psi}=\vec{\nabla}\circ(\bar{\Psi}\vec{\nabla}\Psi-\Psi\vec{\nabla}\bar{\Psi}) \tag{11.3.76}$$

This latter relation and:

$$\partial_t\left[\mathrm{i}(\bar{\Psi}\partial_t\Psi-\Psi\partial_t\bar{\Psi})\right]-\mathrm{i}(\bar{\Psi}\Delta\Psi-\Psi\Delta\bar{\Psi})=0 \tag{11.3.77}$$

gives together:

$$\boxed{\partial_t\left[\mathrm{i}(\bar{\Psi}\partial_t\Psi-\Psi\partial_t\bar{\Psi})\right]-\vec{\nabla}\circ\left[\mathrm{i}(\bar{\Psi}\vec{\nabla}\Psi-\Psi\vec{\nabla}\bar{\Psi})\right]=0} \tag{11.3.78}$$

Again, let us compare this relation with the continuity equation:

$$\partial_t\rho+\vec{\nabla}\circ\vec{j}=0 \tag{11.3.79}$$

Let us recall that during our first study of the Klein-Gordon equation we have seen that in quantum physics equivalent is given by the same equation but with the following meanings: ρ is the probability density, $\vec{j}$ is the flux density of particles. We then have:

$$\boxed{\begin{aligned}&\rho=\mathrm{i}(\bar{\Psi}\partial_t\Psi-\Psi\partial_t\bar{\Psi})\\&\vec{j}=-\mathrm{i}(\bar{\Psi}\vec{\nabla}\Psi-\Psi\vec{\nabla}\bar{\Psi})\end{aligned}} \tag{11.3.80}$$

If the associated wave function Ψ and its conjugate complex $\bar{\Psi}$ are given in a special case by:

$$\Psi=A^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}\qquad\bar{\Psi}=A^{\mathrm{i}(Et-\vec{p}\circ\vec{r})} \tag{11.3.81}$$

The derivatives with respect to time of these functions are obviously:

$$\partial_t\Psi=-\mathrm{i}EA^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}=-\mathrm{i}E\Psi\qquad\partial_t\bar{\Psi}=\mathrm{i}EA^{\mathrm{i}(Et-\vec{p}\circ\vec{r})}=-\mathrm{i}E\bar{\Psi} \tag{11.3.82}$$

And their gradients are calculated as follows:

$$\begin{aligned}\vec{\nabla}\Psi&=\partial_{\vec{r}}A^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}=\mathrm{i}\vec{p}A^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}=\mathrm{i}\vec{p}\Psi\\\vec{\nabla}\bar{\Psi}&=\partial_{\vec{r}}A^{\mathrm{i}(Et-\vec{p}\circ\vec{r})}=-\mathrm{i}\vec{p}A^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}=-\mathrm{i}\vec{p}\bar{\Psi}\end{aligned} \tag{11.3.83}$$

By taking again the expression of the probability density and given previous differential, we get:

$$\begin{aligned}\rho&=\mathrm{i}\left(\bar{\Psi}\partial_t\Psi-\Psi\partial_t\bar{\Psi}\right)\\&=\mathrm{i}\left[A\cancel{e^{\mathrm{i}(Et-\vec{p}\circ\vec{r})}}\cdot\left(-\mathrm{i}EA\cancel{e^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}}\right)\right]-\left[A\cancel{e^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}}\cdot\left(\mathrm{i}EA\cancel{e^{\mathrm{i}(Et-\vec{p}\circ\vec{r})}}\right)\right]\\&=\mathrm{i}\left(-\mathrm{i}EA^2-\mathrm{i}EA^2\right)=\mathrm{i}\left(-2\mathrm{i}EA^2\right)\end{aligned} \tag{11.3.84}$$

The density of probability has therefore for expression:

$$\boxed{\rho=2EA^2} \tag{11.3.85}$$

Taking again the expression of probabilistic current density and considering the differential, we get:

$$\begin{aligned}\vec{J}&=-\mathrm{i}\left(\bar{\Psi}\vec{\nabla}\Psi-\Psi\vec{\nabla}\bar{\Psi}\right)\\&=-\mathrm{i}\left(\left[A\cancel{e^{\mathrm{i}(Et-\vec{p}\circ\vec{r})}}\cdot\left(\mathrm{i}\vec{p}A\cancel{e^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}}\right)\right]-\left[A\cancel{e^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}}\cdot\left(-\mathrm{i}\vec{p}A\cancel{e^{\mathrm{i}(Et-\vec{p}\circ\vec{r})}}\right)\right]\right)\\&=-\mathrm{i}\left[\mathrm{i}\vec{p}A^2-\left(-\mathrm{i}\vec{p}A^2\right)\right]=-\mathrm{i}\left(2\mathrm{i}\vec{p}A^2\right)\end{aligned} \tag{11.3.86}$$

The probabilistic current density has therefore for expression:

$$\boxed{\vec{j}=2\vec{p}A^2} \tag{11.3.87}$$

Putting ourselves in the situation of that time of knowledge of quantum physics, the Klein-Gordon equation has several pathologies and disadvantages:

- The probability density $\rho = 2EA^2$ may become negative (since as we have seen, the energy can also be negative), which is inexplicable. Such a situation does not exist with the Schrödinger equation.

- The Klein-Gordon equation has the disadvantage of being of the second order in t (the Schrödinger equation is of the first order). The temporal evolution requires therefore the knowledge of not only of $\Psi(t_0)$ but also of its derivative $(\partial_t \Psi)_{t=t}$

- If we applied this equation to the hydrogen atom, we would not find the same fine structure[25] energy levels as observed.

All this led at the time preceding the works of Dirac, to reject this equation that, in addition, did not include the spin.

---

[25] "Fine-structure" refers to splitting of levels with the same l but different j

11.3.3 Classical free Dirac equation

So far, any particle was regarded as punctual and without any structure or internal degree freedom. In this context, all the information on the system state at time t is then reputed as entirely contained in the wave function $\Psi(x,y,z,t)$.

However, such a description is not sufficient, as we shall see. This insufficiency comes from the experimental evidence demonstrating that a particle such as an electron or also neutron has a magnetic intrinsic moment, independently of any rotation in space around a center. The existence of this magnetic moment in turn leads to the existence of an intrinsic angular momentum which was named "spin" because it was thought at first that this degree of freedom was linked to a rotation of the particle on itself. This degree of freedom is "internal" - although the electron continues to be regarded as a point particle; that is, along with the electric charge or mass, an intrinsic attribute, given once and for all. It seems so far impossible to physicist to give to the spin a classic analogy! Imagine the electron as a small non-zero radius ball that turns on itself leads to absurdities (for example we found that a point located on the surface of the electron has a much higher speed than c). It remains that the spin of a massic particle is its angular momentum in the repository where it is at rest. It is commonly accepted that hypothesis of the electron spin was formulated first by George Uhlenbeck and Samuel Goudsmit in 11925 (holocene calendar).

The spin of a particle is always half full or unitary, it is a fact of experience until now. The half or unitary characteristic nature of the spin defines two broad families of particles:

- bosons (integer spin)
- fermions (half-integer spin)

obeying very different statistics such as those we have discussed and study in the section of Statistical Mechanics (hence the existence of a relation named "spin-statistics theorem").

Let us return to the case of the electron. The two possible values revealed by measuring S (the μ_l we had in the section of Corpuscular Quantum Physics page 4666) are the eigenvalues $\pm\hbar/2$ (see section Wave Quantum Physics page 4877) associated with the two possible values of a quantum number $m_s=\pm 1/2$ itself associated at the free state ($\vec{L}=\vec{0}$) to the angular momentum:

$$b\leq\sqrt{J(J+1)}\hbar=\sqrt{(L+S)((L+s)+1)}\hbar=\sqrt{S(S+1)}\hbar \tag{11.3.88}$$

Therefore:

$$b\leq\sqrt{S(S+1)}\hbar=\sqrt{\pm\frac{1}{2}\left(\pm\frac{1}{2}+1\right)}\hbar=\sqrt{\frac{3}{4}}\hbar=\frac{\sqrt{3}\hbar}{2} \tag{11.3.89}$$

A complete description of the state of the electron therefore necessarily contains a wave function as usual giving the probability density of presence, but also taking into account the degree of freedom of the spin, hence the notation $\Psi(x,y,z,m_s,t)$. If the coordinates of space are continuous real values, however the spin variable is essentially discrete!

Maintaining the usual interpretation, the quantity $|\Psi(x,y,z,m_s,t)|^2\mathrm{d}r^2$ is the probability of presence around the point selected with the value $m_s\hbar$ for the spin. The condition of normalization of the probabilities introduced as always a sum, which covers not only the orbital degrees (continuous summation, that is to say: integration) but also the degrees of spin (discrete summation):

$$\int\left|\Psi\left(\vec{r},+\frac{1}{2}\right)\right|^2\mathrm{d}r^3+\int\left|\Psi\left(\vec{r},-\frac{1}{2}\right)\right|^2\mathrm{d}r^3=1 \qquad (11.3.90)$$

expressing in particular the fact that we exhaust all the possibilities of the spin by summing on the two possible values. In any case, the electron no longer has one but two wave functions, one for each value of m_s.

The previous notation is not necessarily the best for spin-free particles greater than $1/2$ as we have seen in our study of angular momentum. About the fact of having a variable taking discrete values, it is just as legitimate to put m_s in index of the Ψ and to put: $\Phi_{m_S}(\vec{r},t)$. Finally, it is convenient to use a matrix notation, storing in columns the various functions corresponding to the possible values of the discrete variable m_s. Thus, for the electron, we will now assume that all information in the sense of Wave Quantum Physics is contained in a two-line column vector named "spinor" (see section Spinor Calculus page 2145) and denoted:

$$\begin{bmatrix}\Psi_{+\frac{1}{2}}(\vec{r},t)\\ \Psi_{-\frac{1}{2}}(\vec{r},t)\end{bmatrix} \quad \text{or} \quad \begin{bmatrix}\Psi_{+}(\vec{r},t)\\ \Psi_{-}(\vec{r},t)\end{bmatrix} \qquad (11.3.91)$$

Let us now come back to the free Klein-Gordon equation (more general than the Schrödinger equation, of course, but less than the one including the magnetic field):

$$\hbar^2\frac{\partial^2\Psi}{\partial t^2}=\hbar^2c^2\Delta\Psi-m_0^2c^4\Psi \qquad (11.3.92)$$

This equation is as we know unfortunately incomplete because it contains no information on the spin of the electron (if we focus still only on this particle).

We can, however, in order to find a solution to this problem, make a parallel with the electromagnetic field. That latter includes also a spin, residing in the polarization of the field (see section Electrodynamics page 4538). This polarization is closely related to the vector nature of the electromagnetic field and is reflected in the Maxwell equations, which are as we know first-order derivatives. However, by combining Maxwell's equations, we saw in the Electrodynamics section that we could obtain the wave equations:

$$\nabla^2\vec{E}-\frac{1}{c^2}\frac{\partial^2\vec{E}}{\partial t^2}=\Delta\vec{E}-\frac{1}{c^2}\frac{\partial^2\vec{E}}{\partial t^2}=\vec{0} \quad \text{and} \quad \nabla^2\vec{B}-\frac{1}{c^2}\frac{\partial^2\vec{B}}{\partial t^2}=\Delta\vec{B}-\frac{1}{c^2}\frac{\partial^2\vec{B}}{\partial t^2}=\vec{0} \qquad (11.3.93)$$

which are (very relevant coincidence!) a special case of the Klein-Gordon equation when $m_0=0$:

$$\Delta\Psi-\frac{1}{c^2}\frac{\partial^2\Psi}{\partial t^2}=0 \qquad (11.3.94)$$

However, the wave equations contain less information than the original Maxwell equations: they do not explicitly contain any relation between the various components of the fields $\vec{E}$ and $\vec{B}$, such as the fact that in an electromagnetic wave of wave vector $\vec{k}$ the fields $\vec{E}$ and $\vec{B}$ are mutually perpendicular and both are perpendicular to the wave vector $\vec{k}$ (i.e. they are bot perpendicular to the direction of propagation of the wave). To establish these constraints, we must return to Maxwell's equations and thus to equations with first-order derivatives.

The same is true for fermions (electrons are part of it). Klein-Gordon's equation, even it is not false, is incomplete. We must try here to establish a first-order equation in derivatives which describes well the spin $1/2$ of the electrons of the fermions. This last condition means that this equation must therefore involve the two components of a spinor (in analogy with the one we have determined above):

$$\chi = \begin{bmatrix}\chi_1\\ \chi_2\end{bmatrix} \tag{11.3.95}$$

We will write this equation which we seek as:

$$D\chi = 0 \tag{11.3.96}$$

where D is an 2×2 matrix involving first order derivatives (a first-order differential operator) that we have to determine (and that we will!!!).

To give an example before going further, let us look at how Klein-Gordon's equation can be expressed in such a form.

We have first (free Klein-Gordon equation):

$$\hbar^2\frac{\partial^2\Psi}{\partial t^2} = \hbar^2c^2\Delta\Psi - m_0^2c^4\Psi \tag{11.3.97}$$

or (generalized Klein-Gordon equation):

$$\left[(\mathrm{i}\hbar\partial_t - qU)^2 - \left(-\mathrm{i}\hbar\vec{\nabla} - q\vec{A}\right)^2 c^2\right]\Psi = m_0^2c^4\Psi \tag{11.3.98}$$

What can also be written for the free Klein-Gordon equation:

$$\left(1 + \frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\left(1 - \frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\Psi = \frac{\hbar^2}{m_0^2c^2}\Delta\Psi \tag{11.3.99}$$

or for the generalized Klein-Gordon equation:

$$\begin{gathered}
\left[-\hbar^2\partial_t^2 - 2\mathrm{i}\hbar\partial_t qU + q^2U^2 + \hbar^2\vec{\nabla}^2c^2 - 2\mathrm{i}\hbar\vec{\nabla}q\vec{A}c^2 - q^2\vec{A}^2c^2\right]\Psi = m_0^2c^4\Psi\\
\left[1 + \frac{\hbar^2\partial_t^2}{m_0^2c^4}\right]\Psi = \frac{\left(-q^2\vec{A}^2c^2 - 2\mathrm{i}\hbar\vec{\nabla}q\vec{A}c^2 - \hbar^2\Delta c^2 + q^2U^2 - 2\mathrm{i}\hbar\partial_t qU\right)}{m_0^2c^4}\Psi\\
\left(1 + \frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\left(1 - \frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\Psi = \frac{\left(-q^2\vec{A}^2c^2 - 2\mathrm{i}\hbar\vec{\nabla}q\vec{A}c^2 - \hbar^2\Delta c^2 + q^2U^2 - 2\mathrm{i}\hbar\partial_t qU\right)}{m_0^2c^4}\Psi
\end{gathered} \tag{11.3.100}$$

Let us now restrict ourselves to the case of the free Klein-Gordon equation (the reasoning being similar but ... longer for the generalized version).

The last expression of the free Klein-Gordon equation suggests introducing the two combinations found after (it seems...) numerous trial and errors by our predecessors:

$$\begin{aligned}\Psi_a&=\Psi+\frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial\Psi}{\partial t}=\left(1+\frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\Psi\\ \Psi_b&=\Psi-\frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial\Psi}{\partial t}=\left(1-\frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\Psi\end{aligned}\qquad(11.3.101)$$

from which results:

$$\begin{aligned}\Psi&=\frac{1}{2}\left(\Psi_a+\Psi_b\right)\\ \frac{\partial\Psi}{\partial t}&=\frac{m_0c^2}{2\mathrm{i}\hbar}\left(\Psi_a-\Psi_b\right)\end{aligned}\qquad(11.3.102)$$

Therefore:

$$\left(1+\frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\left(1-\frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\Psi=\frac{\hbar^2}{m_0^2c^2}\Delta\Psi\qquad(11.3.103)$$

Can be written in two ways after respective substitutions:

$$\begin{aligned}\left(1-\frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\Psi_a&=\frac{\hbar^2}{2m_0^2c^2}\Delta\left(\Psi_a+\Psi_b\right)\\ \left(1+\frac{\mathrm{i}\hbar}{m_0c^2}\frac{\partial}{\partial t}\right)\Psi_b&=\frac{\hbar^2}{2m_0^2c^2}\Delta\left(\Psi_a+\Psi_b\right)\end{aligned}\qquad(11.3.104)$$

Either in matrix form:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\begin{bmatrix}\Psi_a\\ \Psi_b\end{bmatrix}=\begin{bmatrix}m_0c^2-\dfrac{\hbar^2}{2m_0}\Delta & -\dfrac{\hbar^2}{2m_0}\Delta\\ \dfrac{\hbar^2}{2m_0}\Delta & -m_0c^2+\dfrac{\hbar^2}{2m_0}\Delta\end{bmatrix}\begin{bmatrix}\Psi_a\\ \Psi_b\end{bmatrix}\qquad(11.3.105)$$

or even:

$$\left(\mathrm{i}\hbar\frac{\partial}{\partial t}\begin{bmatrix}1&0\\0&1\end{bmatrix}-\begin{bmatrix}m_0c^2-\dfrac{\hbar^2}{2m_0}\Delta & -\dfrac{\hbar^2}{2m_0}\Delta\\ \dfrac{\hbar^2}{2m_0}\Delta & -m_0c^2+\dfrac{\hbar^2}{2m_0}\Delta\end{bmatrix}\right)\begin{bmatrix}\Psi_a\\ \Psi_b\end{bmatrix}=\vec{0}\qquad(11.3.106)$$

What we can write:

$$\begin{bmatrix}\mathrm{i}\hbar\dfrac{\partial}{\partial t}-m_0c^2+\dfrac{\hbar^2}{2m_0}\Delta & \dfrac{\hbar^2}{2m_0}\Delta\\ \dfrac{\hbar^2}{2m_0}\Delta & -\mathrm{i}\hbar\dfrac{\partial}{\partial t}-m_0c^2+\dfrac{\hbar^2}{2m_0}\Delta\end{bmatrix}\begin{bmatrix}\Psi_a\\ \Psi_b\end{bmatrix}=\vec{0}\qquad(11.3.107)$$

Therefore, relatively to our initial idea of having a relation in the form:

$$D\chi=0\qquad(11.3.108)$$

We can make the similarity (correspondence term by term) with the prior-previous equation:

$$\chi=\begin{bmatrix}\Psi_a\\ \Psi_b\end{bmatrix}\quad\text{and}\quad D=\begin{bmatrix}\mathrm{i}\hbar\dfrac{\partial}{\partial t}-m_0c^2+\dfrac{\hbar^2}{2m_0}\Delta & \dfrac{\hbar^2}{2m_0}\Delta\\ \dfrac{\hbar^2}{2m_0}\Delta & -\mathrm{i}\hbar\dfrac{\partial}{\partial t}-m_0c^2+\dfrac{\hbar^2}{2m_0}\Delta\end{bmatrix}\qquad(11.3.109)$$

where D is indeed a 2×2 matrix.

$$D=A+\vec{B}\circ\vec{\sigma} \tag{11.3.110}$$

where A is a vector (but represented by tradition as a scalar...), $\vec{B}$ is a vector (and denoted as such and has nothing to do with the notation of the magnetic field) and σ a vector composed of 2×2 symmetric matrices (by reading the rest you will see that posing this makes it possible to find what we are looking for...).

Let us recall that the multiplication between $\vec{B}$ and $\vec{\sigma}$ constitutes a dot product such as that defined in our study of the Spinor Calculus section.

Remark

We reader must be very cautious in the developments that follow, because the traditional notations in the field make it very difficult to distinguish between products, dot products, and products of vector components forming a vector (element-wise multiplication).

Let us put (by the way our predecessors also made numerous trials and errors before putting this ...):

$$\mathrm{D}=\frac{\partial}{\partial t}+\lambda\vec{\sigma}\circ\vec{\nabla} \tag{11.3.111}$$

What we were initially seeking, that is, $\mathrm{D}\xi=0$, then becomes:

$$\frac{\partial}{\partial t}\chi+\lambda\vec{\sigma}\circ\vec{\nabla}\chi=\vec{0} \tag{11.3.112}$$

Thus $A=\partial/\partial t$, $\vec{B}=\lambda\vec{\nabla}$ and for $\vec{\sigma}$ that latter remains (let us imagine...) unknown. We must also determine λ.

Always by analogy with the example above, let us try to find the wave equation to determine the constant λ:

$$\left(\frac{\partial}{\partial t}-\lambda\vec{\sigma}\circ\vec{\nabla}\right)\left(\frac{\partial}{\partial t}+\lambda\vec{\sigma}\circ\vec{\nabla}\right)\chi=\vec{0}\Rightarrow\left(\frac{\partial^2}{\partial t^2}-\lambda^2\left(\vec{\sigma}\circ\vec{\nabla}\right)\left(\vec{\sigma}\circ\vec{\nabla}\right)\right)\chi=\vec{0} \tag{11.3.113}$$

So that we fall back on the wave equation, we must therefore have:

1. First that $\left(\vec{\sigma}\circ\vec{\nabla}\right)\left(\vec{\sigma}\circ\vec{\nabla}\right)=\vec{\nabla}^2$. Indeed (caution! the reader must have ideally at least studied the section of Spinor Calculus to know in detail how we get at this development!):

$$\begin{aligned}\left(\vec{\sigma}\circ\vec{\nabla}\right)\left(\vec{\sigma}\circ\vec{\nabla}\right)&=\begin{bmatrix}\partial_z & \partial_x-\mathrm{i}\partial_y\\ \partial_x+\mathrm{i}\partial_y & -\partial_z\end{bmatrix}\begin{bmatrix}\partial_z & \partial_x-\mathrm{i}\partial_y\\ \partial_x+\mathrm{i}\partial_y & -\partial_z\end{bmatrix}\\ &=\begin{bmatrix}\partial_z^2+\left(\partial_x+\mathrm{i}\partial_y\right)\left(\partial_x-\mathrm{i}\partial_y\right) & \partial_z\left(\partial_x-\mathrm{i}\partial_y\right)-\partial_z\left(\partial_x-\mathrm{i}\partial_y\right)\\ \partial_z\left(\partial_x+\mathrm{i}\partial_y\right)-\partial_z\left(\partial_x+\mathrm{i}\partial_y\right) & \left(\partial_x-\mathrm{i}\partial_y\right)\left(\partial_x+\mathrm{i}\partial_y\right)+\partial_z^2\end{bmatrix}\\ &=\begin{bmatrix}\partial_x^2+\partial_y^2+\partial_z^2 & 0\\ 0 & \partial_x^2+\partial_y^2+\partial_z^2\end{bmatrix}=\mathbb{1}\vec{\nabla}^2=\vec{\nabla}^2\end{aligned} \tag{11.3.114}$$

2. And that $\lambda=c$:

$$\left(\frac{\partial}{\partial t}-\lambda\vec{\sigma}\circ\vec{\nabla}\right)\left(\frac{\partial}{\partial t}+\lambda\vec{\sigma}\circ\vec{\nabla}\right)\chi=\left(\frac{\partial^2}{\partial t^2}-c^2\vec{\nabla}^2\right)\chi=\vec{0} \tag{11.3.115}$$

There are therefore, always in analogy with the previous developments, two possibilities which can be applied to different fields that we will be denoted $\chi^{(\pm)}$ and which are named "Weyl spinors". We thus have a sort of double spinor (as in the parenthesis we have a two components vector formed by 2×2 matrices) such that:

$$\left(\frac{\partial}{\partial t}\pm c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{\pm}=\vec{0} \tag{11.3.116}$$

These equations are named "Weyl equations" as the above relation represents in reality 4 equations (don't forget that the parenthesis is a 2 components vector made of 2×2 matrices and therefore 4 rows). Let us recall that a two dimensional spinor is a 2 components vector that are both in $\mathbb{C}$.

We now have to generalize the Weyl equations to the case of a half-integer spin fermion with mass. This new equation must respect the following constraints:

C1. It must be reduced to the Weyl equations when the mass tends to zero

C2. It must lead to the free Klein-Gordon equation

C3. It must describe particles with a spin

The very clever solution (extremely difficult to guess) then consists in coupling the two Weyl equations by using different factor such as:

$$\begin{aligned}\mathrm{i}\hbar\left(\frac{\partial}{\partial t}+c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{(+)}=m_0c^2\chi^{(-)}\\ \mathrm{i}\hbar\left(\frac{\partial}{\partial t}-c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{(-)}=m_0c^2\chi^{(+)}\end{aligned} \tag{11.3.117}$$

To verify that these factors have been correctly chosen, we apply:

$$\hbar\left(\frac{\partial}{\partial t}+c\vec{\sigma}\circ\vec{\nabla}\right) \tag{11.3.118}$$

to the first equation on both sides such that we get:

$$\mathrm{i}\hbar\left(\frac{\partial}{\partial t}-c\vec{\sigma}\circ\vec{\nabla}\right)\hbar\left(\frac{\partial}{\partial t}+c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{(+)}=m_0c^2\hbar\left(\frac{\partial}{\partial t}-c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{(-)} \tag{11.3.119}$$

As the second equation give us:

$$\mathrm{i}\hbar\left(\frac{\partial}{\partial t}-c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{(-)}=m_0c^2\chi^{(+)} \tag{11.3.120}$$

After rearranging in the latter the complex term a put it as numerator on the right hand side by multiplying by i/i :

$$\hbar\left(\frac{\partial}{\partial t}-c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{(-)}=-\mathrm{i}m_0c^2\chi^{(+)} \tag{11.3.121}$$

and substitute to the previous in the right hand side, we thus find:

$$\mathrm{i}\hbar\left(\frac{\partial}{\partial t}-c\vec{\sigma}\circ\vec{\nabla}\right)\hbar\left(\frac{\partial}{\partial t}+c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{(+)}=-\mathrm{i}m_0^2c^4\chi^{(+)} \tag{11.3.122}$$

or developing the left extreme previous term and keeping the right extreme previous term and dividing by i (remember that the square of any of the three Pauli spin matrices is equal to the identity!):

$$\hbar^2\left(\frac{\partial^2}{\partial t^2}-c^2\nabla^2\right)\chi^{(+)}=-m_0^2c^4\chi^{(+)} \tag{11.3.123}$$

to compare with:

$$\hbar^2\left(\frac{\partial^2}{\partial t^2}-c^2\nabla^2\right)\Psi=-m_0^2c^4\Psi \tag{11.3.124}$$

that is the free Klein-Gordon equation (we prove the same correspondence for the component χ^-) and thus reinforces the validity of the assumptions and developments made so far.

It is usual to combine the two spinors in a single spinor (this becomes a "bispinor") of 4 components (a spinor with 4 components, two of which are in fact associated with the particles and two with the antiparticles as we shall see):

$$\Psi=\begin{bmatrix}\chi^{(+)}\\\chi^{(-)}\end{bmatrix}=\begin{bmatrix}\Psi_1\\\Psi_2\\\Psi_3\\\Psi_4\end{bmatrix} \tag{11.3.125}$$

and to define the following two matrices (commonly named "Gamma matrices") in a so-named "standard form":

$$\gamma^0=\begin{bmatrix}0 & \mathbb{1}\\\mathbb{1} & 0\end{bmatrix} \tag{11.3.126}$$

where $\mathbb{1}$ is the 2×2 unit matrix traditionally defined by:

$$\mathbb{1}=\begin{bmatrix}1 & 0\\0 & 1\end{bmatrix} \tag{11.3.127}$$

and:

$$\gamma^i=\begin{bmatrix}0 & -\sigma_i\\\sigma_i & 0\end{bmatrix}=\alpha^i\cdot\beta=\begin{bmatrix}0 & \sigma_i\\\sigma_i & 0\end{bmatrix}\begin{bmatrix}\mathbb{1} & 0\\0 & -\mathbb{1}\end{bmatrix} \tag{11.3.128}$$

where the σ_i are the "Pauli matrices" given by (see section Spinor Calculus page 2158):

$$\sigma_0=\begin{bmatrix}1 & 0\\0 & 1\end{bmatrix},\sigma_1=\begin{bmatrix}0 & 1\\1 & 0\end{bmatrix},\sigma_2=\begin{bmatrix}0 & -\mathrm{i}\\\mathrm{i} & 0\end{bmatrix},\sigma_3=\begin{bmatrix}1 & 0\\0 & -1\end{bmatrix} \tag{11.3.129}$$

which must satisfy for recall (proved earlier above):

$$\left(\vec{\sigma}\circ\vec{\nabla}\right)\left(\vec{\sigma}\circ\vec{\nabla}\right)=\vec{\nabla}^2 \tag{11.3.130}$$

which is for recall 2×2 matrix. Pauli's matrices are therefore good candidates to solve our problem!

We can also found in the literature the following notation based on the tensor product (see section Tensor Calculus page 2073):

$$\gamma^0=\sigma_1\otimes\mathbb{1}=\begin{bmatrix}0&1\\1&0\end{bmatrix}\otimes\begin{bmatrix}1&0\\0&1\end{bmatrix}=\begin{bmatrix}0&0&1&0\\0&0&0&1\\1&0&0&0\\0&1&0&0\end{bmatrix}=\begin{bmatrix}0&\mathbb{1}\\\mathbb{1}&0\end{bmatrix}\tag{11.3.131}$$

and:

$$\gamma^k=-\mathrm{i}\sigma_2\otimes\sigma_k\tag{11.3.132}$$

Remarks

R1. As we saw in the section of Spinor Calculus (Algebra Chapter), σ_0 is not really a Pauli matrix in itself. However, in some textbooks, it is indicated as being one (this is also our choice here).

R2. As we have also seen in it in the section of Spinor Calculus, let us recall that the Pauli matrices implicitly represent infinitesimal spatial rotations of a spinor.

Caution!!! In the gamma matrices, the traditional notation 0 means in fact that it is a 2×2 matrices having all components equal to zero. It should be instead denoted as seen in the section of Linear Algebra.

This allows us, finally, to combine the equations:

$$\begin{aligned}\mathrm{i}\hbar\left(\frac{\partial}{\partial t}+c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{(+)}=m_0c^2\chi^{(-)}\\\mathrm{i}\hbar\left(\frac{\partial}{\partial t}-c\vec{\sigma}\circ\vec{\nabla}\right)\chi^{(-)}=m_0c^2\chi^{(+)}\end{aligned}\tag{11.3.133}$$

in only one (do not forget the association of the operators $E\rightarrow\mathrm{i}\hbar\partial/\partial t,p\rightarrow-\mathrm{i}\hbar\vec{\nabla}$):

$$\left(\gamma_0\mathrm{i}\frac{\partial}{c\partial t}+\gamma_i\frac{\partial}{\partial x_i}-\frac{m_0c}{\hbar}\right)\Psi=\vec{0}\tag{11.3.134}$$

Using the traditional notation in Tensor Calculus and choosing the natural units ($c=1,\hbar=1$) we have:

$$\boxed{\left(\mathrm{i}\gamma^\mu\partial_\mu-m_0\right)\Psi=\vec{0}}\tag{11.3.135}$$

which is the usual form of the "Dirac equation" (implicitly a system of four coupled differential equations) or "relativistic equation of the electron" with the "covariant derivative":

$$\partial_\mu=\left(\frac{\partial}{c\partial t},\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\right)\tag{11.3.136}$$

and where the null vector is (for recall...) a vector with four components all equal to zero!

We define the "covariant form of the Dirac operator" as:

$$\hat{D}=\mathrm{i}\gamma^{\mu}\partial_{\mu}-m_0 \tag{11.3.137}$$

Notice something important...! Time is derived once and also space at the opposite of Schrödinger equation. This symmetry of treatment between time and space is now compatible with what we know from Special Relativity where space and time and treated equally. So we have solved the issue we had earlier Schrödinger equation.

The Dirac equation is said to have four possible solutions:
$\gamma_0 =$
Electron, spin-up (clock-wise)
Electron, spin-down (counter clockwise)
Positron, spin-up (clock-wise)
Positron, spin-down (counter clockwise)

Figure 11.82: Explicit free Dirac equation with explanations

Remark

In elementary particle physics, the antecedent relation is named the "covariant relativistic equation of fermions" because it describes particles with spin $1/2$.

The matrices γ^μ are named commonly "Dirac matrices". In an even more condensed form (using the "Feynman slash") the Dirac equation is sometimes written:

$$\boxed{(\mathrm{i}\not{\partial}-m_0)\,\Psi=\vec{0}} \tag{11.3.138}$$

or more explicitly in natural units (rare form but still correct):

$$\left(\mathrm{i}\gamma^0\frac{\partial}{\partial t}+\mathrm{i}\vec{\gamma}\circ\vec{\nabla}-m_0\right)\Psi=\vec{0} \tag{11.3.139}$$

Or with a minimum of abbreviations (all terms explicited):

$$\begin{bmatrix} \mathrm{i}\dfrac{\partial}{\partial t}-m_0 & 0 & \mathrm{i}\dfrac{\partial}{\partial z} & \mathrm{i}\dfrac{\partial}{\partial x}+\dfrac{\partial}{\partial y} \\ 0 & \mathrm{i}\dfrac{\partial}{\partial t}-m_0 & \mathrm{i}\dfrac{\partial}{\partial t}-\dfrac{\partial}{\partial y} & -\mathrm{i}\dfrac{\partial}{\partial z} \\ -\mathrm{i}\dfrac{\partial}{\partial z} & -\mathrm{i}\dfrac{\partial}{\partial x}-\dfrac{\partial}{\partial y} & -\mathrm{i}\dfrac{\partial}{\partial t}-m_0 & 0 \\ -\mathrm{i}\dfrac{\partial}{\partial x}+\dfrac{\partial}{\partial y} & \mathrm{i}\dfrac{\partial}{\partial z} & 0 & -\mathrm{i}\dfrac{\partial}{\partial t}-m_0 \end{bmatrix} \begin{pmatrix} \Phi_1 \\ \Phi_2 \\ \Phi_3 \\ \Phi_4 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} \qquad (11.3.140)$$

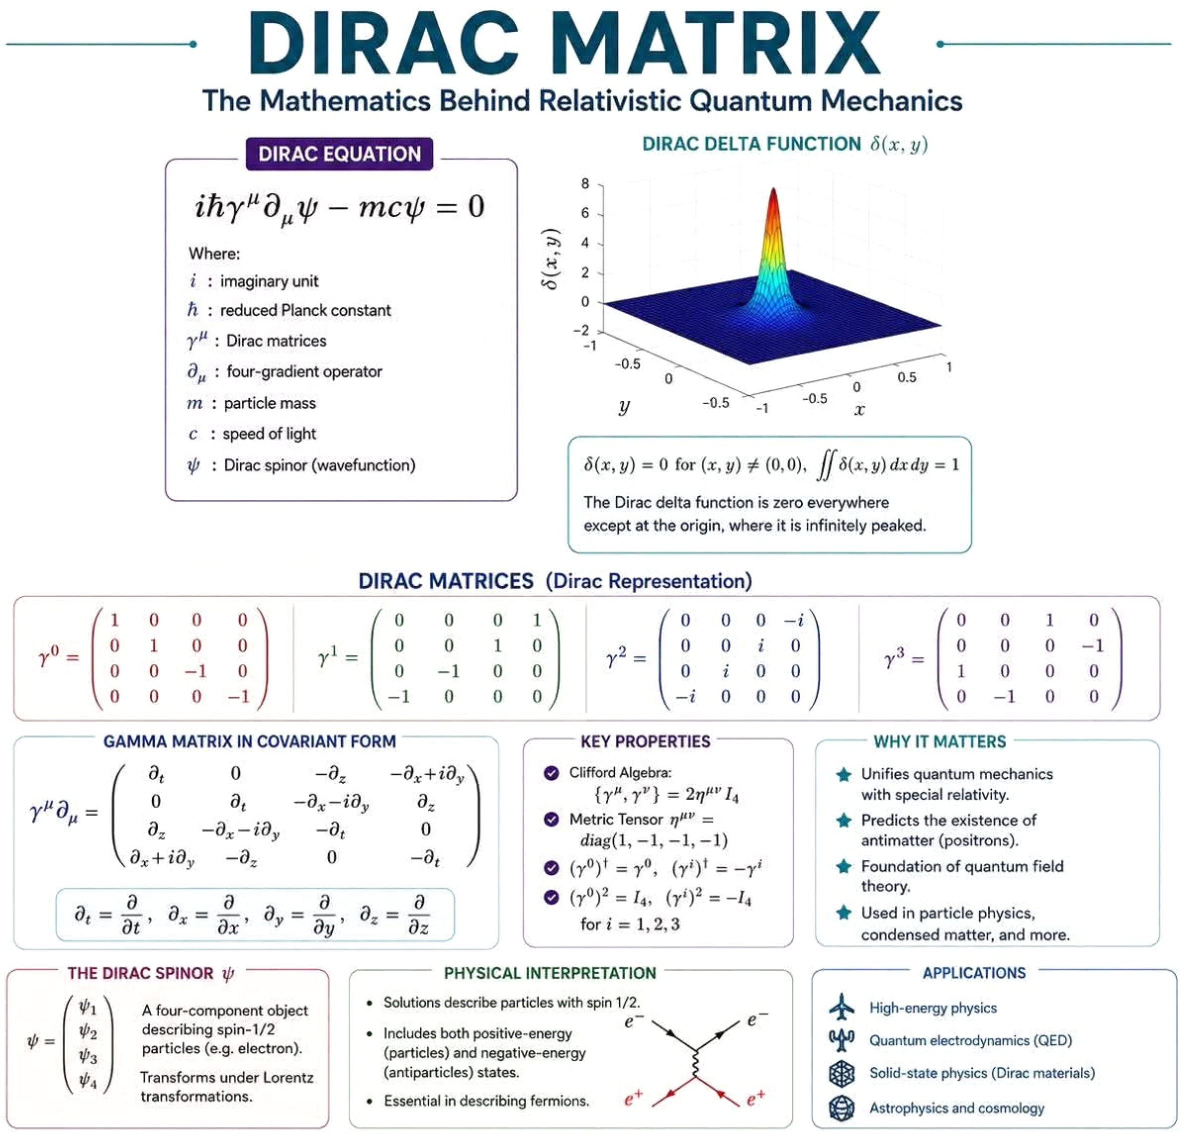
We thus have, as in analogy with Maxwell's equations, a differential equations of the first order which have for properties:

P1. To allow to fall back on the Klein-Gordon equation, in extenso on Wave equation (as for the Maxwell's equations)

P2. To take into account (explicitly) describe the spinor character of wave functions as we shall see by looking more closely at the Pauli matrices.

Remark

Since the Dirac equation applies to the spin $1/2$ particles, it also applies to neutrinos whose mass at rest is almost zero (thus the resolution of the Dirac equation is largely simplified).



DIRAC MATRIX

The Mathematics Behind Relativistic Quantum Mechanics

DIRAC EQUATION

$$i\hbar\gamma^\mu\partial_\mu\psi - mc\psi = 0$$

Where:

i : imaginary unit

$\hbar$: reduced Planck constant

γ^μ : Dirac matrices

∂_μ : four-gradient operator

m : particle mass

c : speed of light

ψ : Dirac spinor (wavefunction)

DIRAC DELTA FUNCTION $\delta(x,y)$

$\delta(x,y)=0$ for $(x,y)\neq(0,0)$, $\iint \delta(x,y)\,dx\,dy = 1$

The Dirac delta function is zero everywhere except at the origin, where it is infinitely peaked.

DIRAC MATRICES (Dirac Representation)

$$\gamma^0 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \quad \gamma^1 = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{pmatrix} \quad \gamma^2 = \begin{pmatrix} 0 & 0 & 0 & -i \\ 0 & 0 & i & 0 \\ 0 & i & 0 & 0 \\ -i & 0 & 0 & 0 \end{pmatrix} \quad \gamma^3 = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix}$$

GAMMA MATRIX IN COVARIANT FORM

$$\gamma^\mu\partial_\mu = \begin{pmatrix} \partial_t & 0 & -\partial_z & -\partial_x+i\partial_y \\ 0 & \partial_t & -\partial_x-i\partial_y & \partial_z \\ \partial_z & -\partial_x-i\partial_y & -\partial_t & 0 \\ \partial_x+i\partial_y & -\partial_z & 0 & -\partial_t \end{pmatrix}$$

$$\partial_t = \frac{\partial}{\partial t},\ \partial_x = \frac{\partial}{\partial x},\ \partial_y = \frac{\partial}{\partial y},\ \partial_z = \frac{\partial}{\partial z}$$

KEY PROPERTIES

- ✓ Clifford Algebra: $\{\gamma^\mu,\gamma^\nu\} = 2\eta^{\mu\nu}I_4$
- ✓ Metric Tensor $\eta^{\mu\nu} = diag(1,-1,-1,-1)$
- ✓ $(\gamma^0)^\dagger = \gamma^0$, $(\gamma^i)^\dagger = -\gamma^i$
- ✓ $(\gamma^0)^2 = I_4$, $(\gamma^i)^2 = -I_4$ for $i = 1,2,3$

WHY IT MATTERS

- ★ Unifies quantum mechanics with special relativity.
- ★ Predicts the existence of antimatter (positrons).
- ★ Foundation of quantum field theory.
- ★ Used in particle physics, condensed matter, and more.

THE DIRAC SPINOR ψ

$$\psi = \begin{pmatrix} \psi_1 \\ \psi_2 \\ \psi_3 \\ \psi_4 \end{pmatrix}$$

A four-component object describing spin-1/2 particles (e.g. electron).

Transforms under Lorentz transformations.

PHYSICAL INTERPRETATION

- Solutions describe particles with spin 1/2.
- Includes both positive-energy (particles) and negative-energy (antiparticles) states.
- Essential in describing fermions.

APPLICATIONS

- High-energy physics
- Quantum electrodynamics (QED)
- Solid-state physics (Dirac materials)
- Astrophysics and cosmology

11.3.3.1 Gamma, alpha, beta matrices

In the purpose now of interpreting the physical content of the Dirac equation, we will use a different representation of the gamma matrices. We have introduced earlier the representation by the following matrices 4×4:

$$\gamma^0=\beta=\begin{bmatrix} 0 & \mathbb{1} \\ \mathbb{1} & 0 \end{bmatrix},\gamma^i=\begin{bmatrix} 0 & -\sigma_i \\ \sigma_i & 0 \end{bmatrix} \tag{11.3.141}$$

named "standard representation" and denoted rigorously:

$$\gamma_S^0=\beta_S=\begin{bmatrix} 0 & \mathbb{1} \\ \mathbb{1} & 0 \end{bmatrix},\gamma_S^i=\begin{bmatrix} 0 & -\sigma_i \\ \sigma_i & 0 \end{bmatrix} \tag{11.3.142}$$

with for recall:

$$\sigma_1=\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix},\sigma_2=\begin{bmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{bmatrix},\sigma_3=\begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \tag{11.3.143}$$

But in fact these matrices are by far not the only 4×4 matrices that satisfy the following set of equalities that we will justify later during our study of the linearised Dirac equation (page 4957):

$$\begin{aligned}&\beta^2 = \alpha_1^2 = \alpha_2^2 = \alpha_3^2 = 1\\&[\alpha_1, \alpha_2]_+ = [\alpha_1, \alpha_3]_+ = [\alpha_2, \alpha_3]_+ = 0\\&[\alpha_1, \beta]_+ = [\alpha_2, \beta]_+ = [\alpha_3, \beta]_+ = 0\end{aligned} \tag{11.3.144}$$

For example, we will use many times the "Dirac representation" defined by:

$$\gamma_D^0 = \beta_D = \begin{bmatrix} \mathbb{1} & 0 \\ 0 & -\mathbb{1} \end{bmatrix}, \gamma_D^i = -\gamma_D^0 \alpha_D^i = \begin{bmatrix} 0 & \sigma_i \\ -\sigma_i & 0 \end{bmatrix} \tag{11.3.145}$$

Or more explicitly:

$$\gamma_D^0 = \beta_D = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix}, \gamma_D^1 = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{bmatrix}, \gamma_D^2 = \begin{bmatrix} 0 & 0 & 0 & -\mathrm{i} \\ 0 & 0 & \mathrm{i} & 0 \\ 0 & \mathrm{i} & 0 & 0 \\ -\mathrm{i} & 0 & 0 & 0 \end{bmatrix}, \gamma_D^3 = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ -1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix} \tag{11.3.146}$$

With the corresponding Dirac alpha and beta matrices:

$$\beta_D = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix}, \alpha_D^1 = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}, \alpha_D^2 = \begin{bmatrix} 0 & 0 & 0 & -\mathrm{i} \\ 0 & 0 & \mathrm{i} & 0 \\ 0 & -\mathrm{i} & 0 & 0 \\ \mathrm{i} & 0 & 0 & 0 \end{bmatrix}, \alpha_D^3 = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{bmatrix} \tag{11.3.147}$$

This representation (also not unique!) is particularly useful because it highlights the spinor character (due to the half-integer spin) of the electron wave function and separates the positive and negative energy components.

Notice that $\gamma^1, \gamma^2, \gamma^3$ are anti-Hermitian:

$$\gamma^{0\dagger} = \gamma^0, \gamma^{1\dagger} = -\gamma^1, \gamma^{2\dagger} = -\gamma^2, \gamma^{3\dagger} = -\gamma^3 \tag{11.3.148}$$

With Maple™ 4.00b it can easily be checked that they satisfy the set of three equalities introduced just earlier (see the Maple™ companion book):

```
>with(linalg):
>beta:=array([[1,0,0,0],[0,1,0,0],[0,0,-1,0],[0,0,0,-1]]);
>alpha1:=array([[0,0,0,1],[0,0,1,0],[0,1,0,0],[1,0,0,0]]);
>alpha2:=array([[0,0,0,-I],[0,0,I,0],[0,-I,0,0],[I,0,0,0]]);
>alpha3:=array([[0,0,1,0],[0,0,0,-1],[1,0,0,0],[0,-1,0,0]]);
>evalm(beta^2);
>evalm(alpha1^2);
>evalm(alpha2^2);
>evalm(alpha3^2);
>readlib(commutat):
```

```
>evalm(c(alpha1,alpha2));
>evalm(c(alpha1,alpha3));
>evalf(evalm(c(alpha2,alpha3)));
>evalf(evalm(c(alpha1,beta)));
>evalf(evalm(c(alpha2,beta)));
>evalf(evalm(c(alpha3,beta)));
```

We can also easily check (elementary linear algebra) that the Dirac representation is obtained from the standard representation by the transformation:

$$\gamma_D^\mu \rightarrow U\gamma_S^\mu U^\dagger \tag{11.3.149}$$

where:

$$\gamma_D^\mu \rightarrow U\gamma_S^\mu U^\dagger \quad \text{with} \quad U=\frac{1}{\sqrt{2}}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix} \tag{11.3.150}$$

Let us recall that $U^\dagger$ is the adjoint matrix (the conjugate of the transposed matrix) of U (see section Linear Algebra page 1953). Now, when all the elements are real as it is the case above and the matrix is a square one symmetric relatively to all its off-diagonal elements then we have obviously that $U=U^\dagger$.

Proof 11.5.2.

$$\begin{aligned}\gamma_D^0=U\gamma_S^0U^\dagger&=\frac{1}{\sqrt{2}}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}\begin{bmatrix}0 & \mathbb{1}\\ \mathbb{1} & 0\end{bmatrix}\frac{1}{\sqrt{2}}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}=\frac{1}{2}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}\begin{bmatrix}0 & \mathbb{1}\\ \mathbb{1} & 0\end{bmatrix}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}\\ &=\frac{1}{2}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}\begin{bmatrix}\mathbb{1} & -\mathbb{1}\\ \mathbb{1} & \mathbb{1}\end{bmatrix}=\frac{1}{2}\begin{bmatrix}\mathbb{1}+\mathbb{1} & -\mathbb{1}+\mathbb{1}\\ \mathbb{1}-\mathbb{1} & -\mathbb{1}-\mathbb{1}\end{bmatrix}=\frac{1}{2}\begin{bmatrix}2\mathbb{1} & 0\\ 0 & -2\mathbb{1}\end{bmatrix}=\begin{bmatrix}\mathbb{1} & 0\\ 0 & -\mathbb{1}\end{bmatrix}\end{aligned} \tag{11.3.151}$$

and:

$$\begin{aligned}\gamma_D^i=U\gamma_S^iU^\dagger&=\frac{1}{\sqrt{2}}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}\begin{bmatrix}0 & -\sigma_i\\ \sigma_i & 0\end{bmatrix}\frac{1}{\sqrt{2}}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}=\frac{1}{2}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}\begin{bmatrix}0 & -\sigma_i\\ \sigma_i & 0\end{bmatrix}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}\\ &=\frac{1}{2}\begin{bmatrix}\mathbb{1} & \mathbb{1}\\ \mathbb{1} & -\mathbb{1}\end{bmatrix}\begin{bmatrix}-\sigma_i & \sigma_i\\ \sigma_i & \sigma_i\end{bmatrix}=\frac{1}{2}\begin{bmatrix}0 & 2\sigma_i\\ -2\sigma_i & 0\end{bmatrix}=\begin{bmatrix}0 & \sigma_i\\ -\sigma_i & 0\end{bmatrix}\end{aligned} \tag{11.3.152}$$

■ Q.E.D.

But notice that there is also another possible choice, named the "chiral representation" defined by:

$$\gamma_C^0=\beta_C=\begin{bmatrix}0 & -\mathbb{1}\\ -\mathbb{1} & 0\end{bmatrix},\gamma_C^i=-\alpha_D^i\gamma_C^0=\begin{bmatrix}0 & \sigma_i\\ -\sigma_i & 0\end{bmatrix} \tag{11.3.153}$$

Or more explicitly:

$$\gamma_C^0=\beta_C=\begin{bmatrix}0 & 0 & -1 & 0\\ 0 & 0 & 0 & -1\\ -1 & 0 & 0 & 0\\ 0 & -1 & 0 & 0\end{bmatrix},\gamma_C^1=\begin{bmatrix}0 & 0 & 0 & 1\\ 0 & 0 & 1 & 0\\ 0 & -1 & 0 & 0\\ -1 & 0 & 0 & 0\end{bmatrix},\gamma_C^2=\begin{bmatrix}0 & 0 & 0 & -\mathrm{i}\\ 0 & 0 & \mathrm{i} & 0\\ 0 & \mathrm{i} & 0 & 0\\ -\mathrm{i} & 0 & 0 & 0\end{bmatrix},\gamma_C^3=\begin{bmatrix}0 & 0 & 1 & 0\\ 0 & 0 & 0 & -1\\ -1 & 0 & 0 & 0\\ 0 & 1 & 0 & 0\end{bmatrix} \tag{11.3.154}$$

With the corresponding chiral alpha and beta matrices:

$$\beta_C=\begin{bmatrix}0 & -\mathbb{1}\\ -\mathbb{1} & 0\end{bmatrix},\alpha_C^i=\begin{bmatrix}\sigma_i & 0\\ 0 & -\sigma_i\end{bmatrix} \tag{11.3.155}$$

Thus more explicitly:

$$\beta_C=\begin{bmatrix}0 & 0 & -1 & 0\\ 0 & 0 & 0 & -1\\ -1 & 0 & 0 & 0\\ 0 & -1 & 0 & 0\end{bmatrix},\alpha_C^1=\begin{bmatrix}0 & 1 & 0 & 0\\ 1 & 0 & 0 & 0\\ 0 & 0 & 0 & -1\\ 0 & 0 & -1 & 0\end{bmatrix},\alpha_C^2=\begin{bmatrix}0 & -\mathrm{i} & 0 & 0\\ \mathrm{i} & 0 & 0 & 0\\ 0 & 0 & 0 & \mathrm{i}\\ 0 & 0 & -\mathrm{i} & 0\end{bmatrix},\alpha_C^3=\begin{bmatrix}1 & 0 & 0 & 0\\ 0 & -1 & 0 & 0\\ 0 & 0 & -1 & 0\\ 0 & 0 & 0 & 1\end{bmatrix} \tag{11.3.156}$$

Its advantage is that both spinors transform independently under rotations and translations. It is particularly useful for massless particles, the equations being considerably simplified. It has been used for the neutrino although neutrino oscillations show that their mass is non-zero[26] (the electron-neutrino has for example a mass of the order of $1.4\cdot 10^{-36}$ [kg]).

But notice that there is again also another possible choice, named the "Weyl representation" defined by:

$$\gamma_W^0=\beta_W=\begin{bmatrix}0 & \mathbb{1}\\ \mathbb{1} & 0\end{bmatrix},\gamma_W^i=\alpha_W^i\gamma_W^0=\begin{bmatrix}0 & \sigma_i\\ -\sigma_i & 0\end{bmatrix} \tag{11.3.157}$$

Or more explicitly:

$$\gamma_W^0=\beta_C=\begin{bmatrix}0 & 0 & 1 & 0\\ 0 & 0 & 0 & 1\\ 1 & 0 & 0 & 0\\ 0 & 1 & 0 & 0\end{bmatrix},\gamma_W^1=\begin{bmatrix}0 & 0 & 0 & 1\\ 0 & 0 & 1 & 0\\ 0 & -1 & 0 & 0\\ -1 & 0 & 0 & 0\end{bmatrix},\gamma_W^2=\begin{bmatrix}0 & 0 & 0 & -\mathrm{i}\\ 0 & 0 & \mathrm{i} & 0\\ 0 & \mathrm{i} & 0 & 0\\ -\mathrm{i} & 0 & 0 & 0\end{bmatrix},\gamma_W^3=\begin{bmatrix}0 & 0 & 1 & 0\\ 0 & 0 & 0 & -1\\ -1 & 0 & 0 & 0\\ 0 & 1 & 0 & 0\end{bmatrix} \tag{11.3.158}$$

With the corresponding Weyl alpha and beta matrices:

$$\beta_W=\begin{bmatrix}0 & \mathbb{1}\\ \mathbb{1} & 0\end{bmatrix},\alpha_W^i=\begin{bmatrix}\sigma_i & 0\\ 0 & -\sigma_i\end{bmatrix} \tag{11.3.159}$$

Thus more explicitly:

$$\beta_W=\begin{bmatrix}0 & 0 & 1 & 0\\ 0 & 0 & 0 & 1\\ 1 & 0 & 0 & 0\\ 0 & 1 & 0 & 0\end{bmatrix},\alpha_W^1=\begin{bmatrix}0 & 1 & 0 & 0\\ 1 & 0 & 0 & 0\\ 0 & 0 & 0 & -1\\ 0 & 0 & -1 & 0\end{bmatrix},\alpha_W^2=\begin{bmatrix}0 & -\mathrm{i} & 0 & 0\\ \mathrm{i} & 0 & 0 & 0\\ 0 & 0 & 0 & \mathrm{i}\\ 0 & 0 & -\mathrm{i} & 0\end{bmatrix},\alpha_W^3=\begin{bmatrix}1 & 0 & 0 & 0\\ 0 & -1 & 0 & 0\\ 0 & 0 & -1 & 0\\ 0 & 0 & 0 & 1\end{bmatrix} \tag{11.3.160}$$

This representation is useful when one seeks to derive the Dirac equation using the irreducible representations of the Lorentz group.

---

[26] The 12015 (holocene calendar) Nobel Prize in Physics has been awarded to Takaaki Kajita and Arthur B. McDonald for the discovery of neutrino oscillations, which shows that neutrinos have mass. There are three flavors of neutrinos: electron, muon, and tau neutrinos. But there are also three different mass neutrinos: ν_1, ν_2, and ν_3. If each flavor of neutrino matched up with one specific mass, then life would be simple... but boring. Neutrinos are tricky, and it turns out that the mass and flavor neutrinos do not overlap perfectly. Instead, Quantum Mechanics comes into play. Each neutrino of a specific flavor is actually a superposition of neutrinos of different masses!

But notice that there is again also another possible choice, named the "Majorana representation" defined by:

$$\gamma_M^0=\beta_M=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&-\mathrm{i}&0\\0&\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix},\gamma_M^1=\begin{bmatrix}0&-\mathrm{i}&0&0\\-\mathrm{i}&0&0&0\\0&0&0&\mathrm{i}\\0&0&\mathrm{i}&0\end{bmatrix},\gamma_M^2=\begin{bmatrix}-\mathrm{i}&0&0&0\\0&\mathrm{i}&0&0\\0&0&-\mathrm{i}&0\\0&0&0&\mathrm{i}\end{bmatrix},\gamma_M^3=\begin{bmatrix}0&0&0&\mathrm{i}\\0&0&\mathrm{i}&0\\0&\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix}\tag{11.3.161}$$

Majorana matrices in the representation above obey also the following mandatory gamma anticommutation relations (as so far we don't know the β and α_i corresponding Majorana matrices) as seen at page 4963 (and that can easily be verified using the same type of Maple™ code as given just earlier!):

$$[\gamma_i,\gamma_j]_+=\gamma_i\gamma_j+\gamma_j\gamma_i=2\eta_{ij}\mathbb{1}_4\tag{11.3.162}$$

Thus, for $i\neq j$:

$$[\gamma_i,\gamma_j]_+=\gamma_i\gamma_j+\gamma_j\gamma_i=0\tag{11.3.163}$$

and it is also immediate using this anticommutation relation that:

$$(\gamma^0)^2=\mathbb{1},(\gamma^i)^2=-\mathbb{1}\tag{11.3.164}$$

A further, purely imaginary representation of the Majorana matrices spread in the literature is given by:

$$\begin{gathered}\tilde{\gamma}_M^0=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&\mathrm{i}&0\\0&-\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix}=\begin{bmatrix}0&\sigma_2\\\sigma_2&0\end{bmatrix},\tilde{\gamma}_M^1=\begin{bmatrix}\mathrm{i}&0&0&0\\0&-\mathrm{i}&0&0\\0&0&\mathrm{i}&0\\0&0&0&-\mathrm{i}\end{bmatrix}=\mathrm{i}\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}\\\tilde{\gamma}_M^2=\begin{bmatrix}0&0&0&\mathrm{i}\\0&0&-\mathrm{i}&0\\0&-\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix}=\begin{bmatrix}0&-\sigma_2\\\sigma_2&0\end{bmatrix},\tilde{\gamma}_M^3=\begin{bmatrix}0&-\mathrm{i}&0&0\\-\mathrm{i}&0&0&0\\0&0&0&-\mathrm{i}\\0&0&-\mathrm{i}&0\end{bmatrix}=-\mathrm{i}\begin{bmatrix}\sigma_1&0\\0&\sigma_1\end{bmatrix}\end{gathered}\tag{11.3.165}$$

That latter Majorana representation can be obtained from the original representation by the unitary transformation:

$$\tilde{\gamma}_M^\mu=\tilde{U}\gamma_M^\mu\tilde{U}^{-1}\quad\text{and}\quad\tilde{U}=\frac{1}{2}=\begin{bmatrix}1&1&1&-1\\-1&1&1&1\\1&1&-1&1\\1&-1&1&1\end{bmatrix}\tag{11.3.166}$$

There is alsoooooo another Majorana representation (sorry...) also denoted identically as previously (sic!) and defined by:

$$\tilde{\gamma}_M^0=\sigma_2\otimes\sigma_1,\tilde{\gamma}_M^1=\mathrm{i}\sigma_1\otimes\mathbb{1},\tilde{\gamma}_M^2=\mathrm{i}\sigma_3\otimes\mathbb{1},\tilde{\gamma}_M^3=\mathrm{i}\sigma_2\otimes\sigma_2\tag{11.3.167}$$

That is explicitly:

$$\tilde{\gamma}_M^0=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&-\mathrm{i}&0\\0&\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix},\tilde{\gamma}_M^1=\begin{bmatrix}0&0&\mathrm{i}&0\\0&0&0&\mathrm{i}\\\mathrm{i}&0&0&0\\0&\mathrm{i}&0&0\end{bmatrix},\tilde{\gamma}_M^2=\begin{bmatrix}\mathrm{i}&0&0&0\\0&\mathrm{i}&0&0\\0&0&-\mathrm{i}&0\\0&0&0&-\mathrm{i}\end{bmatrix},\tilde{\gamma}_M^3=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&\mathrm{i}&0\\0&\mathrm{i}&0&0\\-\mathrm{i}&0&0&0\end{bmatrix}\tag{11.3.168}$$

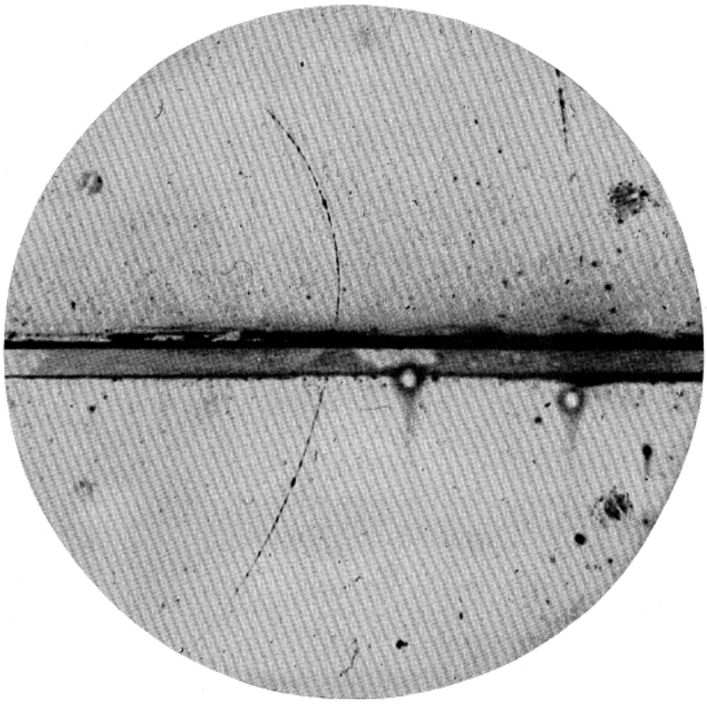
This representation has the interesting property that all matrices γ^μ are purely imaginary! What makes the Dirac field of the Dirac equation a non-complex field where the particles are therefore their own antiparticles!

Remarks

R1. All these possibilities explains why physicists speaks sometimes of Dirac, Majorana or Weyl fermions.

R2. Sadly it seems that there is no international convention on the definition and names of the above representations. It is a bit a mess and depending on the textbook you will not get the same definitions. They're also the leading causes of stress disorders amongst physicists.

Below a photo of what is assumed to be the first official detection and measurement in a Wilson bubble chamber of a positron (see [17]) by Carl David Anderson in 11933 (Holocene calendar) who shared six years later the Nobel Prize in Physics for having observed this particle with Victor Hess and that confirmed the existence of antimatter:



11.3.3.2 Free particle solution

Let us now look for solutions specific to the Dirac equation in the form of a free particle[27]:

$$\Psi=\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}=\Psi_{\vec{p}}e^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})} \tag{11.3.169}$$

---

[27] If the developments may bee to hard for the reader, he can jump straight to the case of the free particle at rest solution at page 4952

By substituting in the Dirac equation and after simplification by $e^{\mathrm{i}\vec{p}\circ\vec{r}-Et}$ we find easily:

$$\boxed{\left(\mathrm{i}\gamma^0(-\mathrm{i}E)+\mathrm{i}\sum_j\gamma^j(\mathrm{i}p_j)-m_0\right)\Psi_{\vec{p}}=\vec{0}} \tag{11.3.170}$$

Indeed in natural units:

$$\begin{aligned}
&(\mathrm{i}\gamma^\mu\partial_\mu-m_0)\,\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}=\mathrm{i}\gamma^\mu\partial_\mu\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}-m_0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\\
&=\mathrm{i}\gamma^0\partial_0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^1\partial_1\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^2\partial_2\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^3\partial_3\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}-m_0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\\
&=\mathrm{i}\gamma^0\frac{\partial}{\partial t}\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^1\frac{\partial}{\partial x}\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^2\frac{\partial}{\partial y}\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^3\frac{\partial}{\partial z}\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}-m_0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\\
&=(-\mathrm{i}E)\mathrm{i}\gamma^0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^0e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\frac{\partial}{\partial t}\Psi_{\vec{p}}\\
&+\mathrm{i}\gamma^1\frac{\partial}{\partial x}\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^2\frac{\partial}{\partial y}\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^3\frac{\partial}{\partial z}\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}-m_0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\\
&=(-\mathrm{i}E)\mathrm{i}\gamma^0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\\
&+\mathrm{i}\gamma^1\mathrm{i}p_x\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^2\mathrm{i}p_y\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^3\mathrm{i}p_z\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}-m_0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\\
&+\mathrm{i}\gamma^1e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\frac{\partial}{\partial x}\Psi_{\vec{p}}+\mathrm{i}\gamma^2e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\frac{\partial}{\partial y}\Psi_{\vec{p}}+\mathrm{i}\gamma^3e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\frac{\partial}{\partial z}\Psi_{\vec{p}}\\
&=(-\mathrm{i}E)\mathrm{i}\gamma^0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}\\
&+\mathrm{i}\gamma^1\mathrm{i}p_x\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^2\mathrm{i}p_y\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}+\mathrm{i}\gamma^3\mathrm{i}p_z\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}-m_0\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}
\end{aligned} \tag{11.3.171}$$

With the representation of Dirac, we get after development (trivial calculation that we can detail on request as always):

$$\begin{pmatrix}E-m_0 & -\vec{p}\circ\vec{\sigma}\\ \vec{p}\circ\vec{\sigma} & -E-m_0\end{pmatrix}\Psi_{\vec{p}}=\vec{0} \tag{11.3.172}$$

Or more explicitly:

$$\begin{pmatrix}(E-m_0)\mathbb{1} & -\vec{p}\circ\vec{\sigma}\\ \vec{p}\circ\vec{\sigma} & (-E-m_0)\mathbb{1}\end{pmatrix}\Psi_{\vec{p}}=\vec{0} \tag{11.3.173}$$

Indeed, with the Einstein summation convention (see section Tensor Calculus page 2044):

$$\begin{aligned}
&\left(\mathrm{i}\gamma^0(-\mathrm{i}E)+\mathrm{i}\sum_j\gamma^j(\mathrm{i}p_j)-m_0\right)\Psi_{\vec{p}}=\left(\gamma^0E-\gamma^jp_j-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}E-\begin{bmatrix}0&\sigma_1\\-\sigma_1&0\end{bmatrix}p_1-\begin{bmatrix}0&\sigma_2\\-\sigma_2&0\end{bmatrix}p_2-\begin{bmatrix}0&\sigma_3\\-\sigma_3&0\end{bmatrix}p_3-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}E&0\\0&-E\end{bmatrix}-\begin{bmatrix}0&\sigma_1p_1\\-\sigma_1p_1&0\end{bmatrix}-\begin{bmatrix}0&\sigma_2p_2\\-\sigma_2p_2&0\end{bmatrix}-\begin{bmatrix}0&\sigma_3p_3\\-\sigma_3p_3&0\end{bmatrix}-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}E&0\\0&-E\end{bmatrix}-\begin{bmatrix}0&\sigma_1p_1+\sigma_2p_2+\sigma_3p_3\\-\sigma_1p_1-\sigma_2p_2-\sigma_3p_3&0\end{bmatrix}-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}E&0\\0&-E\end{bmatrix}-\begin{bmatrix}0&\vec{p}\circ\vec{\sigma}\\-\vec{p}\circ\vec{\sigma}&0\end{bmatrix}-m_0\right)\Psi_{\vec{p}}=\left(\begin{bmatrix}E&0\\0&-E\end{bmatrix}+\begin{bmatrix}0&-\vec{p}\circ\vec{\sigma}\\\vec{p}\circ\vec{\sigma}&0\end{bmatrix}-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}E&-\vec{p}\circ\vec{\sigma}\\\vec{p}\circ\vec{\sigma}&-E\end{bmatrix}-m_0\right)\Psi_{\vec{p}}=\left(\begin{bmatrix}E&-\vec{p}\circ\vec{\sigma}\\\vec{p}\circ\vec{\sigma}&-E\end{bmatrix}\Psi_{\vec{p}}-m_0\Psi_{\vec{p}}\right)\\
&=\begin{pmatrix}E\phi_a-\vec{p}\circ\vec{\sigma}\phi_b-m_0\phi_a\\\vec{p}\circ\vec{\sigma}\phi_a-E\phi_b-m_0\phi_b\end{pmatrix}=\begin{pmatrix}\phi_a(E-m_0)-\vec{p}\circ\vec{\sigma}\phi_b\\\vec{p}\circ\vec{\sigma}\phi_a+\phi_b(-E-m_0)\end{pmatrix}=\begin{pmatrix}E-m_0&-\vec{p}\circ\vec{\sigma}\\\vec{p}\circ\vec{\sigma}&-E-m_0\end{pmatrix}\begin{pmatrix}\phi_a\\\phi_b\end{pmatrix}\\
&=\begin{pmatrix}E-m_0&-\vec{p}\circ\vec{\sigma}\\\vec{p}\circ\vec{\sigma}&-E-m_0\end{pmatrix}\Psi_{\vec{p}}=\vec{0}
\end{aligned}\tag{11.3.174}$$

In order for this matrix equation to have non-zero solutions, as usual, the determinant of the matrix must be zero (see section Linear Algebra page 1980). We easily check that:

$$\begin{aligned}
&\det\begin{pmatrix}E-m_0&-\vec{p}\circ\vec{\sigma}\\\vec{p}\circ\vec{\sigma}&-E-m_0\end{pmatrix}=(E-m_0)(-E-m_0)-(\vec{p}\circ\vec{\sigma})(-\vec{p}\circ\vec{\sigma})\\
&=-(E-m_0)(E+m_0)+\|\vec{p}\|^2=-(E^2-m_0^2)+\|\vec{p}\|^2=-E^2+m_0^2+\|\vec{p}\|^2=\vec{0}
\end{aligned}\tag{11.3.175}$$

Which implies (do not forget that we are in natural units!):

$$\boxed{E=\pm\sqrt{\|\vec{p}\|^2+m_0^2}}\tag{11.3.176}$$

Notice that coming back to our initial guess:

$$\Psi=\Psi_{\vec{p}}e^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}\tag{11.3.177}$$

The same solution with negative energy (positive charge) exist if we consider a particle going backward in time and with a negative motion such that:

$$\Psi=\Psi_{\vec{p}}e^{-\mathrm{i}(Et-\vec{p}\circ\vec{r})}=\Psi_{\vec{p}}e^{-\mathrm{i}((-E)(-t)-(-\vec{p})\circ(-\vec{r}))}\tag{11.3.178}$$

This is therefore a system of equations very funny (...) to solve....... (do not forget that each term of the above relation is implicitly a 2 × 2 matrix).

With Chirale representation we would have obtained (always by adopting the traditional notation of this textbook for the scalar product):

$$\begin{aligned}
&\left(\mathrm{i}\gamma^0(-\mathrm{i}E)+\mathrm{i}\sum_j\gamma^j(\mathrm{i}p_j)-m_0\right)\Psi_{\vec{p}}=\left(\gamma^0E-\gamma^jp_j-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}0&\mathbb{1}\\\mathbb{1}&0\end{bmatrix}E-\begin{bmatrix}0&-\sigma_1\\\sigma_1&0\end{bmatrix}p_1-\begin{bmatrix}0&-\sigma_2\\\sigma_2&0\end{bmatrix}p_2-\begin{bmatrix}0&-\sigma_3\\\sigma_3&0\end{bmatrix}p_3-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}0&E\\E&0\end{bmatrix}-\begin{bmatrix}0&-\sigma_1p_1\\\sigma_1p_1&0\end{bmatrix}-\begin{bmatrix}0&-\sigma_2p_2\\\sigma_2p_2&0\end{bmatrix}-\begin{bmatrix}0&-\sigma_3p_3\\\sigma_3p_3&0\end{bmatrix}-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}0&E\\E&0\end{bmatrix}-\begin{bmatrix}0&-\sigma_1p_1-\sigma_2p_2-\sigma_3p_3\\\sigma_1p_1+\sigma_2p_2+\sigma_3p_3&0\end{bmatrix}-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}0&E\\E&0\end{bmatrix}-\begin{bmatrix}0&-\vec{p}\circ\vec{\sigma}\\\vec{p}\circ\vec{\sigma}&0\end{bmatrix}-m_0\right)\Psi_{\vec{p}}=\left(\begin{bmatrix}0&E\\E&0\end{bmatrix}+\begin{bmatrix}0&\vec{p}\circ\vec{\sigma}\\-\vec{p}\circ\vec{\sigma}&0\end{bmatrix}-m_0\right)\Psi_{\vec{p}}\\
&=\left(\begin{bmatrix}0&\vec{p}\circ\vec{\sigma}+E\\-\vec{p}\circ\vec{\sigma}+E&0\end{bmatrix}-m_0\right)\Psi_{\vec{p}}=\left(\begin{bmatrix}0&\vec{p}\circ\vec{\sigma}+E\\-\vec{p}\circ\vec{\sigma}+E&0\end{bmatrix}\Psi_{\vec{p}}-m_0\Psi_{\vec{p}}\right)\\
&=\begin{pmatrix}0\phi_a+(\vec{p}\circ\vec{\sigma}+E)\phi_b-m_0\phi_a\\(-\vec{p}\circ\vec{\sigma}+E)\phi_a+0\phi_b-m_0\phi_b\end{pmatrix}=\begin{pmatrix}-m_0\phi_a+(\vec{p}\circ\vec{\sigma}+E)\phi_b\\(-\vec{p}\circ\vec{\sigma}+E)\phi_a-m_0\phi_b\end{pmatrix}=\begin{pmatrix}-m_0&\vec{p}\circ\vec{\sigma}+E\\-\vec{p}\circ\vec{\sigma}+E&-m_0\end{pmatrix}\begin{pmatrix}\phi_a\\\phi_b\end{pmatrix}\\
&=\begin{pmatrix}-m_0&\vec{p}\circ\vec{\sigma}+E\\-\vec{p}\circ\vec{\sigma}+E&-m_0\end{pmatrix}\Psi_{\vec{p}}=\vec{0}
\end{aligned}\tag{11.3.179}$$

Since the mass seems always positive, the Dirac equation thus has four linearly independent solutions, two of which have positive energy:

$$E=E_{\vec{p}}=\sqrt{\|\vec{p}\|^2+m_0^2}\tag{11.3.180}$$

and two with negative energy:

$$E=-E_{\vec{p}}\tag{11.3.181}$$

It is therefore indeed the antiparticles that we had determined during our study of the free Klein-Gordon equation but with the spin in addition, hence the doubling of the additional solutions (two possible spin orientations per particle and by antiparticle). With the Chirale representation, we would not have fallen back on this result. Hence the necessity of the use of the representation of Dirac of the Pauli matrices.

We therefore know that there are solutions to the Dirac equation. Let us now determine these. Let us put:

$$\Psi_{\vec{p}}=\begin{pmatrix}\phi_a\\\phi_b\end{pmatrix}\tag{11.3.182}$$

where ϕ_a, ϕ_b are for recall the two double components of the spinor. We thus write the system of equations:

$$\begin{aligned}(E-m_0)\phi_a-\vec{p}\circ\vec{\sigma}\phi_b&=\vec{0}\\\vec{p}\circ\vec{\sigma}\phi_a-(E+m_0)\phi_b&=\vec{0}\end{aligned}\tag{11.3.183}$$

which gives us (do not forget that the term to the denominator is actually a 2×2 matrix...):

$$\boxed{\phi_b=\frac{\vec{p}\circ\vec{\sigma}}{(E+m_0)}\phi_a}\quad\text{and}\quad\boxed{\phi_a=\frac{\vec{p}\circ\vec{\sigma}}{(E-m_0)}\phi_b}\tag{11.3.184}$$

Thus, we have:

$$\Psi_{\vec{p}}=\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=\begin{pmatrix}\phi_a\\ \dfrac{\vec{p}\circ\vec{\sigma}}{(E+m_0)}\phi_a\end{pmatrix}=\begin{pmatrix}\dfrac{\vec{p}\circ\vec{\sigma}}{(E-m_0)}\phi_b\\ \phi_b\end{pmatrix} \tag{11.3.185}$$

We know that solutions exist and Quantum Physics imposes that these solutions are linearly independent. Thus, let us choose the solutions for ϕ_a, ϕ_b as being proportional to:

$$\phi_a,\phi_b=\begin{pmatrix}1\\0\end{pmatrix} \quad \text{or} \quad \phi_a,\phi_b=\begin{pmatrix}0\\1\end{pmatrix} \tag{11.3.186}$$

and as (see section Spinor Calculus page 2158):

$$\vec{p}\circ\vec{\sigma}=\begin{bmatrix}p_z & p_x-\mathrm{i}p_y\\ p_x+\mathrm{i}p_y & -p_z\end{bmatrix} \tag{11.3.187}$$

We then have the following possibilities:

$$\begin{aligned}
&(1)\quad \phi_a=\begin{pmatrix}1\\0\end{pmatrix}\Rightarrow\phi_b=\frac{\vec{p}\circ\vec{\sigma}}{E+m_0}\phi_a=\frac{\vec{p}\circ\vec{\sigma}}{E+m_0}\begin{pmatrix}1\\0\end{pmatrix}=\frac{1}{E+m_0}\begin{pmatrix}p_z\\p_+\end{pmatrix}\qquad p_\pm=p_x\pm\mathrm{i}p_y\\
&(2)\quad \phi_a=\begin{pmatrix}0\\1\end{pmatrix}\Rightarrow\phi_b=\frac{\vec{p}\circ\vec{\sigma}}{E+m_0}\phi_a=\frac{\vec{p}\circ\vec{\sigma}}{E+m_0}\begin{pmatrix}0\\1\end{pmatrix}=\frac{1}{E+m_0}\begin{pmatrix}p_-\\-p_z\end{pmatrix}\\
&(3)\quad \phi_b=\begin{pmatrix}1\\0\end{pmatrix}\Rightarrow\phi_a=\frac{\vec{p}\circ\vec{\sigma}}{E-m_0}\phi_b=\frac{\vec{p}\circ\vec{\sigma}}{E-m_0}\begin{pmatrix}1\\0\end{pmatrix}=\frac{1}{E-m_0}\begin{pmatrix}p_z\\p_+\end{pmatrix}\\
&(4)\quad \phi_b=\begin{pmatrix}0\\1\end{pmatrix}\Rightarrow\phi_a=\frac{\vec{p}\circ\vec{\sigma}}{E-m_0}\phi_b=\frac{\vec{p}\circ\vec{\sigma}}{E-m_0}\begin{pmatrix}0\\1\end{pmatrix}=\frac{1}{E-m_0}\begin{pmatrix}p_-\\-p_z\end{pmatrix}
\end{aligned} \tag{11.3.188}$$

The question is now ... should we use:

$$E=+\sqrt{\|\vec{p}\|^2+m_0^2} \qquad \text{or} \qquad E=-\sqrt{\|\vec{p}\|^2+m_0^2} \tag{11.3.189}$$

Well, for (1) and (2) above we must use $E=+\sqrt{\ldots}$ otherwise $1/(E+m_0)$ becomes a singularity for $\vec{p}=\vec{0}$. For (3) and (4) we must use $E=-\sqrt{\ldots}$ otherwise $1/(E-m_0)$ becomes a singularity for $\vec{p}=\vec{0}$.

Remark

The term $E=+\sqrt{\ldots}$ is often referred to as the "particle solution" in the literature and $E=-\sqrt{\ldots}$ as the "antiparticle solution". The interpretation of this result as an antiparticle would sometimes be named as we already mentioned the "Feynman-Stückelberg inter-operation".

Going back to:

$$\Psi_{\vec{p}}=\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix} \tag{11.3.190}$$

and noting the spinors by (we change the notation to come back to the original one):

$$\chi^{(+)}=\begin{pmatrix}1\\0\end{pmatrix},\chi^{(-)}=\begin{pmatrix}0\\1\end{pmatrix} \tag{11.3.191}$$

We finally have using (1) and (2) and by denoting $N()$ the part of the solution we should normalize (see page 4972), the following possible solutions and which are independent:

$$\Psi_{\vec{p}}^{(1)}=N\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}1\\0\end{pmatrix}\\ \begin{pmatrix}\dfrac{p_z}{E+m_0}\\ \dfrac{p_+}{E+m_0}\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}1\\ \dfrac{\vec{p}\circ\vec{\sigma}}{E+m_0}\end{pmatrix}\chi^{(+)} \tag{11.3.192}$$

$$\Psi_{\vec{p}}^{(2)}=N\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}0\\1\end{pmatrix}\\ \begin{pmatrix}\dfrac{p_-}{E+m_0}\\ \dfrac{-p_z}{E+m_0}\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}1\\ \dfrac{\vec{p}\circ\vec{\sigma}}{E+m_0}\end{pmatrix}\chi^{(-)} \tag{11.3.193}$$

with $E=+\sqrt{\ldots}$ and also:

$$\Psi_{\vec{p}}^{(3)}=N\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}\dfrac{p_z}{E-m_0}\\ \dfrac{p_+}{E-m_0}\end{pmatrix}\\ \begin{pmatrix}1\\0\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}\dfrac{\vec{p}\circ\vec{\sigma}}{E-m_0}\\ 1\end{pmatrix}\chi^{(+)} \tag{11.3.194}$$

$$\Psi_{\vec{p}}^{(4)}=N\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}\dfrac{p_-}{E-m_0}\\ \dfrac{-p_z}{E-m_0}\end{pmatrix}\\ \begin{pmatrix}0\\1\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}\dfrac{\vec{p}\circ\vec{\sigma}}{E-m_0}\\ 1\end{pmatrix}\chi^{(-)} \tag{11.3.195}$$

with $E=-\sqrt{\ldots}$. It is from usage to conventionally associate the two above functions to the "positron" (the positron is used in Hospitals in PET scans - Positron Emission Topography - that is an imaging technique that can help reveal the metabolic or biochemical function of tissues and organs and hence check for signs of cancer, heart disease and brain disorders).

All this can be abbreviated globally:

$$\boxed{\Psi_{E_+}^{(\pm)}(\vec{p})=N\begin{pmatrix}1\\ \dfrac{\vec{p}\circ\vec{\sigma}}{E+m_0}\end{pmatrix}\chi^{(\pm)},\ \Psi_{E_-}^{(\pm)}(\vec{p})=N\begin{pmatrix}\dfrac{\vec{p}\circ\vec{\sigma}}{E-m_0}\\ 1\end{pmatrix}\chi^{(\pm)}} \tag{11.3.196}$$

Let us indicate that the term $\vec{p}\circ\vec{\sigma}$ is therefore the projection of the momentum (momentum) on a mathematical entity directly related to the spin is named "helicity" and defined by:

$$\boxed{\hat{h}=\vec{p}\circ\vec{\sigma}} \tag{11.3.197}$$

Antiparticles have therefore opposite charge and opposite chirality/helicity!

11.3.3.3 Free particle solution at rest

We start again from:

$$\Psi=\Psi_{\vec{p}}e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)}=\Phi_0(\vec{p},E)e^{\mathrm{i}(\vec{p}\circ\vec{r}-Et)} \tag{11.3.198}$$

Let us consider the derivatives of the free particle solution above:

$$\partial_0\Psi=\frac{\partial\Psi}{\partial t}=-\mathrm{i}E\Psi \qquad \partial_x\Psi=\frac{\partial\Psi}{\partial x}=\mathrm{i}p_x\Psi \qquad \ldots \tag{11.3.199}$$

Substituting these into the Dirac equation gives:

$$(\gamma^0E-\gamma^1p_x-\gamma^2p_y-\gamma_3p_z-m)\Psi_0=\vec{0} \tag{11.3.200}$$

which can be written:

$$(\gamma^\mu p_\mu-m)\Psi_0=\vec{0} \tag{11.3.201}$$

This is the Dirac equation in "momentum" – note it contains no derivatives.

For a particle at rest $\vec{p}=\vec{0}$ then:

$$\Psi=\Psi_0(E,\vec{0})e^{-\mathrm{i}Et} \tag{11.3.202}$$

Hence the Dirac equation reduces to:

$$E\gamma^0\Psi_0-m\Psi_0=\vec{0} \tag{11.3.203}$$

Explicitly:

$$E\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&-1\end{bmatrix}\begin{pmatrix}\phi_1\\\phi_2\\\phi_3\\\phi_4\end{pmatrix}=m\begin{pmatrix}\phi_1\\\phi_2\\\phi_3\\\phi_4\end{pmatrix} \tag{11.3.204}$$

We see quite immediately that this equation has for independent orthogonal solutions:

$$\Psi_{0,1}(m,0)=\begin{pmatrix}1\\0\\0\\0\end{pmatrix},\Psi_{0,2}(m,0)=\begin{pmatrix}0\\1\\0\\0\end{pmatrix},\Psi_{0,3}(m,0)=\begin{pmatrix}0\\0\\1\\0\end{pmatrix},\Psi_{0,4}(m,0)=\begin{pmatrix}0\\0\\0\\1\end{pmatrix} \tag{11.3.205}$$

The two first solutions leads us to:

$$\left.\begin{aligned}\Psi_{0,1}(m,0)&=\begin{pmatrix}1\\0\\0\\0\end{pmatrix}\\\Psi_{0,2}(m,0)&=\begin{pmatrix}0\\1\\0\\0\end{pmatrix}\end{aligned}\right\}\Rightarrow E=m \tag{11.3.206}$$

And the last two lead us to:

$$\left.\begin{aligned}\Psi_{0,3}(m,0)&=\begin{pmatrix}0\\0\\1\\0\end{pmatrix}\\ \Psi_{0,4}(m,0)&=\begin{pmatrix}0\\0\\0\\1\end{pmatrix}\end{aligned}\right\}\Rightarrow E=-m \tag{11.3.207}$$

So we still have negative energy solutions (antiparticles)!

Including the time dependence from $\Psi=\Psi_0(E,\vec{0})e^{-\mathrm{i}Et}$ gives:

$$\Psi_1=\begin{pmatrix}1\\0\\0\\0\end{pmatrix}e^{-\mathrm{i}mt},\Psi_2=\begin{pmatrix}0\\1\\0\\0\end{pmatrix}e^{-\mathrm{i}mt},\Psi_3=\begin{pmatrix}0\\0\\1\\0\end{pmatrix}e^{+\mathrm{i}mt},\Psi_4=\begin{pmatrix}0\\0\\0\\1\end{pmatrix}e^{+\mathrm{i}mt} \tag{11.3.208}$$

We therefore have two spin states with $E>0$ and two spin states with $E<0$. More explicitly, Φ_1 then describes an $S=\frac{1}{2}$ (in Planck units) fermion of mass m with spin ↑, Φ_2 describes an $S=\frac{1}{2}$ (in Planck units) fermion of mass m with spin ↓, Φ_3 describes an $S=\frac{1}{2}$ (in Planck units) antifermion of mass m with spin ↑, Φ_4 describes an $S=\frac{1}{2}$ (in Planck units) antifermion of mass m with spin ↓.

In quantum physics we can't just discard the $E<0$ solutions as unphysical as we require a complete set of states, i.e. four solutions!

We can also see something important! The antiparticle solution is the complex conjugate of the particle solution! Keep this in mind for when we will study the Majorana equation later!

For information the reader can check that if we take back the relations proved earlier:

$$\Psi_{\vec{p}}^{(1)}=N\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}1\\0\end{pmatrix}\\ \begin{pmatrix}\dfrac{p_z}{E+m_0}\\ \dfrac{p_+}{E+m_0}\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}1\\ \dfrac{\vec{p}\circ\vec{\sigma}}{E+m_0}\end{pmatrix}\chi^{(+)} \tag{11.3.209}$$

$$\Psi_{\vec{p}}^{(2)}=N\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}0\\1\end{pmatrix}\\ \begin{pmatrix}\dfrac{p_-}{E+m_0}\\ \dfrac{-p_z}{E+m_0}\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}1\\ \dfrac{\vec{p}\circ\vec{\sigma}}{E+m_0}\end{pmatrix}\chi^{(-)} \tag{11.3.210}$$

$$\Psi_{\vec{p}}^{(3)}=N\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}\dfrac{p_z}{E-m_0}\\ \dfrac{p_+}{E-m_0}\end{pmatrix}\\ \begin{pmatrix}1\\0\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}\dfrac{\vec{p}\circ\vec{\sigma}}{E-m_0}\\ 1\end{pmatrix}\chi^{(+)} \tag{11.3.211}$$

$$\Psi_{\bar{p}}^{(4)}=N\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}\dfrac{p_-}{E-m_0}\\ \dfrac{-p_z}{E-m_0}\end{pmatrix}\\ \begin{pmatrix}0\\ 1\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}\dfrac{\vec{p}\circ\vec{\sigma}}{E-m_0}\\ 1\end{pmatrix}\chi^{(-)} \tag{11.3.212}$$

and we put $\vec{p}=\vec{0}$ we fall back on the same type of spinors as we just get above!

11.3.3.4 Majorana equation

An electrically charged particle is different from its antiparticles as it has the opposite electric charge, and electric charge is a measurable, stable property. It is possible, however, for an electrically neutral particle to be its own antiparticle. Photons, which have spin 1 (in units of the rationalized Planck's constant $\hbar$) are a familiar case; neutral ions (spin 0) are a further example, and gravitons (spin 2) another speculated one! Particles that are their own antiparticles must be created by field Ψ that obey:

$$\Psi=\Psi^{\dagger} \tag{11.3.213}$$

that is... real fields (!), because the complex-conjugate field $\Psi^{\dagger}$ create their antiparticles.

The equations for particles with spin 0, spin 1 and spin 2 - the Klein-Gordon, Maxwell (electromagnetism) and Einstein field equations (General Relativity) respectively - readily accommodate real fields, as these equations are formulated using real numbers.

Indeed, when in 11928 (holocene calendar), Paul Dirac discovered the theoretical framework for describing spin-$1/2$ particles, it seemed that complex numbers were unavoidable. Dirac's original equation contained both real and imaginary numbers, and therefore it can only pertain to complex fields. For Dirac, who was concerned with describing electrons, this feature posed no problem, and even came to seem an advantage because it explained why positrons, the antiparticles of electrons, exist.

Enters Ettore Majorana! In his 11937 (holocene calendar) paper, Majorana posed, and answered, the question of whether equations for spin-$1/2$ fields must necessarily, like Dirac's original equation, involve complex numbers.

Considerations of mathematical elegance and symmetry both motivated and guided his investigation. Majorana discovered that, to the contrary, there is a simple, clever modification of Dirac's equation that involves only real numbers. With this discovery, Majorana made the idea that spin-$1/2$ particles could be their own antiparticles theoretically respectable, that is, consistent with the general principles of relativity and quantum theory.

Majorana inquired whether it might be possible for a spin-$1/2$ particle to be its own antiparticle, by attempting to find the equation that such an object would satisfy. To get an equation of Dirac's type (that is, suitable for spin-$1/2$) but capable of governing a real field, required γ matrices that are purely imaginary!

These matrices that we have already introduced earlier and named the "Majorana representation" are defined by:

$$\gamma_M^0=\beta_M=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&-\mathrm{i}&0\\0&\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix},\gamma_M^1=\begin{bmatrix}0&-\mathrm{i}&0&0\\-\mathrm{i}&0&0&0\\0&0&0&\mathrm{i}\\0&0&\mathrm{i}&0\end{bmatrix},\gamma_M^2=\begin{bmatrix}-\mathrm{i}&0&0&0\\0&\mathrm{i}&0&0\\0&0&-\mathrm{i}&0\\0&0&0&\mathrm{i}\end{bmatrix},\gamma_M^3=\begin{bmatrix}0&0&0&\mathrm{i}\\0&0&\mathrm{i}&0\\0&\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix}\tag{11.3.214}$$

And we know that the Majorana matrices in the representation above obey also the following mandatory gamma anticommutation relations (as so far we don't know the β and α_i corresponding Majorana matrices for recall!) as seen at page 4963:

$$[\gamma_i,\gamma_j]_+=\gamma_i\gamma_j+\gamma_j\gamma_i=2\eta_{ij}\mathbb{1}_4\tag{11.3.215}$$

Thus, for $i\neq j$:

$$[\gamma_i,\gamma_j]_+=\gamma_i\gamma_j+\gamma_j\gamma_i=0\tag{11.3.216}$$

and it is also immediate using this anticommutation relation that:

$$(\gamma^0)^2=1,(\gamma^i)^2=-1\tag{11.3.217}$$

Another purely imaginary representation of the Majorana matrices quite common in the literature is also as we know given by:

$$\begin{gathered}\tilde{\gamma}_M^0=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&\mathrm{i}&0\\0&-\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix}=\begin{bmatrix}0&\sigma_2\\\sigma_2&0\end{bmatrix},\tilde{\gamma}_M^1=\begin{bmatrix}\mathrm{i}&0&0&0\\0&-\mathrm{i}&0&0\\0&0&\mathrm{i}&0\\0&0&0&-\mathrm{i}\end{bmatrix}=\mathrm{i}\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}\\\tilde{\gamma}_M^2=\begin{bmatrix}0&0&0&\mathrm{i}\\0&0&-\mathrm{i}&0\\0&-\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix}=\begin{bmatrix}0&-\sigma_2\\\sigma_2&0\end{bmatrix},\tilde{\gamma}_M^3=\begin{bmatrix}0&-\mathrm{i}&0&0\\-\mathrm{i}&0&0&0\\0&0&0&-\mathrm{i}\\0&0&-\mathrm{i}&0\end{bmatrix}=-\mathrm{i}\begin{bmatrix}\sigma_1&0\\0&\sigma_1\end{bmatrix}\end{gathered}\tag{11.3.218}$$

That latter Majorana representation can be obtained from the original representation by the unitary transformation:

$$\tilde{\gamma}_M^\mu=\tilde{U}\gamma_M^\mu\tilde{U}^{-1}\quad\text{and}\quad\tilde{U}=\frac{1}{2}=\begin{bmatrix}1&1&1&-1\\-1&1&1&1\\1&1&-1&1\\1&-1&1&1\end{bmatrix}\tag{11.3.219}$$

There is alsoooooo again as we already know another Majorana representation also denoted identically as previously (sic!) and defined by:

$$\tilde{\gamma}_M^0=\sigma_2\otimes\sigma_1,\tilde{\gamma}_M^1=\mathrm{i}\sigma_1\otimes\mathbb{1},\tilde{\gamma}_M^2=\mathrm{i}\sigma_3\otimes\mathbb{1},\tilde{\gamma}_M^3=\mathrm{i}\sigma_2\otimes\sigma_2\tag{11.3.220}$$

That is explicitly:

$$\tilde{\gamma}_M^0=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&-\mathrm{i}&0\\0&\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix},\tilde{\gamma}_M^1=\begin{bmatrix}0&0&\mathrm{i}&0\\0&0&0&\mathrm{i}\\\mathrm{i}&0&0&0\\0&\mathrm{i}&0&0\end{bmatrix},\tilde{\gamma}_M^2=\begin{bmatrix}\mathrm{i}&0&0&0\\0&\mathrm{i}&0&0\\0&0&-\mathrm{i}&0\\0&0&0&-\mathrm{i}\end{bmatrix},\tilde{\gamma}_M^3=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&\mathrm{i}&0\\0&\mathrm{i}&0&0\\-\mathrm{i}&0&0&0\end{bmatrix}\tag{11.3.221}$$

This representation has the interesting property that all matrices γ^μ are pure imaginary what make the Dirac fields of the Dirac equation a non-complex field where the particles are therefore their own antiparticles.

Indeed, the "Majorana's equation", then, is simply:

$$\boxed{(\mathrm{i}\tilde{\gamma}^\mu\partial_\mu - m_0)\Psi^\dagger = \vec{0}} \tag{11.3.222}$$

Because the $\tilde{\gamma}^\mu$ matrices are purely imaginary, the matrices $\mathrm{i}\tilde{\gamma}^\mu$ are real, and consequently this equation can govern a real field $\tilde{\Psi}$.

Particles corresponding to Majorana spinors are known as "Majorana particles", due to the above self-conjugacy constraint. All the fermions included in the Standard Model have been excluded as Majorana fermions (since they have non-zero electric charge they cannot be antiparticles of themselves) with the exception of the neutrino (which is neutral).

Theoretically, the neutrino is a possible exception to this pattern. If so, neutrinoless double-beta decay, as well as a range of lepton-number violating meson and charged lepton decays, are possible. A number of experiments probing whether the neutrino is a Majorana particle are currently (year 12017 according to holocene calendar) underway.

11.3.4 Linearised Dirac Equation

We saw at the beginning of our study of Wave Quantum Physics that the classic Schrödinger equation of evolution was:

$$\mathrm{i}\hbar\partial_t\Psi = \left(E_\mathrm{p} - \frac{\hbar}{2m}\Delta\right)\Psi \tag{11.3.223}$$

ie a differential equation of the first order with respect to time and the second with respect to the spatial coordinates.

We had then determined the relativistic Schrödinger equation of evolution (free Klein-Gordon equation) given by:

$$\hbar^2\partial_t^2\Psi = \left(\hbar^2c^2\Delta - m_0^2c^4\Delta\right)\Psi \tag{11.3.224}$$

We notice that by passing to a relativistic form, we now have a differential equation of the second order in time AND space.

Then through the generalized Klein-Gordon equation which also contained a second-order differential equation in time and space:

$$\left[(\mathrm{i}\hbar\partial_t - qU)^2 - (-\mathrm{i}\hbar\vec{\nabla} - q\vec{A})^2c^2\right]\Psi = m_0^2c^4\Psi \tag{11.3.225}$$

and with the free Dirac equation we have just proved that we get in the same way a matrix differential equation of first order in time and second order in space:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\begin{bmatrix}\Psi_a\\ \Psi_b\end{bmatrix} = \begin{bmatrix} m_0c^2 - \dfrac{\hbar^2}{2m_0}\Delta & -\dfrac{\hbar^2}{2m_0}\Delta \\ \dfrac{\hbar^2}{2m_0}\Delta & -m_0c^2 + \dfrac{\hbar^2}{2m_0}\Delta \end{bmatrix}\begin{bmatrix}\Psi_a\\ \Psi_b\end{bmatrix} \tag{11.3.226}$$

These changes of order of the differentials of a relativistic model or not impose of course in the case of a first order to know the initial conditions in time and space of the wave equation, which is feasible. However, when a second order appears, it is necessary to know more about the initial conditions of the derivatives of the wave functions (see section Differential and Integral Calculus page 1605). Moreover, even if mathematically the (relative) rigour naturally led us to the different orders obtained, it is strange that changing to a relativist model that we change order of the differentials. Why?: For the quite simple reason that by approximating the relativistic equations we are not able because of the presence of the Planck constant factor to make approximations (development in series of v/c) that would bring us back to the first order. The relativistic and non-relativistic equations seems then a priori incompatible within the non relativistic limits!

The Dirac method to solve this problem will have been the following:

The orders of the Klein-Gordon differential equation coming from the relation of the total energy (see the beginnings of our developments of the free Klein-Gordon equation) in the absence of any field:

$$\begin{aligned}E^2 &= m_0^2c^4 + c^2\|\vec{p}\|^2 = m_0^2c^4 + c^2p_x^2 + c^2p_y^2 + c^2p_z^2 = m_0^2c^4 + c^2p_1^2 + c^2p_2^2 + c^2p_3^2\\ &= m_0^2c^4 + c^2(p_1^2 + p_2^2 + p_3^2) = H^2\end{aligned} \tag{11.3.227}$$

It seems that Dirac would have had the brilliant idea of linearising this Hamiltonian by putting (sadly we don't know how he get this idea):

$$\boxed{H_D = \beta m_0 c^2 + c\alpha_1 p_1 + c\alpha_2 p_2 + c\alpha_3 p_3 = \beta m_0 c^2 + c\vec{\alpha} \circ \vec{p}} \tag{11.3.228}$$

which we will have to determine the parameters β, $\alpha(\alpha_1, \alpha_2, \alpha_3)$ which can be scalars, vectors or matrices (wait a little ... the answer will come). It follows that the Hamiltonian is also a scalar, a vector, or a matrix.

Thus, the simplest relativistic evolution wave equation that we can construct will be:

$$\mathrm{i}\hbar\partial_t \Psi = H\Psi \Rightarrow \mathrm{i}\hbar\partial_t \Psi = H_D \Psi \Rightarrow \mathrm{i}\hbar\partial_t \Psi = (\beta m_0 c^2 + c\vec{\alpha} \circ \vec{p})\Psi \tag{11.3.229}$$

In a much more common form in the literature:

$$\boxed{(\mathrm{i}\hbar\partial_t - \beta m_0 c^2 - c\vec{\alpha} \circ \vec{p})\Psi = 0} \tag{11.3.230}$$

Or also:

$$\boxed{(c\vec{\alpha} \circ \vec{p} + \beta m_0 c^2)\Psi = \mathrm{i}\hbar\partial_t \Psi} \tag{11.3.231}$$

Or in natural units:

$$\boxed{(\vec{\alpha} \circ \vec{p} + \beta m_0)\Psi = \mathrm{i}\hbar\partial_t \Psi} \tag{11.3.232}$$

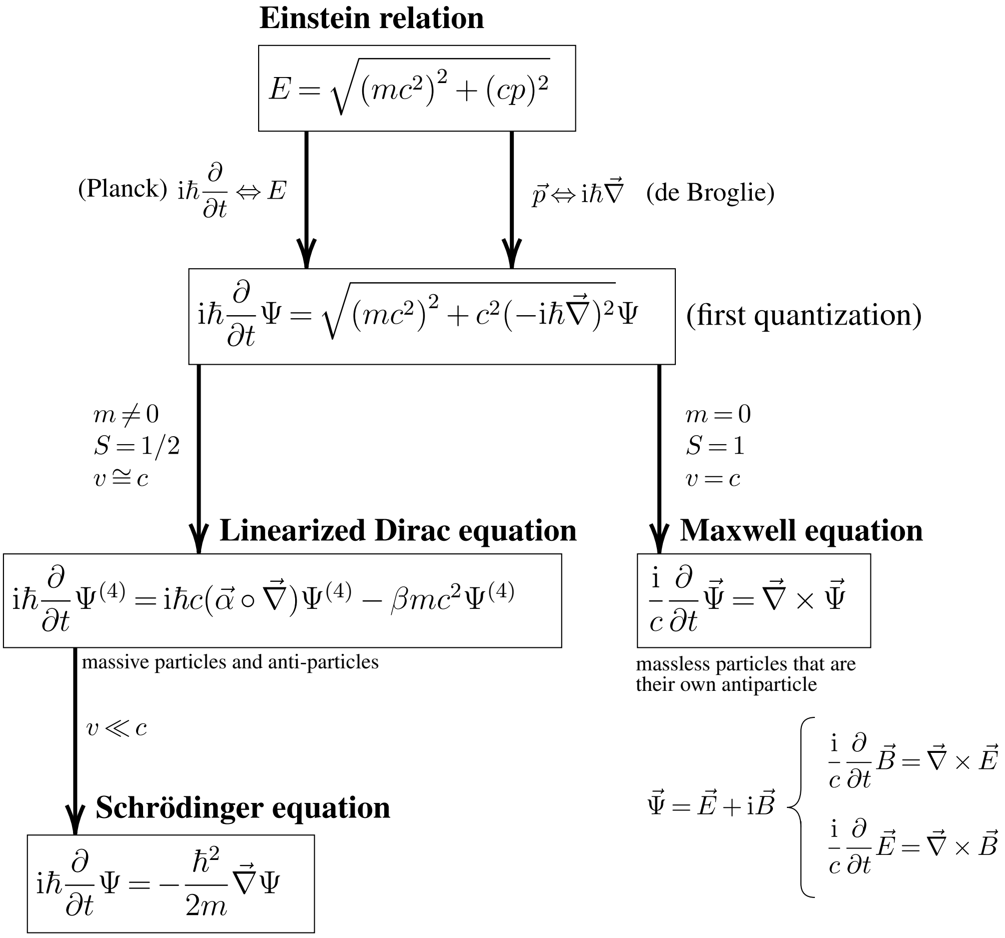
As here:

$$\vec{p} = -\mathrm{i}\hbar\vec{\nabla} \tag{11.3.233}$$

we find then the prior-previous relation also in the form:

$$\boxed{(\mathrm{i}\hbar\partial_t - \mathrm{i}\hbar c\vec{\alpha} \circ \vec{\nabla} + \beta m_0 c^2)\Psi = 0} \tag{11.3.234}$$

So now we have complete the full path of relationships visible in the figure below:



Einstein relation
$E=\sqrt{(mc^2)^2+(cp)^2}$
(Planck) $\mathrm{i}\hbar\frac{\partial}{\partial t}\Leftrightarrow E$
$\vec{p}\Leftrightarrow \mathrm{i}\hbar\vec{\nabla}$ (de Broglie)
$\mathrm{i}\hbar\frac{\partial}{\partial t}\Psi=\sqrt{(mc^2)^2+c^2(-\mathrm{i}\hbar\vec{\nabla})^2}\Psi$
(first quantization)
$m\neq 0$
$S=1/2$
$v\cong c$
$m=0$
$S=1$
$v=c$
Linearized Dirac equation
$\mathrm{i}\hbar\frac{\partial}{\partial t}\Psi^{(4)}=\mathrm{i}\hbar c(\vec{\alpha}\circ\vec{\nabla})\Psi^{(4)}-\beta mc^2\Psi^{(4)}$
massive particles and anti-particles
$v\ll c$
Maxwell equation
$\frac{\mathrm{i}}{c}\frac{\partial}{\partial t}\vec{\Psi}=\vec{\nabla}\times\vec{\Psi}$
massless particles that are their own antiparticle
$\vec{\Psi}=\vec{E}+\mathrm{i}\vec{B}$
$\frac{\mathrm{i}}{c}\frac{\partial}{\partial t}\vec{B}=\vec{\nabla}\times\vec{E}$
$\frac{\mathrm{i}}{c}\frac{\partial}{\partial t}\vec{E}=\vec{\nabla}\times\vec{B}$
Schrödinger equation
$\mathrm{i}\hbar\frac{\partial}{\partial t}\Psi=-\frac{\hbar^2}{2m}\vec{\nabla}\Psi$

Figure 11.83: **Relationships between most famous quantum physics equations**

If the linear momentum were to be zero, we would thus fall back on the energy at rest for the Hamiltonian:

$$\mathrm{i}\hbar\partial_t\Psi=\beta m_0c^2\Psi \tag{11.3.235}$$

where as we shall see later $\beta=\pm 1$.

The validity of this linearisation must be verified by falling back on the results obtained during our previous study of the Dirac equation.

Let us now raise the operator to the square:

$$H_D^2=(\beta m_0c^2+c\alpha_1p_1+c\alpha_2p_2+c\alpha_3p_3)^2 \tag{11.3.236}$$

and let us put:

$$A=(\beta m_0c^2+c\alpha_1p_1)\quad\text{and}\quad B=(c\alpha_2p_2+c\alpha_3p_3) \tag{11.3.237}$$

At this point, it is important to notice that we may be working with operators (typically matrices) that might not commute because the α, β are unknown. Therefore, the squaring will be done as follows:

$$H_D^2=(A+B)^2=A^2+B^2+AB+BA \tag{11.3.238}$$

Thus simply developed but without simplifying the sum $AB+BA$ into a $2AB$ or a $2BA$ since we are not sure for now if they will be commutativity or not.

We therefore develop the Dirac Hamiltonian:

$$\begin{aligned}H_D^2=&(\beta^2m_0^2c^4+c^2\alpha_1^2p_1^2+\beta m_0c^2\cdot c\alpha_1p_1+c\alpha_1p_1\beta m_0c^2)\\&+(c^2\alpha_2^2p_2^2+c^2\alpha_3^2p_3^2+c^2\alpha_2p_2\cdot c^2\alpha_3p_3+c^2\alpha_3p_3\cdot c^2\alpha_2p_2)\\&+(\beta m_0c^2+c\alpha_1p_1)(c\alpha_2p_2+c\alpha_3p_3)+(c\alpha_2p_2+c\alpha_3p_3)(\beta m_0c^2+c\alpha_1p_1)\end{aligned}\tag{11.3.239}$$

By making the products of the terms in brackets and respecting the order of the operators, it comes:

$$\begin{aligned}H_D^2=&\underbrace{\beta^2m_0^2c^4}_{1}+\underbrace{c^2\alpha_1^2p_1^2}_{2}+\underbrace{m_0c^3\beta\alpha_1p_1}_{11}+\underbrace{m_0c^3\alpha_1p_1\beta}_{12}+\underbrace{c^2\alpha_2^2p_2^2}_{3}+\underbrace{c^2\alpha_3^2p_3^2}_{4}\\&+\underbrace{c^2\alpha_2p_2\alpha_3p_3}_{9}+\underbrace{c^2\alpha_3p_3\alpha_2p_2}_{10}+\underbrace{m_0c^3\beta\alpha_2p_2}_{13}+\underbrace{m_0c^3\beta\alpha_3p_3}_{15}+\underbrace{c^2\alpha_1p_1\alpha_2p_2}_{5}\\&+\underbrace{c^2\alpha_1p_1\alpha_3p_3}_{7}+\underbrace{m_0c^3\alpha_2p_2\beta}_{14}+\underbrace{c^2\alpha_2p_2\alpha_1p_1}_{6}+\underbrace{m_0c^3\alpha_3p_3\beta}_{16}+\underbrace{c^2\alpha_3p_3\alpha_1p_1}_{8}\end{aligned}\tag{11.3.240}$$

By grouping certain terms:

$$\begin{aligned}H_D^2=&\underbrace{\beta^2m_0^2c^4}_{1}+c^2\left(\underbrace{\alpha_1^2p_1^2}_{2}+\underbrace{\alpha_2^2p_2^2}_{3}+\underbrace{\alpha_3^2p_3^2}_{4}\right)+c^2\left(\underbrace{\alpha_1\alpha_2}_{5}+\underbrace{\alpha_2\alpha_1}_{6}\right)p_1p_2\\&+c^2\left(\underbrace{\alpha_1\alpha_3}_{7}+\underbrace{\alpha_3\alpha_1}_{8}\right)p_1p_3+c^2\left(\underbrace{\alpha_2\alpha_3}_{9}+\underbrace{\alpha_3\alpha_2}_{10}\right)p_2p_3+m_0c^3\left(\underbrace{\beta\alpha_1}_{11}+\underbrace{\alpha_1\beta}_{12}\right)p_1+\\&+m_0c^3\left(\underbrace{\beta\alpha_2}_{13}\ \underbrace{\alpha_2\beta}_{14}\right)p_2+m_0c^3\left(\underbrace{\beta\alpha_3}_{15}+\underbrace{\alpha_3\beta}_{16}\right)p_3\end{aligned}\tag{11.3.241}$$

To be consistent with our linearisation assumptions, we must have:

$$\begin{aligned}&1\rightarrow\beta^2m_0^2c^4\equiv m_0^2c^4\Rightarrow\beta^2=1\\&2,3,4\rightarrow c^2(\alpha_1^2p_1^2+\alpha_2^2p_2^2+\alpha_3^2p_3^2)\equiv c^2(p_1^2+p_2^2+p_3^2)\Rightarrow\alpha_1^2=\alpha_2^2=\alpha_3^2=1\\&5,6\rightarrow c^2(\alpha_1\alpha_2+\alpha_2\alpha_1)p_1p_2=0\Rightarrow\alpha_1\alpha_2+\alpha_2\alpha_1=0\\&7,8\rightarrow c^2(\alpha_1\alpha_3+\alpha_3\alpha_1)p_1p_3=0\Rightarrow\alpha_1\alpha_3+\alpha_3\alpha_1=0\\&9,10\rightarrow c^2(\alpha_2\alpha_3+\alpha_3\alpha_2)p_2p_3=0\Rightarrow\alpha_2\alpha_3+\alpha_3\alpha_2=0\\&11,12\rightarrow m_0c^3(\beta\alpha_1+\alpha_1\beta)p_1=0\Rightarrow\beta\alpha_1+\alpha_1\beta=0\\&13,14\rightarrow m_0c^3(\beta\alpha_2+\alpha_2\beta)p_2=0\Rightarrow\beta\alpha_2+\alpha_2\beta=0\\&15,16\rightarrow m_0c^3(\beta\alpha_3+\alpha_3\beta)p_3=0\Rightarrow\beta\alpha_3+\alpha_3\beta=0\end{aligned}\tag{11.3.242}$$

and we will see immediately that to satisfy these conditions the α, β will have to be 4×4 matrices.

Written in the form of commutators, we therefore have the following three conditions to satisfy:

$$\boxed{\begin{aligned}&\beta^2=\alpha_1^2=\alpha_2^2=\alpha_3^2=1\\&[\alpha_1,\alpha_2]_+=[\alpha_1,\alpha_3]_+=[\alpha_2,\alpha_3]_+=0\\&[\alpha_1,\beta]_+=[\alpha_2,\beta]_+=[\alpha_3,\beta]_+=0\end{aligned}}\tag{11.3.243}$$

We observe the following:

- The square of each operator β and α_j is equal to 1 (or to the unit matrix if it is a matrix...).
- $[\alpha_i,\alpha_j]_+ = 0, \forall i,j = \{1,2,3\}, i \neq j$ is an anticommutator
- $[\alpha_i,\beta]_+ = 0$ is an anticommutator

These three relations can be summarized as follows:

$$\beta^2 = 1 \qquad [\alpha_i,\alpha_j]_+ = 2\delta_{ij} \qquad [\alpha_i,\beta]_+ = 0 \tag{11.3.244}$$

At this point, we need to look for mathematical objects that meet the three conditions above. We could show that a square matrix of dimension 2 or 3 does not satisfy the three conditions and a scalar even less!

Dirac then adopted by analogy with the previous developments, square matrices of dimension 4 including Pauli matrices and admitted for β a unit matrix (this choice made by Dirac is particular, there are others possible choices hence the necessity to confront the models with experimental observations!).

So what we denoted "1" before is actually a square unit matrix of dimension 4! And so the wave functions must have 4 components and mathematical beings that have specificity are the spinors!

The matrices considered by Dirac (which are a particular choice!) are therefore for α_i, β:

$$\alpha_i = \begin{bmatrix} 0 & \sigma_i \\ \sigma_i & 0 \end{bmatrix} \quad \text{and} \quad \beta = \begin{bmatrix} \mathbb{1} & 0 \\ 0 & -\mathbb{1} \end{bmatrix} \tag{11.3.245}$$

and for example in certain domains of quantum physics we use Weyl's choice:

$$\alpha_i = \begin{bmatrix} \sigma_i & 0 \\ 0 & -\sigma_i \end{bmatrix} \quad \text{and} \quad \beta = \begin{bmatrix} 0 & \mathbb{1} \\ \mathbb{1} & 0 \end{bmatrix} \tag{11.3.246}$$

In the choice considered by Dirac or Weyl, we have the following Pauli matrices and unit matrix:

$$\sigma_1 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \quad \sigma_2 = \begin{bmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{bmatrix} \quad \sigma_3 = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \quad \mathbb{1} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \tag{11.3.247}$$

This leads to the matrices α_i, β (we recognize that the α_i are in fact the gamma matrices γ_i in their Chiral representation as introduced earlier above at the difference of a $-$ sign on one component but that anyway leads to exactly the same results!!!!!):

$$\alpha_1 = \begin{bmatrix} 0 & \sigma_1 \\ \sigma_1 & 0 \end{bmatrix} = \begin{bmatrix} \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} & \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \\ \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} & \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \end{bmatrix} \quad \alpha_2 = \begin{bmatrix} 0 & \sigma_2 \\ \sigma_2 & 0 \end{bmatrix} = \begin{bmatrix} \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} & \begin{bmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{bmatrix} \\ \begin{bmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{bmatrix} & \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \end{bmatrix}$$

$$\alpha_3 = \begin{bmatrix} 0 & \sigma_3 \\ \sigma_3 & 0 \end{bmatrix} = \begin{bmatrix} \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} & \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \\ \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} & \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \end{bmatrix} \quad \beta = \begin{bmatrix} \mathbb{1} & 0 \\ 0 & -\mathbb{1} \end{bmatrix} = \begin{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} & \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \\ \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} & -\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \end{bmatrix} = \begin{bmatrix} \mathbb{1} & 0 \\ 0 & -\mathbb{1} \end{bmatrix} \tag{11.3.248}$$

Remark

Notice that all matrices above are Hermitians!

We can check that the linearisation conditions are satisfied by the preceding matrices:

- First condition:

$$\beta^2=1\rightarrow\left\{\begin{array}{l}\beta_+\cdot\beta_+=\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}=\begin{bmatrix}\mathbb{1}&0\\0&\mathbb{1}\end{bmatrix}=1\\ \beta_-\cdot\beta_-=-\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}\left\{-\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}\right\}=\begin{bmatrix}\mathbb{1}&0\\0&\mathbb{1}\end{bmatrix}=1\end{array}\right\}\tag{11.3.249}$$

  Similarly for the α_j:

$$\begin{gathered}\alpha_1^2=\begin{bmatrix}0&\sigma_1\\\sigma_1&0\end{bmatrix}^2=\begin{bmatrix}0&0&0&1\\0&0&1&0\\0&1&0&0\\1&0&0&0\end{bmatrix}\begin{bmatrix}0&0&0&1\\0&0&1&0\\0&1&0&0\\1&0&0&0\end{bmatrix}=\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{bmatrix}=1\\ \alpha_2^2=\begin{bmatrix}0&\sigma_2\\\sigma_2&0\end{bmatrix}^2=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&\mathrm{i}&0\\0&-\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix}\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&\mathrm{i}&0\\0&-\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix}=\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{bmatrix}=1\\ \alpha_3^2=\begin{bmatrix}0&\sigma_3\\\sigma_3&0\end{bmatrix}^2=\begin{bmatrix}0&0&1&0\\0&0&0&-1\\1&0&0&0\\0&-1&0&0\end{bmatrix}\begin{bmatrix}0&0&1&0\\0&0&0&-1\\1&0&0&0\\0&-1&0&0\end{bmatrix}=\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{bmatrix}=1\end{gathered}\tag{11.3.250}$$

  The first condition is therefore fulfilled!

- Second condition (caution with notations that sadly slip a bit by tradition between matrices and scalars!):

$$\begin{aligned}&[\alpha_i,\alpha_j]_+=\begin{bmatrix}0&\sigma_i\\\sigma_i&0\end{bmatrix}\begin{bmatrix}0&\sigma_j\\\sigma_j&0\end{bmatrix}+\begin{bmatrix}0&\sigma_j\\\sigma_j&0\end{bmatrix}\begin{bmatrix}0&\sigma_i\\\sigma_i&0\end{bmatrix}=\\&\begin{bmatrix}\sigma_i\sigma_j&0\\0&\sigma_i\sigma_j\end{bmatrix}+\begin{bmatrix}\sigma_j\sigma_i&0\\0&\sigma_j\sigma_i\end{bmatrix}=\begin{bmatrix}\sigma_i\sigma_j+\sigma_j\sigma_i&0\\0&\sigma_i\sigma_j+\sigma_j\sigma_i\end{bmatrix}\\&=(\sigma_i\sigma_j+\sigma_j\sigma_i)\begin{bmatrix}1&0\\0&1\end{bmatrix}=\sigma_i\sigma_j+\sigma_j\sigma_i\\&\text{If}\quad i=j\rightarrow 2(\sigma_i\sigma_i)=2(\sigma_i)^2\\&\text{If}\quad i=1\rightarrow 2(\sigma_1)^2=2\begin{bmatrix}0&1\\1&0\end{bmatrix}^2=2\\&\text{If}\quad i=2\rightarrow 2(\sigma_2)^2=2\begin{bmatrix}0&-\mathrm{i}\\\mathrm{i}&0\end{bmatrix}^2=2\\&\text{If}\quad i=3\rightarrow 2(\sigma_3)^2=2\begin{bmatrix}1&0\\0&-1\end{bmatrix}^2=2\end{aligned}\tag{11.3.251}$$

and:

If $i=1$ and $j=2$

$$\sigma_1\sigma_2+\sigma_2\sigma_1=\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\begin{bmatrix}0 & -\mathrm{i}\\ \mathrm{i} & 0\end{bmatrix}+\begin{bmatrix}0 & -\mathrm{i}\\ \mathrm{i} & 0\end{bmatrix}\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}=\begin{bmatrix}\mathrm{i} & 0\\ 0 & -\mathrm{i}\end{bmatrix}+\begin{bmatrix}-\mathrm{i} & 0\\ 0 & \mathrm{i}\end{bmatrix}=0$$

If $i=1$ and $j=3$

$$\sigma_1\sigma_3+\sigma_3\sigma_1=\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}+\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}=\begin{bmatrix}0 & -1\\ 1 & 0\end{bmatrix}+\begin{bmatrix}0 & 1\\ -1 & 0\end{bmatrix}=0 \tag{11.3.252}$$

Therefore (caution! this is in fact a 4×4 matrix!!):

$$[\alpha_i,\alpha_j]_+=\sigma_i\sigma_j+\sigma_j\sigma_i=2\delta_{ij} \tag{11.3.253}$$

The second condition is well fulfilled!

Remark

The last relation should be written:

$$[\alpha_i,\alpha_j]_+=\alpha_i\alpha_j+\alpha_j\alpha_i=2\delta_{ij}\mathbb{1}_4 \tag{11.3.254}$$

and if we take the gamma matrices with the Dirac or any other representation introduce earlier above, the same is satisfied but generalized if we include γ_0 to:

$$\boxed{[\gamma_i,\gamma_j]_+=\gamma_i\gamma_j+\gamma_j\gamma_i=2\eta_{ij}\mathbb{1}_4} \tag{11.3.255}$$

where η_{ij} the Minkowski metric with signature $(+,-,-,-)$. This relation is important because it is sometimes used as the definition of the gamma matrices (!!!) and it makes appears the metric!!!

From the above relation we have immediately for $i\neq j$:

$$[\gamma_i,\gamma_j]_+=\gamma_i\gamma_j+\gamma_j\gamma_i=0 \tag{11.3.256}$$

and it is also immediate using the latter anticommutation relation that:

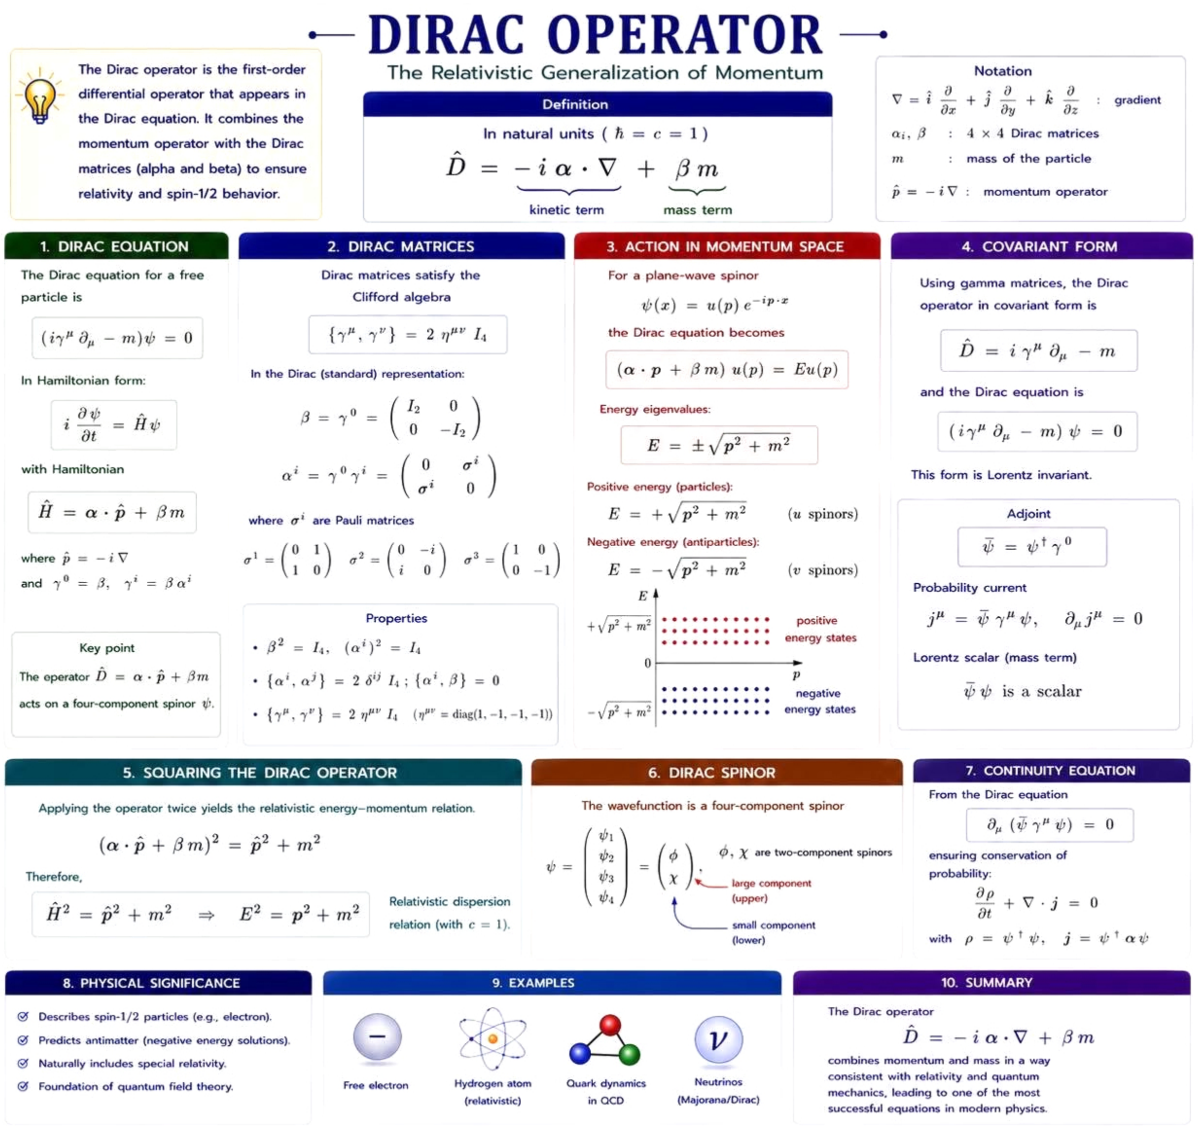
$$(\gamma^0)^2=1,(\gamma^i)^2=-1 \tag{11.3.257}$$

The reader should also know that physicists have derived from the above relation a small dozens of remarkable identities involving the γ-matrices and that also can be used to check that the chosen matrices can have indeed the status of γ-matrices. We will not present and prove these identities actually in this textbook as they are useless relatively to the actual content!

- Third condition:

$$[\alpha_i,\beta]_+=\begin{bmatrix}0 & \sigma_i\\ \sigma_i & 0\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}+\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}\begin{bmatrix}0 & \sigma_i\\ \sigma_i & 0\end{bmatrix}=\begin{bmatrix}0 & -\sigma_i\\ \sigma_i & 0\end{bmatrix}+\begin{bmatrix}0 & \sigma_i\\ -\sigma_i & 0\end{bmatrix}=\begin{bmatrix}0 & 0\\ 0 & 0\end{bmatrix} \tag{11.3.258}$$

The third and last condition is thus fulfilled.



DIRAC OPERATOR

The Relativistic Generalization of Momentum

The Dirac operator is the first-order differential operator that appears in the Dirac equation. It combines the momentum operator with the Dirac matrices (alpha and beta) to ensure relativity and spin-1/2 behavior.

Definition

In natural units ($\hbar = c = 1$)

$$\hat{D} = \underbrace{-i\,\boldsymbol{\alpha}\cdot\nabla}_{\text{kinetic term}} + \underbrace{\beta\,m}_{\text{mass term}}$$

Notation

$\nabla = \hat{\imath}\,\frac{\partial}{\partial x} + \hat{\jmath}\,\frac{\partial}{\partial y} + \hat{k}\,\frac{\partial}{\partial z}$: gradient

$\alpha_i,\ \beta$: 4×4 Dirac matrices

m : mass of the particle

$\hat{p} = -i\nabla$: momentum operator

1. DIRAC EQUATION

The Dirac equation for a free particle is

$$\boxed{(i\gamma^\mu\,\partial_\mu - m)\psi = 0}$$

In Hamiltonian form:

$$\boxed{i\,\frac{\partial\psi}{\partial t} = \hat{H}\psi}$$

with Hamiltonian

$$\boxed{\hat{H} = \boldsymbol{\alpha}\cdot\hat{\mathbf{p}} + \beta m}$$

where $\hat{p} = -i\nabla$

and $\gamma^0 = \beta,\quad \gamma^i = \beta\,\alpha^i$

Key point

The operator $\hat{D} = \boldsymbol{\alpha}\cdot\hat{\mathbf{p}} + \beta m$ acts on a four-component spinor ψ.

2. DIRAC MATRICES

Dirac matrices satisfy the Clifford algebra

$$\boxed{\{\gamma^\mu, \gamma^\nu\} = 2\,\eta^{\mu\nu}\,I_4}$$

In the Dirac (standard) representation:

$$\beta = \gamma^0 = \begin{pmatrix} I_2 & 0 \\ 0 & -I_2 \end{pmatrix}$$

$$\alpha^i = \gamma^0\gamma^i = \begin{pmatrix} 0 & \sigma^i \\ \sigma^i & 0 \end{pmatrix}$$

where σ^i are Pauli matrices

$$\sigma^1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad \sigma^2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \quad \sigma^3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

Properties

- $\beta^2 = I_4,\quad (\alpha^i)^2 = I_4$
- $\{\alpha^i, \alpha^j\} = 2\,\delta^{ij}\,I_4\ ;\ \{\alpha^i, \beta\} = 0$
- $\{\gamma^\mu, \gamma^\nu\} = 2\,\eta^{\mu\nu}\,I_4 \quad (\eta^{\mu\nu} = \mathrm{diag}(1, -1, -1, -1))$

3. ACTION IN MOMENTUM SPACE

For a plane-wave spinor

$$\psi(x) = u(p)\,e^{-ip\cdot x}$$

the Dirac equation becomes

$$\boxed{(\boldsymbol{\alpha}\cdot\mathbf{p} + \beta\,m)\,u(p) = Eu(p)}$$

Energy eigenvalues:

$$\boxed{E = \pm\sqrt{\mathbf{p}^2 + m^2}}$$

Positive energy (particles):

$$E = +\sqrt{\mathbf{p}^2 + m^2} \qquad (u\ \text{spinors})$$

Negative energy (antiparticles):

$$E = -\sqrt{\mathbf{p}^2 + m^2} \qquad (v\ \text{spinors})$$

4. COVARIANT FORM

Using gamma matrices, the Dirac operator in covariant form is

$$\boxed{\hat{D} = i\,\gamma^\mu\,\partial_\mu - m}$$

and the Dirac equation is

$$\boxed{(i\gamma^\mu\,\partial_\mu - m)\,\psi = 0}$$

This form is Lorentz invariant.

Adjoint

$$\boxed{\bar{\psi} = \psi^\dagger\gamma^0}$$

Probability current

$$j^\mu = \bar{\psi}\,\gamma^\mu\,\psi, \qquad \partial_\mu j^\mu = 0$$

Lorentz scalar (mass term)

$\bar{\psi}\,\psi$ is a scalar

5. SQUARING THE DIRAC OPERATOR

Applying the operator twice yields the relativistic energy–momentum relation.

$$(\boldsymbol{\alpha}\cdot\hat{\mathbf{p}} + \beta\,m)^2 = \hat{\mathbf{p}}^2 + m^2$$

Therefore,

$$\boxed{\hat{H}^2 = \hat{\mathbf{p}}^2 + m^2 \quad\Rightarrow\quad E^2 = \mathbf{p}^2 + m^2}$$

Relativistic dispersion relation (with $c = 1$).

6. DIRAC SPINOR

The wavefunction is a four-component spinor

$$\psi = \begin{pmatrix} \psi_1 \\ \psi_2 \\ \psi_3 \\ \psi_4 \end{pmatrix} = \begin{pmatrix} \phi \\ \chi \end{pmatrix},$$

$\phi,\ \chi$ are two-component spinors

large component (upper)

small component (lower)

7. CONTINUITY EQUATION

From the Dirac equation

$$\boxed{\partial_\mu\,(\bar{\psi}\,\gamma^\mu\,\psi) = 0}$$

ensuring conservation of probability:

$$\frac{\partial\rho}{\partial t} + \nabla\cdot\mathbf{j} = 0$$

with $\rho = \psi^\dagger\,\psi,\quad \mathbf{j} = \psi^\dagger\,\boldsymbol{\alpha}\,\psi$

8. PHYSICAL SIGNIFICANCE

- ✓ Describes spin-1/2 particles (e.g., electron).
- ✓ Predicts antimatter (negative energy solutions).
- ✓ Naturally includes special relativity.
- ✓ Foundation of quantum field theory.

9. EXAMPLES

10. SUMMARY

The Dirac operator

$$\hat{D} = -i\,\boldsymbol{\alpha}\cdot\nabla + \beta\,m$$

combines momentum and mass in a way consistent with relativity and quantum mechanics, leading to one of the most successful equations in modern physics.

Referring to the beginning equation written with the Dirac formalism:

$$\mathrm{i}\hbar\partial_t\Psi = H_D\Psi \Rightarrow \mathrm{i}\hbar\partial_t\Psi = \beta m_0 c^2\Psi + c\alpha_1 p_1\Psi + c\alpha_2 p_2\Psi + c\alpha_3 p_3\Psi \tag{11.3.259}$$

With:

$$\beta = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix}, \alpha_1 = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}, \alpha_2 = \begin{bmatrix} 0 & 0 & 0 & -\mathrm{i} \\ 0 & 0 & \mathrm{i} & 0 \\ 0 & -\mathrm{i} & 0 & 0 \\ \mathrm{i} & 0 & 0 & 0 \end{bmatrix}, \alpha_3 = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{bmatrix} \tag{11.3.260}$$

Which gives finally:

$$\mathrm{i}\hbar\partial_t=\begin{bmatrix}\Psi_1\\\Psi_2\\\Psi_3\\\Psi_4\end{bmatrix}=m_0c^2\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&-1\end{bmatrix}\begin{bmatrix}\Psi_1\\\Psi_2\\\Psi_3\\\Psi_4\end{bmatrix}+c\begin{bmatrix}0&0&0&1\\0&0&1&0\\0&1&0&0\\1&0&0&0\end{bmatrix}p_1\begin{bmatrix}\Psi_1\\\Psi_2\\\Psi_3\\\Psi_4\end{bmatrix}+$$
$$c\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&\mathrm{i}&0\\0&-\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix}p_2\begin{bmatrix}\Psi_1\\\Psi_2\\\Psi_3\\\Psi_4\end{bmatrix}+c\begin{bmatrix}0&0&1&0\\0&0&0&-1\\1&0&0&0\\0&-1&0&0\end{bmatrix}p_3\begin{bmatrix}\Psi_1\\\Psi_2\\\Psi_3\\\Psi_4\end{bmatrix}\tag{11.3.261}$$

We find ourselves in front of a state function having 4 components in which:

$$\begin{bmatrix}\Psi_1\\\Psi_2\end{bmatrix}\quad\text{and}\quad\begin{bmatrix}\Psi_3\\\Psi_4\end{bmatrix}\tag{11.3.262}$$

are spinners and the set:

$$\begin{bmatrix}\Psi_1\\\Psi_2\\\Psi_3\\\Psi_4\end{bmatrix}\tag{11.3.263}$$

is therefore "Dirac bispinor" and we denote by:

$$\Psi=\begin{bmatrix}\Psi_1\\\Psi_2\\\Psi_3\\\Psi_4\end{bmatrix}\tag{11.3.264}$$

the "Dirac state function". The reader will have maybe noticed that we fall back on the same concepts as in our study of the free non-linearised Dirac equation. This is quite a good sign!

By developing, it comes:

$$\begin{aligned}\mathrm{i}\hbar\partial_t\Psi_1&=m_0c^2\Psi_1+cp_1\Psi_4-\mathrm{i}cp_2\Psi_4+cp_3\Psi_3\\&=m_0c^2\Psi_1+c(p_1-\mathrm{i}p_2)\Psi_4+cp_3\Psi_3\\i\hbar\partial_t\Psi_2&=m_0c^2\Psi_2+cp_1\Psi_3+\mathrm{i}cp_2\Psi_3-cp_3\Psi_4\\&=m_0c^2\Psi_2+c(p_1+\mathrm{i}p_2)\Psi_4-cp_3\Psi_4\\\mathrm{i}\hbar\partial_t\Psi_3&=-m_0c^2\Psi_3+cp_1\Psi_2-\mathrm{i}cp_2\Psi_2+cp_3\Psi_4\\&=-m_0c^2\Psi_3+c(p_1-\mathrm{i}p_2)\Psi_2+cp_3\Psi_1\\\mathrm{i}\hbar\partial_t\Psi_4&=-m_0c^2\Psi_4+cp_1\Psi_1+icp_2\Psi_1-cp_3\Psi_2\\&=-m_0c^2\Psi_4+c(p_1+\mathrm{i}p_2)\Psi_1-cp_3\Psi_2\end{aligned}\tag{11.3.265}$$

For a free electron, we know that the solution is:

$$\Psi(\vec{r},t)=\Psi_0\exp\left(-\mathrm{i}\frac{Et-\vec{p}\circ\vec{r}}{\hbar}\right)\tag{11.3.266}$$

With Dirac bispinor we have:

$$\Psi(\vec{r},t)=\Psi_\alpha(\vec{r})\exp\left(-\mathrm{i}\frac{Et}{\hbar}\right)\tag{11.3.267}$$

with:

$$\Psi_\alpha(\vec{r})=\begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{bmatrix} \exp\left(\mathrm{i}\frac{\vec{p}\circ\vec{r}}{\hbar}\right) \tag{11.3.268}$$

where b_1 to b_2 are the components of the Dirac bispinor.

We will write:

$$\left.\begin{array}{l} \Psi_1=b_1[\quad] \\ \Psi_2=b_2[\quad] \\ \Psi_3=b_3[\quad] \\ \Psi_4=b_4[\quad] \end{array}\right\} \quad \text{with} \quad [\quad]=\exp\left(\mathrm{i}\frac{\vec{p}\circ\vec{r}}{\hbar}\right)\exp\left(-\mathrm{i}\frac{Et}{\hbar}\right) \tag{11.3.269}$$

By calculating their derivatives with respect to t:

$$\begin{aligned} &\mathrm{i}\hbar\partial_t\Psi_1=\mathrm{i}\hbar\partial_t\left[b_1\exp\left(\mathrm{i}\frac{\vec{p}\circ\vec{r}}{\hbar}\right)\right]\exp\left(-\mathrm{i}\frac{Et}{\hbar}\right)=\mathrm{i}\hbar\left(-v\mathrm{i}\frac{E}{\hbar}\right)b_1[\quad]=Eb_1[\quad] \\ &\mathrm{i}\hbar\partial_t\Psi_2=Eb_2[\quad] \\ &\mathrm{i}\hbar\partial_t\Psi_3=Eb_3[\quad] \\ &\mathrm{i}\hbar\partial_t\Psi_4=Eb_4[\quad] \end{aligned} \tag{11.3.270}$$

With (11.3.269) and (11.3.270) in (11.3.265), it comes:

$$\begin{aligned} Eb_1[\quad]&=m_0c^2b_1[\quad]+c(p_1-\mathrm{i}p_2)b_4[\quad]+cp_3b_3[\quad] \\ Eb_2[\quad]&=m_0c^2b_2[\quad]+c(p_1+\mathrm{i}p_2)b_3[\quad]-cp_3b_4[\quad] \\ Eb_3[\quad]&=-m_0c^2b_3[\quad]+c(p_1-\mathrm{i}p_2)b_2[\quad]+cp_3b_1[\quad] \\ Eb_4[\quad]&=-m_0c^2b_4[\quad]+c(p_1+\mathrm{i}p_2)b_1[\quad]-cp_3b_2[\quad] \end{aligned} \tag{11.3.271}$$

Hence a system of equations whose unknowns are b_1,b_2,b_3,b_4:

$$\begin{cases} (E-m_0c^2)b_1+0b_2-cp_3b_3-c(p_1-\mathrm{i}p_2)b_4=0 & (a) \\ 0b_1+(E-m_0c^2)b_2-c(p_1+\mathrm{i}p_2)b_3+cp_3b_4=0 & (b) \\ -cp_3b_1-c(p_1-\mathrm{i}p_2)b_2+(E+m_0c^2)b_3+0b_4=0 & (c) \\ -c(p_1+\mathrm{i}p_2)b_1+cp_3b_2+0b_3+(E+m_0c^2)b_4=0 & (d) \end{cases} \tag{11.3.272}$$

We have solutions that are not all zero if and only if the determinant of the coefficients is zero (to know the reasons, refer to the section of Linear Algebra at page 1926) and therefore an infinite number of solutions (for the components of the Dirac spinor). Therefore:

$$\begin{vmatrix} E-m_0c^2 & 0 & -cp_3 & -c(p_1-\mathrm{i}p_2) \\ 0 & E-m_0c^2 & -c(p_1+\mathrm{i}p_2) & cp_3 \\ -cp_3 & -c(p_1-\mathrm{i}p_2) & E+m_0c^2 & 0 \\ -c(p_1+\mathrm{i}p_2) & cp_3 & 0 & E+m_0c^2 \end{vmatrix}=0 \tag{11.3.273}$$

By simplifying by c:

$$\begin{vmatrix} \dfrac{E}{c}-m_0c & 0 & -p_3 & -(p_1-\mathrm{i}p_2) \\ 0 & \dfrac{E}{c}-m_0c & -(p_1+\mathrm{i}p_2) & p_3 \\ -p_3 & -(p_1-\mathrm{i}p_2) & \dfrac{E}{c}+m_0c & 0 \\ -(p_1+\mathrm{i}p_2) & p_3 & 0 & \dfrac{E}{c}+m_0c \end{vmatrix}=0 \tag{11.3.274}$$

The division in the preceding determinant allows the calculation of the partial determinants (see section Linear Algebra page 1971):

$$\begin{vmatrix} \left(\dfrac{E}{c}-m_0c\right)^2 & \begin{array}{c}[-p_3^2-(p_1-\mathrm{i}p_2)(p_1+\mathrm{i}p_2)] \\ -[p_3^2+(p_1-\mathrm{i}p_2)(p_1+\mathrm{i}p_2)]\end{array} \\ \begin{array}{c}[-p_3^2-(p_1-\mathrm{i}p_2)(p_1+\mathrm{i}p_2)] \\ -[p_3^2+(p_1-\mathrm{i}p_2)(p_1+\mathrm{i}p_2)]\end{array} & \left(\dfrac{E}{c}+m_0c\right)^2 \end{vmatrix}=0 \tag{11.3.275}$$

In solving the preceding determinant, it comes:

$$\begin{aligned} &\left[\left(\frac{E}{c}-m_0c\right)\left(\frac{E}{c}+m_0c\right)\right]^2-\left[p_3^2+(p_1-\mathrm{i}p_2)(p_1+\mathrm{i}p_2)\right]^2=0 \\ &\left(\frac{E^2}{c^2}-m_0^2c^2\right)^2-\left\{p_3^2+\left[p_1^2-(\mathrm{i}p_2)^2\right]\right\}=0 \\ &\left(\frac{E^2}{c^2}-m_0^2c^2\right)^2-\underbrace{(p_3^2+p_1^2+p_2^2)}_{(p^2)^2}=0 \end{aligned} \tag{11.3.276}$$

Hence the following relation:

$$\frac{E^2}{c^2}-m_0^2c^2=p^2\Leftrightarrow E^2-m_0^2c^4=p^2c^2 \tag{11.3.277}$$

The values of the energy given by the Dirac equation are thus (we recognize here a famous relation determined in the section of Special Relativity!):

$$E=\pm\sqrt{m_0^2c^4+p^2c^2} \tag{11.3.278}$$

Therefore:

$$E_+=+\sqrt{m_0^2c^4+p^2c^2} \tag{11.3.279}$$

$$E_-=-\sqrt{m_0^2c^4+p^2c^2} \tag{11.3.280}$$

If we adopt for E_+ two constant values for b_1 and b_2 we have two relations to calculate b_3 and b_4, thus:

- With (11.3.272 c):

  $$-cp_3b_1-c(p_1-\mathrm{i}p_2)b_2+(E_++m_0c^2)b_3=0 \tag{11.3.281}$$

  Thus:

  $$b_3=\frac{c\left[p_3b_1+(p_1-\mathrm{i}p_2)b_2\right]}{E_++m_0c^2} \tag{11.3.282}$$

- With (11.3.272 d):

  $$-c(p_1+\mathrm{i}p_2)b_1-cp_3b_2+(E_++m_0c^2)b_4=0 \tag{11.3.283}$$

Thus:

$$b_4 = \frac{c\left[(p_1 + \mathrm{i}p_2)b_1 - p_3 b_2\right]}{E_+ + m_0 c^2} \tag{11.3.284}$$

By adopting $b_1 = 1$, $b_2 = 0$, it comes:

$$b_3 = \frac{cp_3}{E_+ + m_0 c^2} = \frac{cp_z}{E_+ + m_0 c^2} \qquad b_4 = \frac{c(p_1 + \mathrm{i}p_2)}{E_+ + m_0 c^2} = \frac{cp_+}{E_+ + m_0 c^2} \tag{11.3.285}$$

Taking the natural units:

$$b_3 = \frac{p_z}{E_+ + m_0} \qquad b_4 = \frac{p_+}{E_+ + m_0} \tag{11.3.286}$$

If we adopt for E_- two constant values for b_3, b_4 we have two relations to calculate b_1, b_2, thus:

- With (11.3.272 a):

$$(E_- - m_0 c^2)b_1 - cp_3 b_3 - c(p_1 - \mathrm{i}p_2)b_4 = 0 \tag{11.3.287}$$

Thus:

$$b_1 = \frac{c\left[p_3 b_3 + (p_1 - \mathrm{i}p_2)b_4\right]}{E_- - m_0 c^2} \tag{11.3.288}$$

- With (11.3.272 b):

$$(E_- - m_0 c^2)b_2 - c(p_1 + \mathrm{i}p_2)b_3 - cp_3 b_4 = 0 \tag{11.3.289}$$

Thus:

$$b_2 = \frac{c\left[-p_3 b_4 + (p_1 + \mathrm{i}p_2)b_3\right]}{E_- - m_0 c^2} \tag{11.3.290}$$

Notice that by adopting $b_3 = 1$, $b_4 = 0$ it comes:

$$b_1 = \frac{cp_3}{E_- - m_0 c^2} = \frac{cp_z}{E_- - m_0 c^2} \qquad b_2 = \frac{c(p_1 + \mathrm{i}p_2)}{E_- - m_0 c^2} = \frac{cp_+}{E_- - m_0 c^2} \tag{11.3.291}$$

With the natural units:

$$b_1 = \frac{p_3}{E_- - m_0} = \frac{p_z}{E_- - m_0} \qquad b_2 = \frac{p_1 + \mathrm{i}p_2}{E_- - m_0} = \frac{p_+}{E_- - m_0} \tag{11.3.292}$$

By adopting $b_3 = 0$, $b_4 = 1$ it comes:

$$b_1 = \frac{c(p_1 - \mathrm{i}p_2)}{E_- - m_0 c^2} = \frac{cp_-}{E_- - m_0 c^2} \qquad b_2 = \frac{-cp_3}{E_- - m_0 c^2} = \frac{-cp_z}{E_- - m_0 c^2} \tag{11.3.293}$$

Either with the natural units:

$$b_1 = \frac{p_-}{E_- - m_0} \qquad b_2 = \frac{-p_z}{E_- - m_0} \tag{11.3.294}$$

Even if the method is different, we fall back on the coefficients of the spinors obtained in our study of the classical free Dirac equation. This comfort us in the assumptions made at the beginning of this linearisation and validates these results. Moreover, the preceding relations also indicate a degeneracy of order two of the energy for each value of the pulsation. In the absence of an external field, the free electron is therefore not influenced by the orientation of its spin. We thus find the same results for either the classical or linearised free Dirac equation.

However, Dirac's explanation for the positive and negative energies is that his equation applies not only to the state of a positive energy particle (in this case the electron) but also to the state of a particle with negative energy (its antiparticle is the "positron"). The absolute value of these two energies being strictly equal.

The presence of the negative sign affecting the energy posed a problem at the time for its interpretation (in the context where we omit the time variable since we had seen when studying the free Klein-Gordon equation, a particle with negative energy can be seen as a particle that goes back in time).

If we reason in the case where the term p^2c^2 is small compared to m_0c^2, we ask ourselves: how and what are the consequences of a transition between a state of energy m_0c^2 and that of the state of energy $-m_0c^2$ with a gap of $-m_0c^2$ (we will find again this value in our study of materialization in the section of Nuclear Physics).

Dirac uses the image of a sea of negative energy named "Dirac sea" (since, remember, the number of solutions to our matrix system is infinite, hence the analogy with a sea than a discrete context) in which all negative energy states are occupied by the electrons and the positive energy states would be empty. If an electron is subjected to a transition (via, for example, a photon of energy greater than $2m_0c^2$), it leaves this sea leaving behind a gap (the famous "hole" of positive charge to which the electronics sometimes refers to...). This gap becomes a positive charge, of energy E_+. The appearance of this gap is assimilated to the appearance of a particle having a positive charge. Obviously, we can imagine the opposite case, it is only a matter of conventions.

11.3.4.1 Linearised Dirac Equation continuity equation

Now let us consider the probability density/current. This is where the perceived problems with the Klein-Gordon equation arose! For this, identically as we did for the Generalized Klein-Gordon equation, we start with the linearised Dirac equation (in natural units to simplify):

$$(\vec{\alpha}\circ\vec{p}+\beta m_0)\Psi=\mathrm{i}\partial_t\Psi \qquad (11.3.295)$$

or:

$$(\mathrm{i}\vec{\alpha}\vec{\nabla}+\beta m_0)\Psi=\mathrm{i}\partial_t\Psi \qquad (11.3.296)$$

Where we know now obviously that:

1. $\vec{\alpha}$ are Pauli matrices
2. $\vec{\alpha}$ and $\vec{\beta}$ are Hermitian

Writing the above relation explicitly gives us:

$$-\mathrm{i}\alpha_x\frac{\partial\Psi}{\partial x}-\mathrm{i}\alpha_y\frac{\partial\Psi}{\partial y}-\mathrm{i}\alpha_z\frac{\partial\Psi}{\partial z}+m_0\beta\Psi=\mathrm{i}\frac{\partial\Psi}{\partial t} \qquad (11.3.297)$$

and its Hermitian conjugate:

$$+\mathrm{i}\alpha_x^\dagger\frac{\partial\Psi^\dagger}{\partial x}+\mathrm{i}\alpha_y^\dagger\frac{\partial\Psi^\dagger}{\partial y}+\mathrm{i}\alpha_z^\dagger\frac{\partial\Psi^\dagger}{\partial z}+m_0\beta^\dagger\Psi^\dagger=-\mathrm{i}\frac{\partial\Psi^\dagger}{\partial t} \tag{11.3.298}$$

Now, exactly as we did with the Generalized Klein-Gordon equation, we take the first above expansion that we multiply by $\Phi^\dagger$ and we subtract by the second Hermitian expansion that we multiply by Φ:

$$\Psi^\dagger\left(-\mathrm{i}\alpha_x\frac{\partial\Psi}{\partial x}-\mathrm{i}\alpha_y\frac{\partial\Psi}{\partial y}-\mathrm{i}\alpha_z\frac{\partial\Psi}{\partial z}+m_0\beta\Psi\right)-\Psi\left(+\mathrm{i}\alpha_x^\dagger\frac{\partial\Psi^\dagger}{\partial x}+\mathrm{i}\alpha_y^\dagger\frac{\partial\Psi^\dagger}{\partial y}+\mathrm{i}\alpha_z^\dagger\frac{\partial\Psi^\dagger}{\partial z}+m_0\beta^\dagger\Psi^\dagger\right)=\mathrm{i}\Psi^\dagger\frac{\partial\Psi}{\partial t}+\mathrm{i}\Psi\frac{\partial\Psi^\dagger}{\partial t} \tag{11.3.299}$$

Remembering that α and β are Hermitian, we can write:

$$\Psi^\dagger\left(-\mathrm{i}\alpha_x\frac{\partial\Psi}{\partial x}-\mathrm{i}\alpha_y\frac{\partial\Psi}{\partial y}-\mathrm{i}\alpha_z\frac{\partial\Psi}{\partial z}+m_0\beta\Psi\right)-\Psi\left(+\mathrm{i}\alpha_x^\dagger\frac{\partial\Psi^\dagger}{\partial x}+\mathrm{i}\alpha_y\frac{\partial\Psi^\dagger}{\partial y}+\mathrm{i}\alpha_z\frac{\partial\Psi^\dagger}{\partial z}+m_0\beta\Psi^\dagger\right)=\mathrm{i}\Psi^\dagger\frac{\partial\Psi}{\partial t}+\mathrm{i}\Psi\frac{\partial\Psi^\dagger}{\partial t} \tag{11.3.300}$$

The right hand side can easily be simplified by chain derivation rule:

$$\Psi^\dagger\left(-\mathrm{i}\alpha_x\frac{\partial\Psi}{\partial x}-\mathrm{i}\alpha_y\frac{\partial\Psi}{\partial y}-\mathrm{i}\alpha_z\frac{\partial\Psi}{\partial z}+m_0\beta\Psi\right)-\Psi\left(+\mathrm{i}\alpha_x\frac{\partial\Psi^\dagger}{\partial x}+\mathrm{i}\alpha_y\frac{\partial\Psi^\dagger}{\partial y}+\mathrm{i}\alpha_z\frac{\partial\Psi^\dagger}{\partial z}+m_0\beta\Psi^\dagger\right)=\mathrm{i}\frac{\partial\Psi^\dagger\Psi}{\partial t} \tag{11.3.301}$$

Se see also that the terms $m_0\beta\Psi$ cancels each other, then it remains:

$$\Psi^\dagger\left(-\mathrm{i}\alpha_x\frac{\partial\Psi}{\partial x}-\mathrm{i}\alpha_y\frac{\partial\Psi}{\partial y}-\mathrm{i}\alpha_z\frac{\partial\Psi}{\partial z}\right)-\Psi\left(+\mathrm{i}\alpha_x\frac{\partial\Psi^\dagger}{\partial x}+\mathrm{i}\alpha_y\frac{\partial\Psi^\dagger}{\partial y}+\mathrm{i}\alpha_z\frac{\partial\Psi^\dagger}{\partial z}\right)=\mathrm{i}\frac{\partial\Psi^\dagger\Psi}{\partial t} \tag{11.3.302}$$

We multiply both sides by i and rearrange a bit:

$$\Psi^\dagger\left(\alpha_x\frac{\partial\Psi}{\partial x}+\alpha_y\frac{\partial\Psi}{\partial y}+\alpha_z\frac{\partial\Psi}{\partial z}\right)+\Psi\left(\alpha_x\frac{\partial\Psi^\dagger}{\partial x}+\alpha_y\frac{\partial\Psi^\dagger}{\partial y}+\alpha_z\frac{\partial\Psi^\dagger}{\partial z}\right)+\frac{\partial\Psi^\dagger\Psi}{\partial t}=0 \tag{11.3.303}$$

Now using the identity:

$$\Psi^\dagger\alpha_x\frac{\partial\Psi}{\partial x}+\frac{\partial\Psi^\dagger}{\partial x}\alpha_x\Psi=\frac{\partial(\Psi^\dagger\alpha_x\Psi)}{\partial x} \tag{11.3.304}$$

Gives the linearised continuity Dirac equation:

$$\boxed{\vec{\nabla}(\Psi^\dagger\vec{\alpha}\Psi)+\frac{(\Psi^\dagger\Psi)}{\partial t}=0} \tag{11.3.305}$$

The probability density and current can be identified as:

$$\boxed{\rho=\Psi^\dagger\Psi\qquad\text{and}\qquad\vec{j}=\Psi^\dagger\vec{\alpha}\Psi} \tag{11.3.306}$$

where:

$$\rho=\Psi^\dagger\Psi=|\Psi_1|^2+|\Psi_2|^2+|\Psi_3|^2+|\Psi_4|^2>0 \tag{11.3.307}$$

Then, unlike the generalized Klein-Gordon equation, the Dirac equation has probability densities which are always positive!

In regard of what we have seen earlier, we can introduce the "four-vector fermion current":

$$j^{\mu}=\Psi^{\dagger}\gamma^{\mu}\Psi=(\psi^{\dagger}\gamma^{0}\Psi,\Psi^{\dagger}\vec{\gamma}\Psi)=(\rho,\vec{j}) \tag{11.3.308}$$

and ρ is the probability density as we know:

$$\rho=j^{0}=\Psi^{\dagger}\gamma^{0}\Psi=\Psi^{\dagger}\Psi \tag{11.3.309}$$

Now let us come back to the normalization of N that appeared during our study of the free Dirac particle solution page 4951. If we proceed by analogy (...), remember first that we get with the Klein-Gordon equation that:

$$\rho=2EA^{2}=2E \tag{11.3.310}$$

And just now we get that:

$$\rho=\Psi^{\dagger}\Psi \tag{11.3.311}$$

So now knowing this, let us consider the following solution that we have obtained:

$$\Psi_{\vec{p}}^{(1)}=N\begin{pmatrix}\phi_a\\ \phi_b\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}1\\0\end{pmatrix}\\ \begin{pmatrix}\dfrac{p_z}{E+m_0}\\ \dfrac{p_x+\mathrm{i}p_y}{E+m_0}\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}\begin{pmatrix}1\\0\end{pmatrix}\\ \begin{pmatrix}\dfrac{p_z}{E+m_0}\\ \dfrac{p_+}{E+m_0}\end{pmatrix}\end{pmatrix}=N\begin{pmatrix}1\\ \dfrac{\vec{p}\circ\vec{\sigma}}{E+m_0}\end{pmatrix}\chi^{(+)} \tag{11.3.312}$$

that to simplify we will denote as Ψ. Then (still in natural units):

$$\begin{aligned}\rho=\Psi^{\dagger}\Psi&=|N|^2\left(1+\frac{p_z^2}{E+m}+\frac{p_x^2+p_y^2}{E+m}\right)=|N|^2\left(\frac{(E+m)^2+|\vec{p}|^2}{(E+m)^2}\right)\\&=|N|^2\left(\frac{(E+m)^2+(\sqrt{E^2-m^2})^2}{(E+m)^2}\right)=|N|^2\left(\frac{(E+m)^2+E^2-m^2}{(E+m)^2}\right)\\&=|N|^2\frac{2E^2+2Em}{(E+m)^2}=|N|^2\frac{2E(E+m)}{(E+m)^2}=|N|^2\frac{2E}{E+m}\end{aligned} \tag{11.3.313}$$

Now to get the same result as for the Klein-Gordon equation, we must have:

$$\rho=2EA^2=|N|^2\frac{2E}{E+m} \tag{11.3.314}$$

Hence:

$$N=\pm A\sqrt{E+M} \tag{11.3.315}$$

Or more differently written:

$$N=\pm\Psi_0\sqrt{E+M} \tag{11.3.316}$$

11.3.4.2 Linearised Dirac Equation Angular Momentum + Helicity Conservation

For the Dirac linearised equation model is orbital angular momentum a good quantum number? I.e. does:

$$\vec{L}=\vec{r}\times\vec{p}=\begin{pmatrix} yp_z-zp_y \\ zp_x-xp_z \\ xp_y-yp_x \end{pmatrix} \tag{11.3.317}$$

commute with the Hamiltonian:

$$[H,\vec{L}]=[\vec{\alpha}\circ\vec{p}+\beta m_0,\vec{r}\times\vec{p}] \tag{11.3.318}$$

where for recall the corresponding Dirac alpha and beta matrices are:

$$\beta_D=\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&-1\end{bmatrix},\alpha_D^1=\begin{bmatrix}0&0&0&1\\0&0&1&0\\0&1&0&0\\1&0&0&0\end{bmatrix},\alpha_D^2=\begin{bmatrix}0&0&0&-\mathrm{i}\\0&0&\mathrm{i}&0\\0&-\mathrm{i}&0&0\\\mathrm{i}&0&0&0\end{bmatrix},\alpha_D^3=\begin{bmatrix}0&0&1&0\\0&0&0&-1\\1&0&0&0\\0&-1&0&0\end{bmatrix} \tag{11.3.319}$$

To check this, let us consider the x component of $\vec{L}$ (we implicitly assume that we work with the Dirac alpha and beta matrices so we don't denote the lower index D anymore):

$$[H,L_x]=[\vec{\alpha}\circ\vec{p},(\vec{r}\times\vec{p})_x]=[\alpha_1p_x+\alpha_2p_y+\alpha_3p_z+\beta m_0,yp_z-zp_y] \tag{11.3.320}$$

So we may think that:

$$[H,L_x]=[\alpha_1p_x+\alpha_2p_y+\alpha_3p_z+\beta m_0,yp_z-zp_y]=\alpha_1p_x+\alpha_2p_y+\alpha_3p_z,0]=0 \tag{11.3.321}$$

even if the shortcut is nice and may look correct... this is a wrong shortcut in fact especially when we deal with differential operators as both arguments of the commutator (typical well known trap in maths when we do things too quickly)!!!

Remark

The term βm_0 disappears as it is not a differential operator (only a real matrix with a constant factor m_0). By cons, the first term has the $\vec{p}$ in it, and this latter is a vector of differential operators!

We already know that for the linear momentum, the only non-zero contributions come form:

$$[x,p_x]=[y,p_y]=[z,p_z]=\mathrm{i}\hbar \tag{11.3.322}$$

Hence (we use a lot here the Poisson brackets properties seen at page 3189):

$$\begin{aligned}[H,L_x]&=[\vec{\alpha}\circ\vec{p},yp_z-zp_y]\\&=[\vec{\alpha}\circ\vec{p},yp_z]-[\vec{\alpha}\circ\vec{p},zp_y]\\&=[\alpha_1p_x+\alpha_2p_y+\alpha_3p_z,yp_z]-[\alpha_1p_x+\alpha_2p_y+\alpha_3p_z,zp_y]\\&=[\alpha_1p_x,yp_z]+[\alpha_2p_y,yp_z]+[\alpha_3p_z,yp_z]-[\alpha_1p_x,zp_y]-[\alpha_2p_y,zp_y]-[\alpha_3p_z,zp_y]\\&=[\alpha_1p_x,y]p_z+y[\alpha_1p_x,p_z]+[\alpha_2p_y,y]p_z+y[\alpha_2p_y,p_z]+[\alpha_3p_z,y]p_z+z[\alpha_3p_z,p_z]\\&-[\alpha_1p_x,z]p_y-z[\alpha_1p_x,p_y]-[\alpha_2p_y,z]p_y-z[\alpha_2p_y,p_y]-[\alpha_3p_z,z]p_y-z[\alpha_3p_z,p_y]\\&=0+0-\mathrm{i}\alpha_2p_z+0+0+0-0-0-0-0+\mathrm{i}\alpha_3p_x-0\\&=-\mathrm{i}(\alpha_2p_z-\alpha_3p_y)\end{aligned} \tag{11.3.323}$$

Two techniques were employed along the way: between the 4th and the 5th line of the above development, we used (see page 3189):

$$[A,BC]=[A,B]C+B[A,C] \tag{11.3.324}$$

and between the 7th and 8th we used:

$$[p_k,x_l]=-[x_l,p_k]=-\mathrm{i}\delta_{kl} \tag{11.3.325}$$

The same strategy can be adopted to solve for $[H,L_y]$ and $[H,L_z]$:

$$\begin{aligned}[H,L_y]&=\mathrm{i}(\alpha_1 p_z-\alpha_3 p_x)\\ [H,L_z]&=-\mathrm{i}(\alpha_1 p_x-\alpha_2 p_x)\end{aligned} \tag{11.3.326}$$

Thus $[H,\vec{L}]$ can be determined by:

$$\begin{aligned}[H,\vec{L}]&=[H,L_x]\vec{e}_x+[H,L_y]\vec{e}_y+[H,L_z]\vec{e}_z\\ &=-\mathrm{i}(\alpha_2 p_z-\alpha_3 p_y)\vec{e}_x+\mathrm{i}(\alpha_1 p_z-\alpha_3 p_x)\vec{e}_y+(-\mathrm{i}(\alpha p_y-\alpha_2 p_x)\,\vec{e}_z\end{aligned} \tag{11.3.327}$$

Therefore:

$$\boxed{[H,\vec{L}]=-\mathrm{i}\vec{\alpha}\times\vec{p}\neq\vec{0}} \tag{11.3.328}$$

Hence the angular momentum does not commute with the Hamiltonian and is not a constant of motion!

Introduce a new 4×4 operator:

$$\boxed{\vec{S}=\frac{1}{2}\vec{\Sigma}=\frac{1}{2}\begin{bmatrix}\vec{\sigma} & 0\\ 0 & \vec{\sigma}\end{bmatrix}} \tag{11.3.329}$$

where as we know, the $\vec{\sigma}$ are the Pauli spin matrices i.e.:

$$\Sigma_1=\begin{bmatrix}0&1&0&0\\1&0&0&0\\0&0&0&1\\0&0&1&0\end{bmatrix},\Sigma_2=\begin{bmatrix}0&-\mathrm{i}&0&0\\\mathrm{i}&0&0&0\\0&0&0&-\mathrm{i}\\0&0&\mathrm{i}&0\end{bmatrix},\Sigma_3=\begin{bmatrix}1&0&0&0\\0&-1&0&0\\0&0&1&0\\0&0&0&-1\end{bmatrix} \tag{11.3.330}$$

Now consider the commutator:

$$[H,\vec{\Sigma}]=[\vec{\alpha}\circ\vec{p}+\beta m_0,\vec{\Sigma}] \tag{11.3.331}$$

here (obvious!):

$$[\beta,\vec{\Sigma}]=\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}\begin{bmatrix}\vec{\sigma}&0\\0&\vec{\sigma}\end{bmatrix}-\begin{bmatrix}\vec{\sigma}&0\\0&\vec{\sigma}\end{bmatrix}\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}=0 \tag{11.3.332}$$

and hence:

$$[H,\vec{\Sigma}]=[\vec{\alpha}\circ\vec{p},\vec{\Sigma}] \tag{11.3.333}$$

Consider the x component:

$$[H,\Sigma_1]=[\alpha_1 p_x+\alpha_2 p_y+\alpha_3 p_z,\Sigma_1]=p_x[\alpha_1,\Sigma_1]+p_y[\alpha_2,\Sigma_1]+p_z[\alpha_3,\Sigma_1] \tag{11.3.334}$$

Taking each of the commutators in turn:

$$\begin{aligned}
[\alpha_1,\Sigma_1]&=\begin{bmatrix}0&\sigma_x\\ \sigma_x&0\end{bmatrix}\begin{bmatrix}\sigma_x&0\\0&\sigma_x\end{bmatrix}-\begin{bmatrix}\sigma_x&0\\0&\sigma_x\end{bmatrix}\begin{bmatrix}0&\sigma_x\\ \sigma_x&0\end{bmatrix}=0\\
[\alpha_2,\Sigma_1]&=\begin{bmatrix}0&\sigma_y\\ \sigma_y&0\end{bmatrix}\begin{bmatrix}\sigma_x&0\\0&\sigma_x\end{bmatrix}-\begin{bmatrix}\sigma_x&0\\0&\sigma_x\end{bmatrix}\begin{bmatrix}0&\sigma_y\\ \sigma_y&0\end{bmatrix}\\
&=\begin{bmatrix}0&\sigma_y\sigma_y-\sigma_y\sigma_x\\ \sigma_y\sigma_x-\sigma_x\sigma_y&0\end{bmatrix}=\begin{bmatrix}0&-2\mathrm{i}\sigma_z\\-2\mathrm{i}\sigma_z&0\end{bmatrix}=-2\mathrm{i}\alpha_3\\
[\alpha_3,\Sigma_1]&=2\mathrm{i}\alpha_2
\end{aligned} \tag{11.3.335}$$

Hence:

$$[H,\Sigma_1]=p_x[\alpha_1,\Sigma_1]+p_y[\alpha_2,\Sigma_1]+p_z[\alpha_3,\Sigma_1]=-2\mathrm{i}p_y\alpha_3+2\mathrm{i}p_z\alpha_2=2\mathrm{i}(\vec{\alpha}\times\vec{p})_x \tag{11.3.336}$$

The same strategy can be used to solve for $[H,\Sigma_2]$ and $[H,\Sigma_3]$:

$$\begin{aligned}
[H,\Sigma_2]&=-\mathrm{i}(\alpha_1 p_z-\alpha_3 p_x)\\
[H,\Sigma_3]&=\mathrm{i}(\alpha_1 p_y-\alpha_2 p_x)
\end{aligned} \tag{11.3.337}$$

Therefore:

$$\boxed{[H,\vec{\Sigma}]=2\mathrm{i}\vec{\alpha}\times\vec{p}\neq\vec{0}} \tag{11.3.338}$$

Hence the observable corresponding to the operator $\vec{\Sigma}$ is also not a constant of motion. However, referring back to our relation:

$$[H,\vec{L}]=-\mathrm{i}\vec{\alpha}\times\vec{p} \tag{11.3.339}$$

We have:

$$[H,\vec{S}]=\frac{1}{2}[H,\vec{\Sigma}]=\mathrm{i}\vec{\alpha}\times\vec{p}=-[H,\vec{L}] \tag{11.3.340}$$

Therefore:

$$\boxed{[H,\vec{S}+\vec{L}]=[H,\vec{L}]+[H,\vec{S}]=[H,\vec{L}]-[H,\vec{L}]=\vec{0}} \tag{11.3.341}$$

Because:

$$\vec{S}=\frac{1}{2}\begin{bmatrix}\vec{\sigma}&0\\0&\vec{\sigma}\end{bmatrix} \tag{11.3.342}$$

Thus, Dirac equation proved a description of "intrinsic" angular moment (i.e. spin).

How let us show that helicity $\hat{h}$ (projection of the spin along the direction of motion for recall), does commute with the Hamiltonian, which means that helicity is a conserved quantity. Let us recall the definition of helicity:

$$\hat{h}=\frac{\vec{p}\circ\vec{\sigma}}{2\|\vec{p}\|} \tag{11.3.343}$$

So we want to calculate:

$$[H,\hat{h}]=\left[\vec{\alpha}\circ\vec{p}+\beta m_0,\frac{\vec{p}\circ\vec{\sigma}}{2\|\vec{p}\|}\right] \tag{11.3.344}$$

We see here a problem... Indeed, on the left term we have 4×4 matrices, and on the right term a 2×2 matrices. So we try by moving to then generalized total spin matrix introduced earlier above:

$$[H,\hat{h}]=\left[\vec{\alpha}\circ\vec{p}+\beta m_0,\frac{\vec{p}\circ\vec{\Sigma}}{2\|\vec{p}\|}\right] \tag{11.3.345}$$

Therefore if we focus on a only a component given that the direction is only along the z-axis, we can write:

$$\begin{aligned}[H,\hat{h}_z]&=\left[\alpha_3p_z+\beta m_0,\frac{p_z\Sigma_3}{2\|\sqrt{p_z^2}\|}\right]=\left[\alpha_3p_z+\beta m_0,\frac{\Sigma_3}{2}\right]=\frac{1}{2}\left[\alpha_3p_z+\beta m_0,\begin{bmatrix}\sigma_1 & 0\\ 0 & \sigma_1\end{bmatrix}\right]\\ &=\frac{1}{2}\left\{(\alpha_3p_z+\beta m_0)\begin{bmatrix}\sigma_3 & 0\\ 0 & \sigma_3\end{bmatrix}-\begin{bmatrix}\sigma_3 & 0\\ 0 & \sigma_3\end{bmatrix}(\alpha_3p_z+\beta m_0)\right\}\end{aligned} \tag{11.3.346}$$

And, for recall, as:

$$\beta_D=\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&-1\end{bmatrix}=\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix},\alpha_D^3=\begin{bmatrix}0&0&1&0\\0&0&0&-1\\1&0&0&0\\0&-1&0&0\end{bmatrix}=\begin{bmatrix}0&\sigma_3\\\sigma_3&0\end{bmatrix} \tag{11.3.347}$$

Hence:

$$\begin{aligned}[H,\hat{h}_z]=&\frac{1}{2}\left\{(\alpha_3p_z+\beta m_0)\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}-\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}(\alpha_3p_z+\beta m_0)\right\}\\ =&\frac{1}{2}\left\{\left(\begin{bmatrix}0&\sigma_3\\\sigma_3&0\end{bmatrix}p_z+\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}m_0\right)\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}-\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}\left(\begin{bmatrix}0&\sigma_3\\\sigma_3&0\end{bmatrix}p_z+\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}m_0\right)\right\}\\ =&\frac{1}{2}\begin{bmatrix}0&\sigma_3p_z\\\sigma_3p_z&0\end{bmatrix}\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}+\frac{1}{2}m_0\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}-\frac{1}{2}\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}\begin{bmatrix}0&\sigma_3p_z\\\sigma_3p_z&0\end{bmatrix}\\ &-\frac{m_0}{2}\begin{bmatrix}\sigma_3&0\\0&\sigma_3\end{bmatrix}\begin{bmatrix}\mathbb{1}&0\\0&-\mathbb{1}\end{bmatrix}\\ =&\frac{1}{2}\begin{bmatrix}0&\sigma_3p_z\sigma_3\\\sigma_3p_z\sigma_3&\end{bmatrix}-\frac{1}{2}\begin{bmatrix}0&\sigma_3\sigma_3p_z\\\sigma_3\sigma_3p_z&\end{bmatrix}\end{aligned} \tag{11.3.348}$$

If:

$$\sigma_3p_z\sigma_3=\sigma_3\sigma_3p_z \tag{11.3.349}$$

then helicity commutes with the Hamiltonian, and therefore helicity is a conserved quantity. Let us verify the previous equality:

$$\sigma_3p_z\sigma_3=\begin{bmatrix}1&0\\0&-1\end{bmatrix}p_z\begin{bmatrix}1&0\\0&-1\end{bmatrix}=\begin{bmatrix}p_z&0\\0&-p_z\end{bmatrix}\begin{bmatrix}1&0\\0&-1\end{bmatrix}=\begin{bmatrix}p_z&0\\0&p_z\end{bmatrix} \tag{11.3.350}$$

and:

$$\sigma_3\sigma_3 p_z=\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}p_z=\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix}p_z=\begin{bmatrix}p_z & 0\\ 0 & p_z\end{bmatrix} \tag{11.3.351}$$

Therefore:

$$[H,\hat{h}_z]=\frac{1}{2}\begin{bmatrix}0 & \sigma_3 p_z\sigma_3\\ \sigma_3 p_z\sigma_3 & \end{bmatrix}-\frac{1}{2}\begin{bmatrix}0 & \sigma_3\sigma_3 p_z\\ \sigma_3\sigma_3 p_z & \end{bmatrix}=0 \tag{11.3.352}$$

The same strategy can be adopted to solve for $[H,h_1]$ and $[H,h_2]$:

$$[H,h_1]=0[H,h_2]\quad=0 \tag{11.3.353}$$

Therefore:

$$\boxed{[H,\hat{h}]=0} \tag{11.3.354}$$

Helicity is therefore a conserved quantity!

11.3.5 Generalized Dirac Equation

In the case of the free electron, we have thus often seen and proved that the Hamiltonian has as expression:

$$E=(p^2c^2+m_0^2c^4)^{1/2} \tag{11.3.355}$$

In the case of an electron moving in an electromagnetic field, we have also proved in our study the Klein-Gordon equation at the beginning of this section that:

$$(E-qU)^2=\left(\vec{p}-q\vec{A}\right)^2c^2+m_0^2c^4 \tag{11.3.356}$$

Therefore:

$$E=\left[\left(\vec{p}-q\vec{A}\right)^2c^2+m_0^2c^4\right]^{\frac{1}{2}}+qU \tag{11.3.357}$$

OK finish for the recall!

If we now take back the Dirac Hamiltonian for the free electron proved earlier above (which for recall is a 4×4 matrix):

$$H_D=c\vec{\alpha}\circ\vec{p}+\beta m_0c^2 \tag{11.3.358}$$

and from the fact that we must add to the Hamiltonian the term of potential electrostatic energy via the potential vector, we get:

$$H_D=c\vec{\alpha}\circ\left(\vec{p}-q\vec{A}\right)+qU+\beta m_0c^2 \tag{11.3.359}$$

where the potential U will also have to be expressed in the form of a diagonal 4×4 matrix.

We then get the generalized Hamiltonian of Dirac in the following traditional form:

$$\boxed{(H_D-qU)=c\vec{\alpha}\circ\left(\vec{p}-q\vec{A}\right)+\beta m_0c^2} \tag{11.3.360}$$

Therefore we have in another well known form:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=\left[c\vec{\alpha}\circ\left(\vec{p}-q\vec{A}\right)+qU+\beta m_0c^2\right]\Psi \tag{11.3.361}$$

Or in natural units:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=\left[\vec{\alpha}\circ\left(\vec{p}-q\vec{A}\right)+qU+\beta m_0\right]\Psi \tag{11.3.362}$$

And as we know $\vec{p}=\mathrm{i}\vec{\nabla}=\mathrm{i}\partial_\mu$ and $\vec{\alpha}=\vec{\gamma}$, hence the well known form (using $q=e$ for the electron charge) of the generalized Dirac equation:

$$\boxed{\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=\left[\gamma^\mu\left(\mathrm{i}\partial_\mu-eA_\mu\right)+eU+\beta m_0\right]\Psi} \tag{11.3.363}$$

Caution!!! There is no principle of physics yet (in the beginning in the 121st century according to the holocene calendar) that says physicals laws or constants have to be the same everywhere and always. Indeed, the reader must remember that the "laws" of physics are **descriptive**, not **imperative** and therefore they are some observed regularity in what we can observe experimentally with sufficiently wide occurrence or relevance! Asking whether the laws can change is no more and no less than asking whether regularities which have been observed up till now might not be quite as universal as was thought. The answer to that is: YES! This could drive the reader a bit mad. Indeed, how can we possibly do Science if the rules keep changing? But if you are a professional active scientist, you have to face up to that possibility - and you have a responsibility to check out if there is evidence beyond reasonable doubt about it! We will repeat this warning multiple times in this textbook as its seems that this is something necessary!

11.3.6 Pauli Equation

In quantum mechanics, the "Pauli equation" or "Schrödinger–Pauli equation" is the formulation of the Schrödinger equation for spin-$1/2$ particles, which takes into account the interaction of the particle's spin with an external electromagnetic field. It is the non-relativistic limit of the Dirac equation and can be used where particles are moving at speeds much less than the speed of light, so that relativistic effects can be neglected. It was formulated by Wolfgang Pauli in 11927 (holocene calendar).

Let us now consider a two-component representation of the spinor:

$$\Psi(\vec{r},t)=\begin{bmatrix}\phi_a(\vec{r},t)\\ \phi_b(\vec{r},t)\end{bmatrix} \tag{11.3.364}$$

and let us recall that:

$$\alpha=\begin{bmatrix}0 & \vec{\sigma}\\ \vec{\sigma} & 0\end{bmatrix} \quad \text{and} \quad \beta=\begin{bmatrix}\mathbb{1} & 0\\ 0 & -\mathbb{1}\end{bmatrix} \tag{11.3.365}$$

Therefore it comes:

$$\mathrm{i}\hbar\frac{\partial\Psi}{\partial t}=c\begin{bmatrix}0 & \vec{\sigma}\\ \vec{\sigma} & 0\end{bmatrix}\circ\left(\vec{p}-q\vec{A}\right)\Psi+qU\Psi+\begin{bmatrix}\mathbb{1} & 0\\ 0 & -\mathbb{1}\end{bmatrix}m_0c^2\Psi \tag{11.3.366}$$

Hence:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\begin{bmatrix}\phi_a\\ \phi_b\end{bmatrix}=c\begin{bmatrix}0 & \vec{\sigma}\\ \vec{\sigma} & 0\end{bmatrix}\circ\left(\vec{p}-q\vec{A}\right)\begin{bmatrix}\phi_a\\ \phi_b\end{bmatrix}+qU\begin{bmatrix}\phi_a\\ \phi_b\end{bmatrix}+\begin{bmatrix}\mathbb{1} & 0\\ 0 & -\mathbb{1}\end{bmatrix}m_0c^2\begin{bmatrix}\phi_a\\ \phi_b\end{bmatrix} \tag{11.3.367}$$

What after simplification gives:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\begin{bmatrix}\phi_a\\ \phi_b\end{bmatrix}=\begin{pmatrix}c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_b\\ c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_a\end{pmatrix}+qU\begin{bmatrix}\phi_a\\ \phi_b\end{bmatrix}+m_0c^2\begin{bmatrix}\phi_a\\ -\phi_b\end{bmatrix} \tag{11.3.368}$$

Before continuing, let us open an important parenthesis, otherwise we will not be able to find a solution to these two equations.

Let us recall that one of the spinors solution of the free Dirac equation was given by (as we have proved it earlier above):

$$\phi_b=\frac{\vec{p}\circ\vec{\sigma}}{E+m_0}\phi_a \qquad (11.3.369)$$

Either in International Standard units:

$$\phi_b=\frac{c\vec{p}\circ\vec{\sigma}}{E+m_0c^2}\phi_a \qquad (11.3.370)$$

In order to simplify the calculation of the prior-previous equations we will reduce the situation to a non-relativistic case, that is to say when the mass energy is much greater than the kinetic energy. Therefore the previous solution becomes (we forget the second which would cause problems ...):

$$\phi_b\cong\frac{\vec{p}\circ\vec{\sigma}}{2m_0c}\phi_a \qquad (11.3.371)$$

The idea is simple but someone had to think about it! It should be noticed that depending on the authors and professors it is the following term which is named "helicity":

$$\frac{\vec{p}\circ\vec{\sigma}}{2m_0c}=\frac{\vec{p}\circ\vec{\sigma}}{2\|\vec{p}\|} \qquad (11.3.372)$$

as it is the projection (as we will see later) of the spin operator on the linear momentum.

The idea is then to find a solution to:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\begin{bmatrix}\phi_a\\ \phi_b\end{bmatrix}=\begin{pmatrix}c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_b\\ c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_a\end{pmatrix}+qU\begin{bmatrix}\phi_a\\ \phi_b\end{bmatrix}+m_0c^2\begin{bmatrix}\phi_a\\ -\phi_b\end{bmatrix} \qquad (11.3.373)$$

such that we make a non-relativistic approximation and we cancel the magnetic field (in extenso the vector potential), we fall back on:

$$\phi_b=\frac{\vec{p}\circ\vec{\sigma}}{2m_0c}\phi_a \qquad (11.3.374)$$

After many trials and errors (yes Quantum Physics was not made in one day... not even if one year...) we find that a particular solution satisfying our previous idea is:

$$\begin{bmatrix}\phi_a\\ \phi_b\end{bmatrix}=\begin{bmatrix}\phi_{a0}\\ \phi_{b0}\end{bmatrix}e^{-\mathrm{i}\frac{mc^2t}{\hbar}} \qquad (11.3.375)$$

Indeed:

$$\begin{gathered}
\mathrm{i}\hbar\frac{\partial}{\partial t}\begin{bmatrix}\phi_{a0}\\ \phi_{b0}\end{bmatrix}e^{-\mathrm{i}\frac{mc^2t}{\hbar}}=\begin{pmatrix}c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{b0}e^{-\mathrm{i}\dfrac{mc^2t}{\hbar}}\\ c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{a0}e^{-\mathrm{i}\frac{mc^2t}{\hbar}}\end{pmatrix}+\left(qU\begin{bmatrix}\phi_{a0}\\ \phi_{b0}\end{bmatrix}+m_0c^2\begin{bmatrix}\phi_{a0}\\ -\phi_{b0}\end{bmatrix}\right)e^{-\mathrm{i}\frac{mc^2t}{\hbar}}\\
\mathrm{i}\hbar\begin{bmatrix}\dfrac{\partial}{\partial t}\phi_{a0}\\ \dfrac{\partial}{\partial t}\phi_{b0}\end{bmatrix}e^{-\mathrm{i}\frac{mc^2t}{\hbar}}+\mathrm{i}\hbar\begin{bmatrix}\phi_{a0}\\ \phi_{b0}\end{bmatrix}\frac{\partial}{\partial t}e^{-\mathrm{i}\frac{mc^2t}{\hbar}}=\begin{pmatrix}c\vec{\sigma}\left(\vec{p}-q\vec{A}\right)\phi_{b0}\\ c\vec{\sigma}\left(\vec{p}-q\vec{A}\right)\phi_{a0}\end{pmatrix}e^{-\mathrm{i}\dfrac{mc^2t}{\hbar}}+\left(qU\begin{bmatrix}\phi_{a0}\\ \phi_{b0}\end{bmatrix}+m_0c^2\begin{bmatrix}\phi_{a0}\\ -\phi_{b0}\end{bmatrix}\right)e^{-\mathrm{i}\dfrac{mc^2t}{\hbar}}\\
\mathrm{i}\hbar\begin{bmatrix}\dfrac{\partial}{\partial t}\phi_{a0}\\ \dfrac{\partial}{\partial t}\phi_{b0}\end{bmatrix}e^{-\mathrm{i}\frac{mc^2t}{\hbar}}+mc^2\begin{bmatrix}\phi_{a0}\\ \phi_{b0}\end{bmatrix}e^{-\mathrm{i}\dfrac{mc^2t}{\hbar}}=\begin{pmatrix}c\vec{\sigma}\left(\vec{p}-q\vec{A}\right)\phi_{b0}\\ c\vec{\sigma}\left(\vec{p}-q\vec{A}\right)\phi_{a0}\end{pmatrix}e^{-\mathrm{i}\frac{mc^2t}{\hbar}}+\left(qU\begin{bmatrix}\phi_{a0}\\ \phi_{b0}\end{bmatrix}+m_0c^2\begin{bmatrix}\phi_{a0}\\ -\phi_{b0}\end{bmatrix}\right)e^{-\mathrm{i}\frac{mc^2t}{\hbar}}\\
\mathrm{i}\hbar\frac{\partial}{\partial t}\begin{bmatrix}\phi_{a0}\\ \phi_{b0}\end{bmatrix}=\begin{pmatrix}c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{b0}\\ c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{a0}\end{pmatrix}+qU\begin{bmatrix}\phi_{a0}\\ \phi_{b0}\end{bmatrix}-2m_0c^2\begin{bmatrix}0\\ \phi_{b0}\end{bmatrix}
\end{gathered}\tag{11.3.376}$$

We finally have 2 equations (yes yes... we know that in fact as spinor has two components and therefore in reality we don't have 2 equations but 4 equations...!):

$$\begin{gathered}
\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0}=c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{b0}+qU\phi_{a0}\\
\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{b0}=c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{a0}+qU\phi_{b0}-2m_0c^2\phi_{b0}
\end{gathered}\tag{11.3.377}$$

Now let us consider only the second equation:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{b0}=c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{a0}+qU\phi_{b0}-2m_0c^2\phi_{b0}\tag{11.3.378}$$

Assuming (for free, after which it will be necessary to compare that assumption to experimental results) that the term $|\partial_t\phi_b|$ is much smaller than $|2m_0c^2\phi_{b0}|$ we can write:

$$0\cong c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{a0}+qU\phi_{b0}-2m_0c^2\phi_{b0}\tag{11.3.379}$$

By making the same assumption with $|qU\phi_{b0}|$ we have:

$$0\cong c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{a0}-2m_0c^2\phi_{b0}\tag{11.3.380}$$

We then have (do not forget that the denominator is a diagonal matrix in reality ...):

$$\phi_{b0}\cong\frac{\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)}{2m_0c}\phi_{a0}\tag{11.3.381}$$

Now, we see that if the magnetic field (in extenso the vector potential) vanishes, we fall back well on our starting idea! So the bet was good!

Because of all these downward approximations, the ϕ_b component is often taken as the "small" component of the wave function Ψ, relatively to the large component ϕ_a.

The first equation:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0}=c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\phi_{b0}+qU\phi_{a0}\tag{11.3.382}$$

can now be simplified easily by taking the previous solution such that:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0} \cong c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\left(\frac{\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)}{2m_0c}\right)\phi_{a0}+qU\phi_{a0} \tag{11.3.383}$$

Therefore:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0} \cong \frac{c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)}{2m_0c}\phi_{a0}+qU\phi_{a0} \tag{11.3.384}$$

Using the remarkable identity proved in the section of Spinor Calculus:

$$(\vec{\sigma}\circ\vec{a})(\vec{\sigma}\circ\vec{b})=(\vec{a}\circ\vec{b})\mathbb{1}+\mathrm{i}\circ(\vec{a}\times\vec{b}) \tag{11.3.385}$$

we get:

$$\begin{aligned}\vec{\sigma}\circ(\vec{p}-q\vec{A})\vec{\sigma}\circ(\vec{p}-q\vec{A}) &= \left(\vec{p}-q\vec{A}\right)^2+\mathrm{i}\vec{\sigma}\circ\left[\left(\vec{p}-q\vec{A}\right)\times\left(\vec{p}-q\vec{A}\right)\right]\\ &= \left(\vec{p}-q\vec{A}\right)^2+\mathrm{i}\vec{\sigma}\circ\left[\left(-\mathrm{i}\hbar\vec{\nabla}-q\vec{A}\right)\times\left(-\mathrm{i}\hbar\vec{\nabla}-q\vec{A}\right)\right]\end{aligned} \tag{11.3.386}$$

Let us detail the cross product by remembering that it will act as an operator on ϕ_{a0}:

$$\begin{aligned}&\vec{\sigma}\circ\left(-\mathrm{i}\hbar\vec{\nabla}-q\vec{A}\right)\times\left(-\mathrm{i}\hbar\vec{\nabla}-q\vec{A}\right)\phi_{a0}\\ &=\underbrace{\vec{\sigma}\circ\left(-\mathrm{i}\hbar\vec{\nabla}\times-\mathrm{i}\hbar\vec{\nabla}\right)\phi_{a0}}_{=0}+\vec{\sigma}\circ\left(-\mathrm{i}\hbar\vec{\nabla}\times-q\vec{A}\right)\phi_{a0}+\vec{\sigma}\circ\left(-q\vec{A}\times-\mathrm{i}\hbar\vec{\nabla}\right)\phi_{a0}+\underbrace{\vec{\sigma}\circ\left(-q\vec{A}\times-q\vec{A}\right)\phi_{a0}}_{=0}\\ &=\mathrm{i}\hbar q\left[\vec{\sigma}\circ\left(\vec{\nabla}\times\vec{A}\right)\phi_{a0}+\vec{\sigma}\circ\left(\vec{A}\times\vec{\nabla}\right)\phi_{a0}\right]\end{aligned} \tag{11.3.387}$$

But, we have (see section Spinor Calculus page 2158):

$$\begin{aligned}&\vec{\sigma}\circ\left(\vec{\nabla}\times\vec{A}\right)\phi_{a0}+\vec{\sigma}\circ\left(\vec{A}\times\vec{\nabla}\right)\phi_{a0}=\\ &=\begin{bmatrix}\partial_xA_y-\partial_yA_x & (\partial_yA_z-\partial_zA_y)-\mathrm{i}(\partial_zA_x-\partial_xA_z)\\ (\partial_yA_z-\partial_zA_y)+\mathrm{i}(\partial_zA_x-\partial_xA_z) & -(\partial_xA_y-\partial_yA_x)\end{bmatrix}\\ &+\begin{bmatrix}A_x\partial_y-A_y\partial_x & (A_y\partial_z-A_z\partial_y)-\mathrm{i}(A_z\partial_x-A_x\partial_z)\\ (A_y\partial_z-A_z\partial_y)+\mathrm{i}(A_z\partial_x-A_x\partial_z) & -(A_x\partial_y-A_y\partial_x)\end{bmatrix}\end{aligned} \tag{11.3.388}$$

Let us just look at the component in the upper left corner (if not the calculations are too long and boring to do) of this sum of matrices. We must not forget that this component of the matrix will act on the first component as an operator on ϕ_{a0} (written with the same notation as the spinor itself to avoid to many indices):

$$\begin{aligned}&(\partial_xA_y\phi_{a0}-\partial_yA_x\phi_{a0})+(A_x\partial_y\phi_{a0}-A_y\partial_x\phi_{a0})\\ &=(\partial_x(A_y\phi_{a0})-\partial_y(A_x\phi_{a0}))+(A_x\partial_y\phi_{a0}-A_y\partial_x\phi_{a0})\\ &=(\partial_x(A_y\phi_{a0})-A_y\partial_x\phi_{a0}))+(A_x\partial_y\phi_{a0}-\partial_y(A_x\phi_{a0}))\end{aligned} \tag{11.3.389}$$

But:

$$\partial_x(A_y\phi_{a0})=A_y\partial_x\phi_{a0}+\phi_{a0}\partial_xA_y\Rightarrow\partial_x(A_y\phi_{a0})-A_y\partial_x\phi_{a0}=\phi_{a0}\partial_xA_y \tag{11.3.390}$$

$$\partial_y(A_x\phi_{a0})=A_x\partial_y\phi_{a0}+\phi_{a0}\partial_yA_x\Rightarrow A_x\partial_y\phi_{a0}-\partial_y(A_x\phi_{a0})=-\phi_{a0}\partial_yA_x \tag{11.3.391}$$

Therefore:

$$(\partial_x(A_y\phi_{a0})-A_y\partial_x\phi_{a0}))+(A_x\partial_y\phi_{a0}-\partial_y(A_x\phi_{a0}))=\phi_{a0}\partial_xA_y-\phi_{a0}\partial_yA_x \tag{11.3.392}$$

But, we recognize here the third component of a cross product that does not act as an operator. Finally, it comes:

$$\vec{\sigma}\circ\left(-\mathrm{i}\hbar\vec{\nabla}-q\vec{A}\right)\times\left(-\mathrm{i}\hbar\vec{\nabla}-q\vec{A}\right)\phi_{a0}=\vec{\sigma}\circ\left(-\mathrm{i}\hbar\vec{\nabla}\times-q\vec{A}\right)\phi_{a0}=\mathrm{i}\hbar q\vec{\sigma}\circ\left(\vec{\nabla}\times\vec{A}\right)\phi_{a0} \tag{11.3.393}$$

Therefore:

$$\begin{gathered}\left(\vec{p}-q\vec{A}\right)^2+\mathrm{i}\vec{\sigma}\circ\left[\left(-\mathrm{i}\hbar\vec{\nabla}-q\vec{A}\right)\times\left(-\mathrm{i}\hbar\vec{\nabla}-q\vec{A}\right)\right]=\left(\vec{p}-q\vec{A}\right)^2-\hbar q\vec{\sigma}\circ\left(\vec{\nabla}\times\vec{A}\right)\\=\left(\vec{p}-q\vec{A}\right)^2-\hbar q\vec{\sigma}\circ\vec{B}\end{gathered} \tag{11.3.394}$$

Thus, the relation of the main component:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0}\cong\frac{c\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)\vec{\sigma}\circ\left(\vec{p}-q\vec{A}\right)}{2m_0c}\phi_{a0}+qU\phi_{a0} \tag{11.3.395}$$

becomes:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0}\cong\frac{\left(\vec{p}-q\vec{A}\right)^2-\hbar q\vec{\sigma}\circ\vec{B}}{2m_0}\phi_{a0}+qU\phi_{a0} \tag{11.3.396}$$

The reader will notice that the notations are not the most enjoyable (between vectors, matrices and constants it is necessary to follow well to know what is in there ...).

After rearrangement:

$$\boxed{\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0}\cong\left[\frac{\left(\vec{p}-q\vec{A}\right)^2}{2m_0}-\frac{\hbar q}{2m_0}\vec{\sigma}\circ\vec{B}+qU\right]\phi_{a0}} \tag{11.3.397}$$

which constitutes the "Pauli equation", or Schrödinger-Pauli equation", and thus describes in a relativistic way the two components of ϕ_{a0} of the spin of the electron (this is really a two-equation system).

The expression:

$$\boxed{\frac{\hbar q}{2m_0}\vec{\sigma}\circ\vec{B}} \tag{11.3.398}$$

is named the "Stern-Gerlach term" and represents the interaction energy of the magnetic field with the intrinsic moment of the electron (this is a 2×2 matrix for recall). And the term:

$$\frac{\left(\vec{p}-q\vec{A}\right)^2}{2m_0}-\frac{\hbar q}{2m_0}\vec{\sigma}\circ\vec{B}+qU \tag{11.3.399}$$

is named the "Pauli Hamiltonian" and denoted H_P.

The Pauli equation, and therefore that of Dirac (since the latter is more general), give the correct gyromagnetic factor for a free electron of $g=2$. To verify this, let us take as it has been done experimentally, a constant magnetic field.

We can easily verify that the choice of a vector potential corresponding to a constant magnetic field is then:

$$\vec{A}=\frac{1}{2}\vec{B}\times\vec{x} \tag{11.3.400}$$

This choice will have the effect of make disappear the vector potential in favour of the magnetic field in the Pauli equation, which will reveal the interaction between the orbital angular momentum and the magnetic field as we shall see:

Indeed, we have:

$$\vec{B}=\vec{\nabla}\times\vec{A}=\vec{\nabla}\times\left(\frac{1}{2}\vec{B}\times\vec{r}\right) \tag{11.3.401}$$

As requested by a reader, here is the proof of that latter relation:

$$\begin{aligned}&\vec{\nabla}\times\left(\frac{1}{2}\vec{B}\times\vec{r}\right)=\vec{\nabla}\times\left(\begin{pmatrix}B_yz-B_zy\\B_zx-B_xz\\B_xy-B_yx\end{pmatrix}\right)=\frac{1}{2}\begin{bmatrix}\partial_y(B_xy-B_yx)-\partial_z(B_zx-B_xz)\\\partial_z(B_yz-B_zy)-\partial_x(B_xy-B_yx)\\\partial_x(B_zx-B_xz)-\partial_y(B_yz-B_zy)\end{bmatrix}\\&=\frac{1}{2}\begin{pmatrix}B_x+B_x\\B_y+B_y\\B_z+B_z\end{pmatrix}=\begin{pmatrix}B_x\\B_y\\B_z\end{pmatrix}=\vec{B}\end{aligned} \tag{11.3.402}$$

We then have in Pauli equation:

$$\begin{aligned}\left(\vec{p}-q\vec{A}\right)^2=\left(\vec{p}-\frac{q}{2}\vec{B}\times\vec{x}\right)^2=\|\vec{p}\|^2-q(\vec{B}\times\vec{x})\circ\vec{p}+\underbrace{\frac{q^2}{4}\|\vec{B}\times\vec{x}\|^2}_{\cong 0}=\\=\|\vec{p}\|^2-q(\vec{B}\times\vec{x})\circ\vec{p}\end{aligned} \tag{11.3.403}$$

But, let us recall that we have seen in the section of Vector Calculus page 1830 that:

$$(\vec{x}\times\vec{y})\circ\vec{z}=\vec{x}\circ(\vec{y}\times\vec{z}) \tag{11.3.404}$$

This gives us therefore:

$$\|\vec{p}\|^2-q(\vec{B}\times\vec{x})\circ\vec{p}=\|\vec{p}\|^2-q\vec{B}\circ(\vec{x}\times\vec{p})=\|\vec{p}\|^2-q\vec{B}\circ\vec{L} \tag{11.3.405}$$

where:

$$\vec{L}=\vec{x}\times\vec{p} \tag{11.3.406}$$

denoted also $\vec{b}$ (see sections of Classical Mechanics page 3244 and Corpuscular Quantum Physics page 4629), is therefore an operator representing the angular momentum.

Therefore we have:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0}\cong\left[\frac{\|\vec{p}\|^2}{2m_0}-\frac{q\vec{B}\circ\vec{L}}{2m_0}-\frac{\hbar q}{2m_0}\vec{\sigma}\circ\vec{B}+qU\right]\phi_{a0} \tag{11.3.407}$$

By proceeding as Dirac did, that is, by defining the spin operator as the matrix (oh! we fall back on something known and seen in the section of Wave Quantum Physics!! it's beautiful no!?):

$$\boxed{\vec{S}=\frac{1}{2}\hbar\vec{\sigma}} \tag{11.3.408}$$

This relationship will be very useful to us in the section Quantum Computing. Let us indicate the following notation (quite logic) in the literature for the intrinsic magnetic moment:

$$\vec{\mathcal{M}}=\frac{\hbar q}{2m_0}\vec{\sigma} \tag{11.3.409}$$

The Pauli equation is then written:

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0}\cong\left[\frac{\|\vec{p}\|^2}{2m_0}-\frac{q\vec{B}\circ\vec{L}}{2m_0}-\frac{q}{m_0}\vec{S}\circ\vec{B}+qU\right]\phi_{a0} \tag{11.3.410}$$

or after factorization (the Hamiltonian will then be named "Pauli Hamiltonian for a constant direction magnetic field"):

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0}\cong\left[\frac{\|\vec{p}\|^2}{2m_0}-\frac{q}{2m_0}(\vec{L}+2\vec{S})\circ\vec{B}+qU\right]\phi_{a0} \tag{11.3.411}$$

or even more condensed by being careful to differentiate what is an operator, what is a vector and what is a simple multiplication from an inner product and what is a function of a spinor ... (only happiness...) and by putting:

$$g=2 \tag{11.3.412}$$

as being the "Landé g-factor[28]" (see the quantum origin further below at page 4989) or "gyromagnetic factor", we have:

$$\boxed{\mathrm{i}\hbar\frac{\partial}{\partial t}\phi_{a0}\cong\left[\frac{\|\vec{p}\|^2}{2m_0}-(\vec{\mu}_L+g\vec{\mu}_S)\circ\vec{B}+qU\right]\phi_{a0}} \tag{11.3.413}$$

with $\vec{\mu}_L$ being the "orbital magnetic moment" (by comparing with the expression of the magnetic moment proved in the Magnetostatic section you will see that it actually has the same form and also the same units), $\vec{\mu}_S$ the "magnetic moment of spin".

Sometimes we find the expression in parentheses in the above-mentioned relationship as follows:

$$\vec{\mu}=\vec{\mu}_L+g\vec{\mu}_S \tag{11.3.414}$$

---

[28] It's important to specify the "Landé" in front of the g because experiments have provided evidence that $g=2$ is inaccurate! More precise calculations done by Julian Schwinger (see [438] sections 6.2 and 6.3 pages 184 to 196), and named the "Schwinger g-factor", gives a correction of $+\alpha/2\pi$ (anomalous magnetic dipole moment) that let to $g\cong 2+\alpha/2\pi\cong 2.0011614$. Even more precise calculation give $g\cong 2.0023193804386$.

So we have just seen that we can derive the electron's spin g-factor by starting with the Dirac equation for an electron in a weak electromagnetic field and looking at its non-relativistic limit. We then find that there is a supplementary interaction energy term having a factor 2.

With all this the Stern-Gerlach term (magnetic moment) becomes explicitly:

$$\boxed{\vec{\mathcal{M}}_S=g\frac{q}{2m_0}\frac{1}{2}\hbar\vec{\sigma}=\frac{g}{2}\mu_B\vec{\sigma}=g\frac{q}{2m_0}S} \tag{11.3.415}$$

Recalling that:

$$\mu_B=\frac{q\hbar}{2m_0} \tag{11.3.416}$$

is the Bohr magneton which we had introduced rigorously in the section of Corpuscular Quantum Physics.

Interestingly ... the neutron has (experimental observation!) a spin magnetic moment that is non-zero yet its charge is zero ... so it must be composed of charged particles (if we remain within the framework of a model of the explanation of nature by particles ...). It is interesting to know that in practice we have for the electron, the proton and the neutron:

$$\begin{aligned}\mu_{\text{electron}}&\cong\mu_g\\ \mu_{\text{proton}}&\cong 2.79\mu_B\\ \mu_{\text{neutron}}&\cong -1.91\mu_B\end{aligned} \tag{11.3.417}$$

and the following values were measured for spin $1/2$ particles such as the electron, proton and neutron (caution! the sign may change depending on how the Dirac equation is written):

$$\begin{aligned}g_e&\cong 2\\ g_p&\cong -5.585\\ g_n&=3.826\end{aligned} \tag{11.3.418}$$

Therefore the Dirac theory in the non-relativistic framework predicts in a good approximation that the elementary particles of spin $1/2$ have a gyromagnetic factor of 2, and this prediction consistent with the experiment for the electron is the greatest triumph of the Dirac equation. The deviations of the theoretical value (consequent deviations!) for the proton and the neutron are perfectly explained in the framework of quantum electrodynamics. These deviations show that the structure of the proton and that of the neutron are more complex (subparticle composition) than a spin $1/2$ point particle whereas in the case of the electron, it seems that it has no underlying substructure.

Remark

The gyromagnetic factor is sometimes taken as negative but it is only a matter of convention.

It is by the way the interaction term between the magnetic field and the addition of the orbital angular momentum and intrinsic spin:

$$\boxed{E_p=-\frac{q}{2m_0}(\vec{L}+2\vec{S})\circ\vec{B}} \tag{11.3.419}$$

of the Pauli Hamiltonian which gives the values measured by the Zeeman effect! Reason why this expression is sometimes named "Zeeman energy" and sometimes written in the form of a Hamiltonian operator:

$$\hat{H}_Z = -\frac{q}{2m_0}(\vec{L}+2\vec{S})\circ\vec{B} \tag{11.3.420}$$

Remark

The above treatment of the Zeeman effect describes the phenomenon when the magnetic field is small enough and that the orbital and spin angular momentum can be considered to be coupled (see section Wave Quantum Physics page 4899). For extremely strong magnetic fields this coupling is broken and another approach must be taken. The strong field effect is named the "Paschen-Back effect".

We know that this last relation can also be written for any single particle (see section Wave Quantum Physics page 4877) immersed in a magnetic field collinear to the z-axis and zero in the other directions:

$$\begin{aligned} E_p &= -(\vec{\mu}_L + g\vec{\mu}_S)\circ\vec{B} = -\frac{q}{2m_0}(\vec{L}+2\vec{S})\circ\vec{B} = -\frac{q}{2m_0}(L_z+2S_z)B_z \\ &= -\frac{q}{2m_0}(m_l\hbar+2s\hbar)B = -\frac{q}{2m_0}\hbar(m_l+2s)B \\ &= -\gamma\hbar(m_l+2s)B = -\mu_B\hbar(m_l+2s)B \end{aligned} \tag{11.3.421}$$

where γ is the "gyromagnetic ratio" and the μ_B the "Bohr magnetron" (and we saw in the proof of this relation that the Bohr magnetron is only a special case with the Landé g factor equal to that of the electron).

Let us now focus only on the smallest variation in energy between two states of the orbital angular momentum (since the smallest variation is 1 by the quantification of l). It will then always be equal to the form:

$$\Delta E_{p,l} = -\gamma\hbar B \tag{11.3.422}$$

Remark

As $\gamma\hbar \cong 5.8\cdot 10^{-5}$ [eV $\cdot$ T^{-1}] and that largest field which can regularly be produced in a lab is around 10 [T]. Thus, $\Delta E_{p,l}\cong 10^{-3}$ [eV]. This is a very small energy. Thus magnetic effects are wiped out by thermal fluctuation at about 10 [K]! Thus experiments which measure the magnetism of non-interacting systems must be carried out at low temperatures. These experiments typically measure the susceptibility of the system with a Faraday balance or a magnetometer (SQUID: Superconducting QUantum Interference Device).

This variation of energy will be restored in the form of electromagnetic waves corresponding to:

$$h\nu = h\frac{\omega}{2\pi} = -\gamma\hbar B = -\gamma\frac{h}{2\pi}B \tag{11.3.423}$$

hence:

$$\omega = -\gamma B \tag{11.3.424}$$

which is the "Larmor relation" (not to be confused with the "Larmor radius" seen in the Magnetostatic section). But in practice we mainly use the relation:

$$\nu = -\gamma \frac{B}{2\pi} \tag{11.3.425}$$

which gives what we name the "resonance frequency" of the orbital angular momentum.

Similarly, for the intrinsic kinetic moment, we get for a constant orbital kinetic moment (during the spin transition from $+1/2$ to $-1/2$ or vice versa):

$$\Delta E_{p,s} = -\Delta(\gamma\hbar 2s)B = -\gamma\hbar B\Delta(2s) = -2\gamma\hbar B\Delta s = -2\gamma\hbar B \tag{11.3.426}$$

and putting $g = 2$ it comes:

$$\Delta E_{p,s} = -g\gamma\hbar B \tag{11.3.427}$$

hence:

$$\omega = -g\gamma B \tag{11.3.428}$$

and obviously:

$$\boxed{\nu = -g\gamma \frac{B}{2\pi}} \tag{11.3.429}$$

This last study of energy variation due to the application of a magnetic field and the resulting energy emission frequencies is the basis of "nuclear magnetic resonance (NMR)", which therefore works only for the particles having the magnetic moment of spin μ_S (by construction of the Pauli Hamiltonian).

NMR consists in modifying the nuclear magnetic moment, in other words, to pass the nucleus from one level of energy to another by applying magnetic fields to the sample to be studied. When the energy of the photons constituting these magnetic fields corresponds to the energy of transition from one level of energy to the other, these photons can be absorbed by the nucleus: we then say that there is "nuclear resonance".

We can characterize the transition energy of the nuclear magnetic spin moment by giving the frequency of the electromagnetic wave that allows resonance. For the usual fields (of the order of the Tesla), the proton resonance takes place in the range of radio waves (100 [MHz] approximately): 42 [MHz] in a field of 1.0 [T] and 63 [MHz] In a field of 1.5 [T].

Let us point out that on the way that in some textbooks, since we have:

$$\Delta E_{p,s} = -g\gamma\hbar B \tag{11.3.430}$$

Then for a particle with two possible states of spin the energy of each of the level is then obviously half the above difference, which is often denoted by:

$$E_{\pm,s} = \hbar\omega_{\pm} = -\frac{g\gamma\hbar B}{2} = -\frac{g\mu_B B}{2} \tag{11.3.431}$$

11.3.6.1 Landé g-factor

We have seen previously that the Landé g-factor is a multiplicative term appearing in the expression for the energy levels of an atom in a weak magnetic field. We seek now for a more detailed expression and you will see that all the abstract stuff we have introduced during our study of orbital-spin coupling in the section of Wave Quantum Physics will be useful to us.

In the weak field limit, we assume that the magnetic dipole moment of the atom is proportional to the total angular momentum $\vec{J}$:

$$\vec{\mu}_J = g_J m_B \vec{J} \tag{11.3.432}$$

where m_B is still the Bohr magneton and g_J is the Landé g factor for $\vec{J}$. To find a value of g_J, we relate $\vec{J}$ to the known values of g_L and g_S and we use (see section Wave Quantum Physics page 4881):

$$\vec{J} = \vec{L} + \vec{S} \tag{11.3.433}$$

and therefore:

$$\vec{\mu}_J = \vec{\mu}_L + \vec{\mu}_S \tag{11.3.434}$$

with the assumption that:

$$\vec{\mu}_L = g_L m_B \vec{L} \qquad \text{and} \qquad \vec{\mu}_S = g_S m_B \vec{S} \tag{11.3.435}$$

Hence:

$$\vec{\mu}_J = g_J m_B \vec{J} = g_L m_B \vec{L} + g_S m_B \vec{S} \tag{11.3.436}$$

Therefore after simplification:

$$g_J \vec{J} = g_L \vec{L} + g_S \vec{S} \tag{11.3.437}$$

We then take the dot product with $\vec{J}$ and get:

$$g_J \vec{J} \circ \vec{J} = g_L \vec{L} \circ \vec{J} + g_S \vec{S} \circ \vec{J} \tag{11.3.438}$$

Therefore:

$$g_J \|\vec{J}\|^2 = g_L \vec{L} \circ (\vec{L} + \vec{S}) + g_S \vec{S} \circ (\vec{L} + \vec{S}) = g_L (\|\vec{L}\|^2 + \vec{L} \circ \vec{S}) + g_S \circ (\vec{S} \circ \vec{L} + \|\vec{S}\|^2) \tag{11.3.439}$$

That is often written for simplification purposes:

$$g_J J^2 = g_L (L^2 + \vec{L} \circ \vec{S}) + g_S (\vec{S} \circ \vec{L} + S^2) \tag{11.3.440}$$

Now let us recall that in the section of Wave Quantum Physics during the study of spin-orbit coupling (see page 4900) we have proved that (still simplifying the notation of the norm of a vector):

$$\vec{L} \circ \vec{S} = \frac{1}{2} \left(J^2 - L^2 - S^2 \right) \tag{11.3.441}$$

Therefore:

$$\begin{aligned} g_J J^2 &= g_L(L^2+0.5\left(J^2-L^2-S^2\right))+g_S(0.5\left(J^2-L^2-S^2\right)+S^2) \\ &= 0.5g_L(J^2-L^2-S^2)+0.5g_S(J^2-L^2+S^2) \end{aligned} \tag{11.3.442}$$

Now we introduce the eigenvalues of J^2, L^2 and J^2 as we have determined the during our study of Angular Momentum and Spin (see page 4877) and we simplify by $\hbar^2$ directly and that gives:

$$g_J J(J+1)=0.5g_L(J(J+1)-L(L+1)-S(S+1))+0.5g_S(J(J+1)-L(L+1)+S(S+1)) \tag{11.3.443}$$

Therefore:

$$\boxed{g_J=\frac{g_L(J(J+1)-L(L+1)-S(S+1))+g_S(J(J+1)-L(L+1)+S(S+1))}{2J(J+1)}} \tag{11.3.444}$$

If we put $g_L=1$ and $g_S\cong 2$ (implying that the spin angular momentum is twice as effective in producing a magnetic moment) then the above expression simplifies to:

$$\begin{aligned} g_J &\cong \frac{(J(J+1)-L(L+1)-S(S+1))+2(J(J+1)-L(L+1)+S(S+1))}{2J(J+1)} \\ &= \frac{3J(J+1)+S(S+1)-L(L+1)}{2J(J+1)} \\ &= \frac{3J(J+1)}{2J(J+1)}+\frac{S(S+1)-L(L+1)}{2J(J+1)}=\frac{3}{2}+\frac{S(S+1)-L(L+1)}{2J(J+1)} \end{aligned} \tag{11.3.445}$$

Now following the same reasoning, let us determine in a most robust way the relation:

$$E_p=-\frac{q}{2m_0}(\vec{L}+2\vec{S})\circ\vec{B} \tag{11.3.446}$$

determined earlier above.

The problem with evaluating the scalar product above is that $\vec{L}$ and $\vec{S}$ continually change in direction as shown in the vector model. The strategy for dealing with this problem is to use the direction of the total angular momentum $\vec{J}$ as a coordinate axis and obtain the projection of each of the vectors in that direction. This is done by taking the scalar product of each vector with a unit vector in the $\vec{J}$ direction:

$$\begin{aligned} E_p &= -\frac{q}{2m_0}(\vec{L}+2\vec{S})\circ\left(\vec{B}\frac{J^2}{J^2}\right)=-\frac{q}{2m_0}(\vec{L}+2\vec{S})\circ\left(\vec{B}\frac{\vec{J}\circ\vec{J}}{J^2}\right)=-\frac{q}{2m_0}\left(\frac{(\vec{L}+2\vec{S})}{J}\circ\vec{J}\right)\left(\frac{\vec{J}\circ\vec{B}}{J}\right) \\ &= -\frac{q}{2m_0}\left(\frac{(\vec{L}+2\vec{S})\circ\vec{J}}{J^2}\right)J_zB \end{aligned} \tag{11.3.447}$$

Using the fact that:

$$\vec{J}=\vec{L}+\vec{S} \tag{11.3.448}$$

we get:

$$E_p = -\frac{q}{2m_0}\frac{\left(\vec{L}+2\vec{S}\right)\circ\left(\vec{L}+\vec{S}\right)J_zB}{J^2} \tag{11.3.449}$$

These vector relationships must be evaluated and expressed in terms of quantum numbers in order to evaluate the energy shifts. Carrying out the scalar products above leads to:

$$E_p = -\frac{q}{2m_0}\frac{\left(L^2+2S^2+3\vec{L}\circ\vec{S}\right)J_zB}{J^2} = -\frac{q}{2m_0}\frac{\left(L^2+2S^2+3\vec{L}\circ\vec{S}\right)m_jB}{J^2} \tag{11.3.450}$$

And we have also proved in the section of Wave Quantum Physics that:

$$J^2 = L^2+S^2+2\vec{L}\circ\vec{S} \tag{11.3.451}$$

Rearranging gives the scalar product term needed:

$$3\vec{L}\circ\vec{S} = \frac{3}{2}(J^2-L^2-S^2) \tag{11.3.452}$$

Substitution into the energy expression gives:

$$E_p = -\frac{q}{2m_0}\frac{\left(L^2+2S^2+\frac{3}{2}(J^2-L^2-S^2)\right)m_jB}{J^2} \tag{11.3.453}$$

which can be reduced to:

$$E_p = -\frac{q}{2m_0}\frac{(3J^2-L^2+S^2)\,m_jB}{2J^2} = -\mu_B g_L m_j B \tag{11.3.454}$$

where using eigenvalues we have:

$$g_L = \frac{3J(J+1)-L(L+1)+S(S+1)}{2J(J+1)} = \frac{3}{2}+\frac{S(S+1)-L(L+1)}{2J(J+1)} \tag{11.3.455}$$

so we fall back on the approximation of g_J!

So finally:

$$\boxed{E_p = -\frac{q}{2m_0}\left(\frac{3}{2}+\frac{S(S+1)-L(L+1)}{2J(J+1)}\right)m_jB = -\mu_B g_L m_j B \cong -\mu_B g_J m_j B} \tag{11.3.456}$$

✍**Example:**

Let us give a word about the fine structure of sodium atoms.

As we have seen in the section of Corpuscular Quantum Physics and following the aufbau principle (also introduced in the same section) for the atom of Sodium Na we have seen that its electronic configuration was:

$$1s^2 2s^2 2p^6 3s \tag{11.3.457}$$

Explicitly we then say (following orbital-spin coupling notation), that is ground state is then:

$$n^{2s+1}l_j = 3^2 s_{1/2} \tag{11.3.458}$$

The first excited state is obtained (still following the aufbau principle) by promoting the $3s$ electron to the $3p$ orbital, to obtain the:

$$1s^2 2s^2 2p^6 3p \tag{11.3.459}$$

configuration. In a sodium-vapour lamp for example, sodium atoms are excited to the $3p$ level by an electrical discharge, and return to the ground state by emitting yellow light of wavelength 589 [nm].

Now let us recall the following table (see section Wave Quantum Physics page 4889):

Orbital type	***s***	***p***	***d***	***f***	**...**
l	0	1	2	3	...
j	$\dfrac{1}{2}$	$\dfrac{1}{2},\dfrac{3}{2}$	$\dfrac{3}{2},\dfrac{5}{2}$	$\dfrac{5}{2},\dfrac{7}{2}$	...
Notation:	$s_{1/2}$	$p_{1/2},p_{3/2}$	$d_{3/2},d_{5/2}$	$f_{5/2},f_{7/2}$	...

Therefore for the ground state $3^2 s_{1/2}$ of the Sodium we get $l=0$ and $j=1/2$. And in the absence of magnetic field $B=0$ we have:

$$E_p = -\mu_B g_L m_j B = -\mu_B g_L m_j \cdot 0 = 0 \tag{11.3.460}$$

so there is no fine structure of the Sodium spectrum.

But when the electron move to $3p$ under the influence of a weak magnetic field, we have (still look to the table above) that $l=1$ with $j=1/2$ and $j=3/2$.

Therefore a fine structure appears for $3p$ and we get that the transition $3s \rightarrow 3p$ is split into a doublet that we name for Sodium the "D-lines" and respectively each line is named D_1 and D_2 lines.

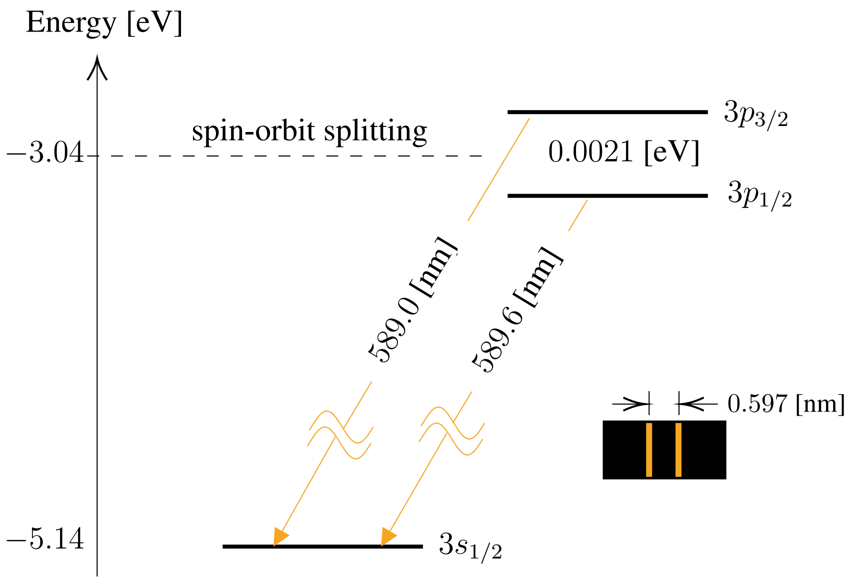

Figure 11.85: Example of fine structure in Sodium (Source: Hyperphysics)

The fact that there is a doublet shows the smaller dependence of the atomic energy levels on the total angular momentum. This effect is called the "spin-orbit effect".

In fact this doublet are also visible without the presence of an additional externally applied magnetic field, but with a magnetic fields these levels are further split by the magnetic interaction (and therefore more easily measurable), showing dependence of the energies on the z-component of the total angular momentum. This splitting gives the Zeeman effect for sodium.

Now let us roughly approximate the magnetic field necessary to create this doublet by taking:

$$|E_p| = \mu_B g_L m_j B = 0.0021\,[\text{eV}] \tag{11.3.461}$$

Assuming[a] same g_L and same m_j we get $B = 18$ [T]. This is a very large magnetic field by laboratory standards. Large magnets with dimensions over a meter, used for NMR and ESR experiments, have magnetic fields on the order of a Tesla.

Experimentally (therefore in reality) it was the opposite, the field was applied and the g_L were determined as we get:

Term	J	L	S	Experimental g_L	Calculated g_L
$\mathbf{3p_{3/2}}$	$3/2$	1	$1/2$	$4/3$	$4/3$
$\mathbf{3p_{1/2}}$	$1/2$	1	$1/2$	$2/3$	$2/3$
$\mathbf{3s_{1/2}}$	$1/2$	0	$1/2$	2	2

Table 11.12: g_L Lande' g-factor for Sodium Na

where g_L was calculated using:

$$g_L = \frac{3}{2} + \frac{S(S+1) - L(L+1)}{2J(J+1)} \tag{11.3.462}$$

---

[a] In fact even if we calculate precisely m_j for each orbit we get almost the same result with less than 10% error

However.... what we have seen above is the way the Landé g-factor is derivend an expressed most of the times in european universities. In most american universities the expression is different because the derivation is based on a different choice at the beginning of the proof. Let us see how!

The magnetic moment of an atom comes from two parts: orbital motion $(\vec{\mu}_L)$ and electron spin $(\vec{\mu}_S)$:

$$\vec{\mu}=\vec{\mu}_L+\vec{\mu}_S=-g_L\mu_B\frac{\vec{L}}{\hbar}-g_S\mu_B\frac{\vec{S}}{\hbar} \tag{11.3.463}$$

where μ_B is the Bohr magneton, $g_L\cong 1$, and $g_S\cong 2$.

The total angular momentum is the vector sum of orbital and spin angular momenta:

$$\vec{J}=\vec{L}+\vec{S} \tag{11.3.464}$$

Because of spin-orbit coupling, L and S rapidly precess around the constant total angular momentum vector $\vec{J}$. Only the component of $\vec{\mu}$ parallel to $\vec{J}$ has a non-zero time average:

$$\vec{\mu}_{\text{effective}}=\left(\frac{\vec{\mu}\circ\vec{J}}{J^2}\right)\vec{J}=-g_J\mu_B\frac{\vec{J}}{\hbar} \tag{11.3.465}$$

We substitute $\vec{\mu}$ into the dot product projection:

$$\vec{\mu}\cdot\vec{J}=-\mu_B\left(g_L\vec{L}\circ\vec{J}+g_S\vec{S}\circ\vec{J}\right) \tag{11.3.466}$$

To evaluate $\vec{L}\circ\vec{J}$ and $\vec{S}\circ\vec{J}$, we use the relations $\vec{L}=\vec{J}-\vec{S}$ and $\vec{S}=\vec{J}-\vec{L}$ and we square $\vec{S}=\vec{J}-\vec{L}$ to get:

$$S^2=J^2+L^2-2(\vec{J}\circ\vec{L}) \tag{11.3.467}$$

This gives the dot product:

$$\vec{L}\circ\vec{J}=\frac{J^2+L^2-S^2}{2} \tag{11.3.468}$$

Similarly, squaring $\vec{L}=\vec{J}-\vec{S}$ gives:

$$\vec{S}\circ\vec{J}=\frac{J^2+S^2-L^2}{2} \tag{11.3.469}$$

Replacing the operator squares with their quantum mechanical eigenvalues ($J^2\rightarrow J(J+1)\hbar^2, L^2\rightarrow L(L+1)\hbar^2, S^2\rightarrow S(S+1)\hbar^2$) and using $g_L=1$ and $g_S\cong 2$ yields to:

$$g_J=\frac{g_L[J(J+1)+L(L+1)-S(S+1)]+g_S[J(J+1)+S(S+1)-L(L+1)]}{2J(J+1)} \tag{11.3.470}$$

Setting $g_L \cong 1$ and $g_S \cong 2$ simplifies this directly to the "Landé g-factor" expression" or "splitting factor" (which determines the splitting of the energy levels in the presence of weak external magnetic field) as we can found it in most american textbooks:

$$\boxed{g_J \cong 1 + \frac{J(J+1)+S(S+1)-L(L+1)}{2J(J+1)}} \tag{11.3.471}$$

Also often denoted more technically:

$$\begin{aligned} g_J \left\langle J, J_z \right| \vec{J}\cdot\vec{J} \left| J, J_z \right\rangle &= \left\langle J, J_z \right| g_L \vec{L}\cdot\vec{J} + g_S \vec{S}\cdot\vec{J} \left| J, J_z \right\rangle \\ &= \left\langle J, J_z \right| g_L \left[\vec{L}^2 + \frac{1}{2}\left(\vec{J}^2 - \vec{L}^2 - \vec{S}^2\right)\right] + g_S \left[\vec{S}^2 + \frac{1}{2}\left(\vec{J}^2 - \vec{L}^2 - \vec{S}^2\right)\right] \left| J, J_z \right\rangle \\ &= \frac{g_L \hbar^2}{2}[J(J+1)+L(L+1)-S(S+1)] + \frac{g_S \hbar^2}{2}[J(J+1)-L(L+1)+S(S+1)] \\ g_J &= g_L \frac{J(J+1)+L(L+1)-S(S+1)}{2J(J+1)} + g_S \frac{J(J+1)-L(L+1)+S(S+1)}{2J(J+1)} \end{aligned} \tag{11.3.472}$$

It is very important to note that for singlet states the spin quantum number $S=0$ so that $J=L$ and the Landé g-factor expression becomes equal to the gyromagnetic ratio $=2$. Hence the above formulation reduces to that of the "normal Zeeman effect" which was explained earlier in terms of only the orbital angular momentum and its associated magnetic moment.

The following table gives the calculated Lande g-factors for some common term symbols in the approximation $g_S = 2$:

Term symbol	S	L	J	g_J
$^2\mathrm{S}_{1/2}$	1/2	0	1/2	2
$^3\mathrm{S}_1$	1	0	1	2
$^4\mathrm{S}_{3/2}$	3/2	0	3/2	2
$^5\mathrm{S}_2$	2	0	2	2
$^6\mathrm{S}_{5/2}$	5/2	0	5/2	2
$^7\mathrm{S}_3$	3	0	3	2
$^1\mathrm{P}_1$	0	1	1	1
$^2P_{1/2}$	1/2	1	1/2	2/3
$^2P_{3/2}$	1/2	1	3/2	4/3
$^3\mathrm{P}_0$	1	1	0	-
$^3\mathrm{P}_1$	1	1	1	3/2
$^3\mathrm{P}_2$	1	1	2	3/2
$^4\mathrm{P}_{1/2}$	3/2	1	1/2	8/3
$^4\mathrm{P}_{3/2}$	3/2	1	3/2	26/15
$^4P_{5/2}$	3/2	1	5/2	8/5
$^5\mathrm{P}_1$	2	1	1	5/2
$^5\mathrm{P}_2$	2	1	2	11/6
$^5\mathrm{P}_3$	2	1	3	5/3
$^6\mathrm{P}_{3/2}$	5/2	1	3/2	12/5
$^6\mathrm{P}_{5/2}$	5/2	1	5/2	66/35
$^6\mathrm{P}_{7/2}$	5/2	1	7/2	12/7
$^7\mathrm{P}_2$	3	1	2	7/3
$^7\mathrm{P}_3$	3	1	3	23/12
$^7\mathrm{P}_4$	3	1	4	7/4
$^1\mathrm{D}_2$	0	2	2	1
...	...	...	...	...

Remark

According to three of the most standard quantum mechanics textbooks (Griffiths, Merzbacher and Peskin), as well as most (though not quite all) publications we can find, the term "Landé g-factor" refers specifically to g_J, while the term "g-factor" or "g-value" refers to the more general case of any dimensionless factor in an equation for a magnetic moment (not specifically related to the electron!).

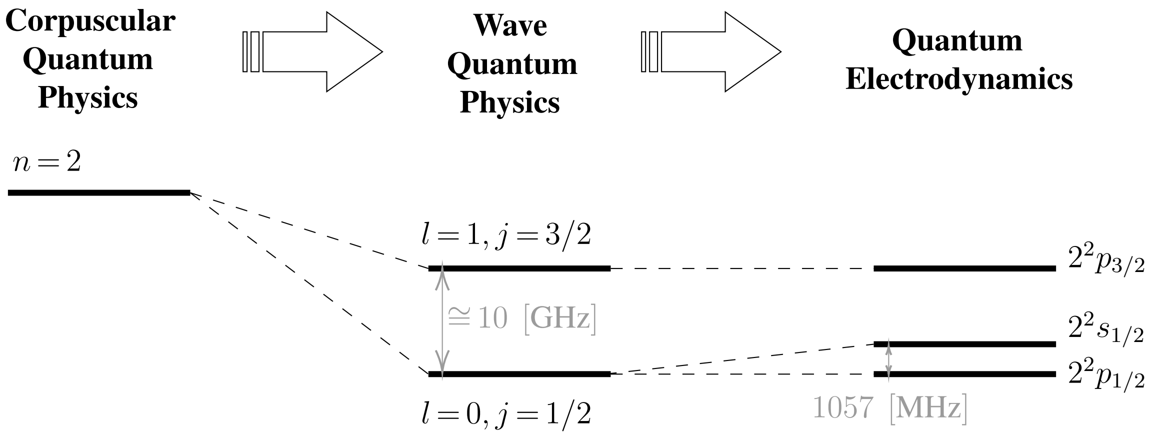
11.3.6.2 Lamb Shift

But this is not the end with our fine structure...

Indeed, if we apply what we have seen so far to the Hydrogen atom when the electron goes to $n=1$ to $n=2$ (without magnetic field but using ad hoc excitation!), we know that for the layers s and p:

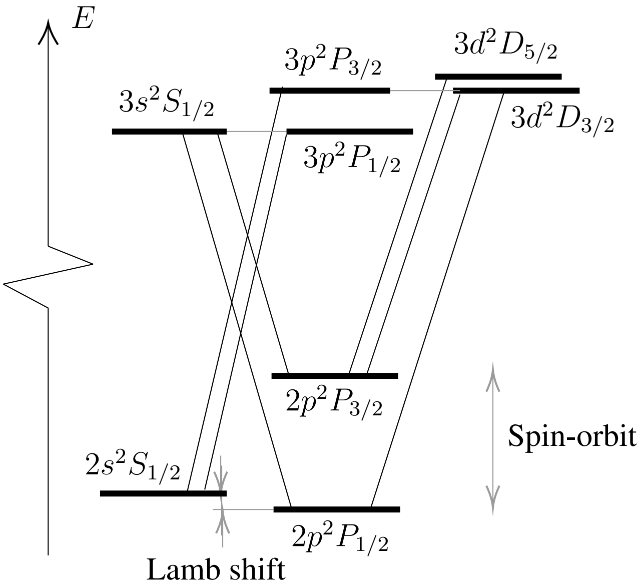
$$\begin{aligned} l=0 &\Rightarrow j=1/2 \\ l=1 &\Rightarrow j=1/2,3/2 \end{aligned} \tag{11.3.473}$$

and therefore we get with the Bohr model, and the Dirac Model and in laboratories:



Corpuscular Quantum Physics
Wave Quantum Physics
Quantum Electrodynamics
$n=2$
$l=1, j=3/2$
$\cong 10$ [GHz]
$l=0, j=1/2$
$2^2p_{3/2}$
$2^2s_{1/2}$
$2^2p_{1/2}$
1057 [MHz]

Or in a more technical and traditional view:



E
$3p^2P_{3/2}$
$3d^2D_{5/2}$
$3s^2S_{1/2}$
$3d^2D_{3/2}$
$3p^2P_{1/2}$
$2p^2P_{3/2}$
Spin-orbit
$2s^2S_{1/2}$
$2p^2P_{1/2}$
Lamb shift

So here there is an issue between theory and experiment because in labs it is clear that $2^2s_{1/2}$ and $2^2p_{1/2}$ are not degenerated (that means in other words, for recall, they don't have the same energy level) when theory gives us clearly that they should be degenerated (i.e. have the same energy levels)!

Indeed, let us recall that for $j=1/2$ we have:

$$j=l+s=\frac{1}{2} \tag{11.3.474}$$

So all the possible authorized pairs that lead to this result are:

$$\begin{aligned}j&=l+s=0+\frac{1}{2}=\frac{1}{2}\\ j&=l+s=1-\frac{1}{2}=\frac{1}{2}\end{aligned} \tag{11.3.475}$$

Therefore we have indeed that $s_{1/2}$ and $p_{1/2}$ that should be degenerated but that are not experimentally whatever the level n.

Indeed, the (energy) degeneration doesn't come in this case from the term $(\vec{L}+2\vec{S})\circ\vec{B}$ as $\vec{B}\cong\vec{0}$ in the Lamb experiment. We must just apply $\vec{J}=\vec{L}+\vec{S}$ in this case!

The (experimentally) measured positions show the $2s^2p_{1/2}$ level is shifted upwards relative to the position $(n=2, j=1/2)$ and is therefore not degenerate with the $2p^2p_{1/2}$ level. Such a shift occurs for all the s-electrons in laboratories (but the energy shift decreases with increasing n).

The most right splitting can only be explained by Quantum Electrodynamics (QED) and is known as the "Lamb shift" of the s level and denoted "Ly-α" in the special case of hydrogen. Indeed, according to the Dirac equation, these both sates should have the same energy. This shift was first observed in 11947-11952 according to holocene calendar (Lamb–Retherford experiment[29]) and was crucial for the development of QED where the electromagnetic field is quantised and has a zero point energy (this means that even in the case of number of photons equal to zero, there is a fluctuating electric field). In 11948 (holocene calendar), Theodore A. Welton succeeded (reasonably after a lot of assumptions and approximations...) in accounting for the Lamb shift between the two above levels in terms of the perturbation of the electronic orbit brought about by vacuum fluctuations.

Due to this fluctuating field the electron performs small oscillations and its charge is effectively smeared out over a range of about 0.1 fermi. This causes the electron spin g-factor to be slightly different from 2. There is also a slight weakening of the force on the electron when it is very close to the nucleus, causing the $2s_{1/2}$ electron (which has penetration all the way to the nucleus) to be slightly higher in energy than the $2p_{1/2}$ electron.

When the Lamb shift was experimentally determined, it provided a high precision verification of theoretical calculations made with the quantum theory of electrodynamics. These calculations predicted that electrons continually exchanged photons, this being the mechanism by which the electromagnetic force acted. The effect of the continuous emission and absorption of photons on the electron g-factor could be calculated with great precision.

The tiny Lamb shift, measured with great precision, agreed to many decimal places with the calculated result from quantum electrodynamics. The measured precision gives us the electron spin g-factor as:

$$g_e\cong 2.00231930436256(35) \tag{11.3.476}$$

compared to the theoretical prediction of $2.00233183620(86)4$ using QED (Quantum Electrodynamics).

Since 11956 (holocence calendar) the Dyson series (from Freeman Dyson) is used to calculate the exact value of the g factor of the electron (maybe in the future we will have the time to prove where that series comes from):

$$g_e=2\cdot\left(1+C_1\left(\frac{\alpha}{\pi}\right)+C_2\left(\frac{\alpha}{\pi}\right)^2+C_3\left(\frac{\alpha}{\pi}\right)^3+C_4\left(\frac{\alpha}{\pi}\right)^4+C_5\left(\frac{\alpha}{\pi}\right)^5\ldots\right) \tag{11.3.477}$$

---

[29] They carried out the experiment using microwave techniques to stimulate radio-frequency transitions between the both level of interest. The energy difference Lamb and Rutherford found was a rise of about 1000 [MHz]

where each constant C_i corresponds to the calculation of a given number of Feynman diagrams (involving complex curvilinear integrals whose exact calculations/numerical calculation are kept confidential because of publication competitions between scientists and whose calculations are a bit awkward because involving divergent infinite integrals that need to be renormalized to give finite values...) and alpha is the fine-structure constant. The expression between the parenthesis is named the "magnetic anomaly" or the "anomalous magnetic moment".

In many scientific papers the magnetic anomaly is also defined as:

$$a=\frac{g_e-2}{2} \tag{11.3.478}$$

When we write these lines actual calculations give (C_2 needed the computation of 72 Feynman diagrams, C_4 needed the computation of 891 Feynman diagrams, C_5 need in year 12018 the computation of $12,726$ Feynman integrals on supercomputers...):

$$\begin{aligned}g_e&=2\cdot\left(1+\frac{\alpha}{2\pi}-0.328\left(\frac{\alpha}{\pi}\right)^2+1.181\left(\frac{\alpha}{\pi}\right)^3-1.912\left(\frac{\alpha}{\pi}\right)^4+7.795\left(\frac{\alpha}{\pi}\right)^5+\ldots\right)\\&\cong 2\cdot 1.001159652182032=2.00231930436406\end{aligned} \tag{11.3.479}$$

where the first value $\alpha/2\pi$ is the named the "Schwing factor" (it's even engraved above his name on his tombstone...). For more informations on this topic see [110].

As reported in *Measurement of the Electron Magnetic Moment* (see [171]) published in 12023 (holocene calendar), the electron magnetic moment, $-\mu/\mu_B=g/2=1.00115965218059(13)$ [0.13 ppt]. It is the most precisely determined property of an elementary particle by the Standard Model to 1 part in 10^{12}.

The Lamb shift has since played a significant role through vacuum energy fluctuations in theoretical prediction of Hawking radiation from Black Holes.

The muon magnetic anomaly denoted a_μ is very interesting as it leads to some stress in the physics community in this early 121st century (holocene calendar). Indeed, if we look at the figure below (credit adapted from A. Boccaletti et al. 2024 arXiv:2407.10913):

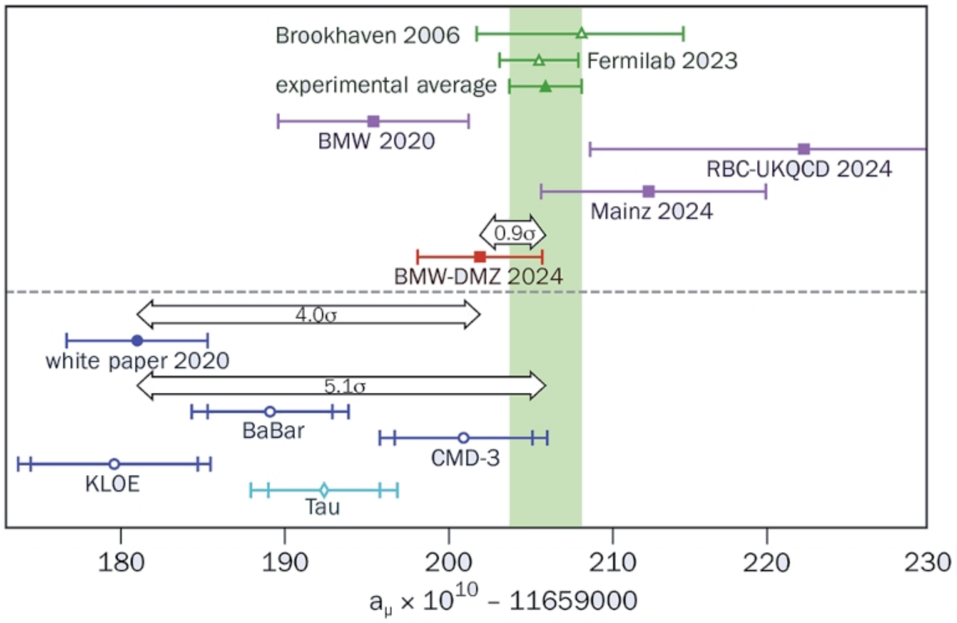


Figure 11.86: **Landscape of muon $g-2$ Measurements of a_μ (source: CERN)**

measurements of a_μ (green triangles) compared to the Standard Model predictions[30] using lattice Quantum Chromodynamics (purple squares), data-driven predictions using e^+e^- annihilation to hadrons (blue circles), tau-lepton decays (cyan diamond) and a hybrid approach (red square) show statistical compatibility or incompatibility as indicated by arrows between the latest experimental average (filled green triangle) in 12025 (holocene calendar), a 12020 (holocene calendar) white paper (filled blue circle) and the most precise prediction (red square) also in 12025 (holocene calendar).

These (apparent?) incompatibilities (tension) may be an opening for a new type of physics beyond the Standard Model. To follow!...

---

[30] It took to the Budapest–Marseille–Wuppertal collaboration (BMW) a billion core-hours on the Mira supercomputer to compute the hadronic light-by-light contribution to the muon's magnetic moment in 12020 (holocene calendar).

The electron is not a point-like magnet as Dirac's simple theory predicted. Its interaction with the quantum vacuum makes its magnetic moment slightly larger than expected. This tiny difference is the **anomalous magnetic moment (a_e)**.

A SPINNING ELECTRON DISTURBS THE QUANTUM VACUUM
